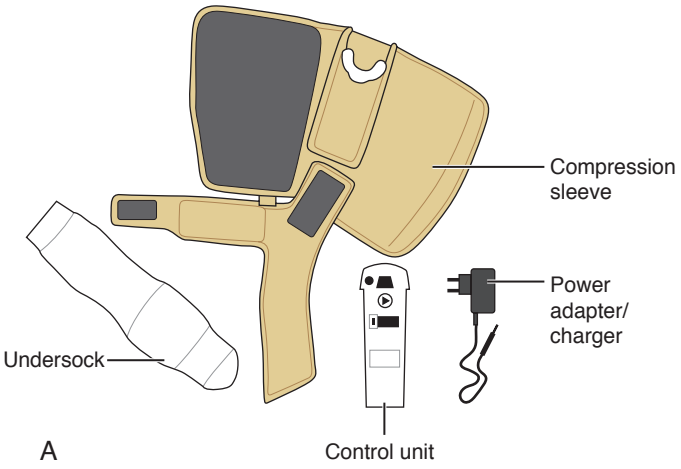
Figure 157.4 Intermittent compression device. (From Enoch S, Grey JE, Harding KG. ABC of wound healing. Non-surgical and drug treatments. *BMJ*. 2006; 332:900–903.)



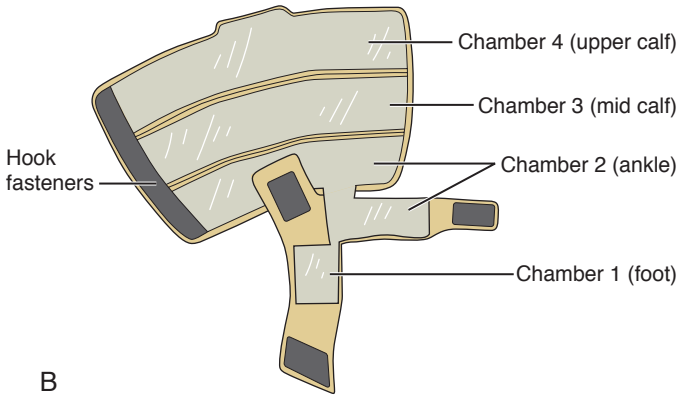


Figure 157.5 ACT Device: **(A)** outer side views and **(B)** underside views. (From Harding KG, Vanscheidt W, Partsch H, et al. Adaptive compression therapy for venous leg ulcers: a clinically effective, patient-centered approach. *Int Wound*. 2016; 13(3):317–325.)

and ulcer size were independent predictors of ulcer healing. Decreased odds of healing were observed in patients with larger calf circumference and ulcer size. The authors concluded that ulcer healing can be better achieved with multicomponent bandaging systems with sub-bandage healing pressures between 35 and 45 mm Hg. Good healing results were obtained in patients with small (<5 cm^2) ulcers and smaller (<33 cm) calf circumferences.[45]

Intermittent Pneumatic Compression

Intermittent pneumatic compression (IPC) is a mechanical compression method in which external pressure is applied by the intermittent inflation of pneumatic boots (Fig. 157.4). Some devices include a single inflation chamber at a single pressure, while others include 2 to 3 chambers with different pressures at the ankle, calf, and thigh. These devices can be used to treat venous leg ulcers and lymphedema.[46] A Cochrane review authored by Nelson et al.[47] identified seven randomized trials, including 367 patients treated with IPC. In one trial (80 patients), IPC was found to be more beneficial than compression stockings in ulcer healing (62% vs. 28%; $P = .002$). In four trials, IPC plus compression stocking therapy was compared with compression stocking therapy alone. Of these four trials, only one (45 patients) showed increased ulcer healing (relative risk [RR] for healing, 11.4%; 95% confidence interval [CI], 1.6-82) in the IPC plus compression stocking group. The remaining three trials noted no evidence of benefit of IPC over compression stockings in ulcer healing. In one trial (104 patients), a higher rate of healed ulcers was associated with devices in which the inflation was rapid compared with those with slow inflation (86% vs. 61%; log rank $P = .003$). Based on these studies, IPC may be effective in controlling edema, particularly in patients with a lymphedema component, but there is no strong evidence to support its use in the treatment of venous ulcers.[47]

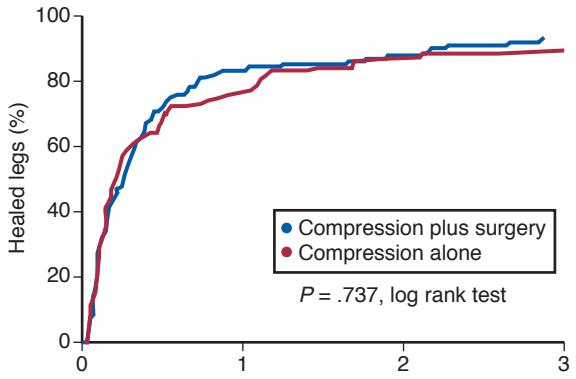
Adaptive Pressure Multichamber System. Recently, multicomponent pneumatic compression devices have become available to treat patients with C6 disease and poor compliance to compression stockings and/or bandages.[48]

The ACTitouch device (ACT; Fig. 157.5) provides adaptive, intermittent, and sustained pneumatic compression. The device consists of a foot, and ankle and calf cuffs, linked together to form one complete functional unit. The inflation of the cuffs is controlled by a small, lightweight, low voltage microprocessor that monitors and continuously adjusts the degree of inflation of each cuff to the targeted pressure.[48] The device can function in IPC and/or sustained pressure mode. When operated in sustained mode, a graded compression of 40 mm Hg is applied at the ankle, 30 mm Hg at midcalf, and 20 mm Hg at the knee. The IPC mode provided intermittent compression of 50 mm Hg at the foot and ankle, 45 mm Hg at the midcalf, and 40 mm Hg at the knee.

In a prospective randomized study, 90 patients with C6 disease were divided in two groups: ACT ($n = 38$) and a four-layer bandage system ($n = 52$). Patients were instructed to wear the device for most of the day with 2 hours of IPC mode.[48]

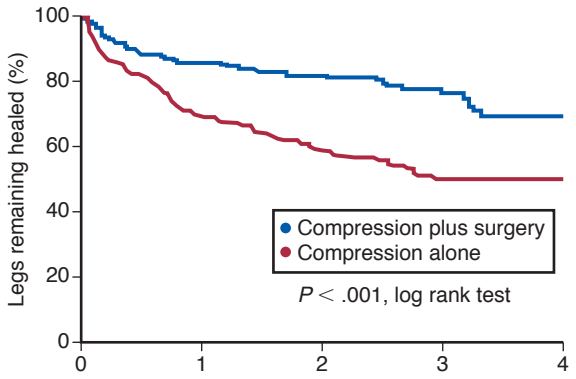
At 12 weeks, ulcer healing rate and time to ulcer healing were similar between the treatments.

In the ACT group, treatment performance was significantly higher in terms of exudate management, skin protection, removal ease, bathing, and sleep comfort. Quality of life (QoL) was



Numbers at risk				
Compression plus surgery	185	33	13	6
Compression alone	156	24	15	5

Figure 157.6 Ulcer healing rates were not statistically significantly different between the groups at 3 years (compression, 89%; surgery-compression, 93%; $P = .73$). (From Barwell JR, Davies CE, Deacon J, et al. Comparison of surgery and compression with compression alone in chronic venous ulceration [ESCHAR study]: randomized controlled trial. *Lancet*. 2004;363:1854–1859.)



Numbers at risk					
Compression plus surgery	216	166	124	68	27
Compression alone	226	139	98	45	10

Figure 157.7 The rates of ulcer recurrence at 4 years were 56% for the compression-alone group and 27% for the compression-surgery group. (From Barwell JR, Davies CE, Deacon J, et al. Comparison of surgery and compression with compression alone in chronic venous ulceration [ESCHAR study\: randomized controlled trial. *Lancet*. 2004;363:1854–1859.)

measured using the EQ-5D-3L health questionnaire[49] completed at baseline and at the end of the study. The quality-of-life score was found to be 0.1025 higher in patients wearing the ACT device ($P < 0.0375$). The ACT system may be considered in patients with C6 disease who failed graduated compression stockings and other means of compression therapy (Unna Boot, bandages, CircAid).[48]

Surgery Versus Compression in C6 Disease. In the Effect of Surgery and Compression on Healing and Recurrence (ESCHAR) study, 500 patients with leg ulcers were randomized to compression alone and compression plus surgery (high ligation and stripping of the saphenous vein).[50] Compression consisted of multilayered bandaging every week until healing, then class 2 knee-high stockings. Whereas 24-week healing rates were similar in the two groups (65% vs. 65%; hazard, 0.84 [95% CI, 0.77-1.24]; $P = .85$), at 24 months the recurrence rate was significantly lower in the compression-surgery group (12% vs. 28%; hazard, 2.76 [95% CI, 1.78-4.27]; $P < .0001$). In a second report published in 2007, long-term results of the ESCHAR trial were analyzed.[44] Overall ulcer healing rates were not statistically significantly different between the groups at 3 years (Fig. 157.6). The rates of ulcer recurrence at 4 years were 56% for the compression-alone group and 27% for the compression-surgery group (Fig. 157.7).[44] The benefit of the combined compression-surgery approach was noted mostly in the subgroup of patients with superficial or segmental deep vein reflux (Fig. 157.8).[50,51]

The ESCHAR trial and other studies[52] provide strong evidence that compression therapy, in conjunction with appropriate surgical intervention (high ligation and stripping, endovenous ablation of saphenous veins by thermal and chemical methods), is a vital part of the ongoing care and treatment of patients with venous ulcers. The clinical practice guidelines of the Society for Vascular Surgery (SVS) and the American Venous Forum (AVF)[53] also support this approach.

Pharmacologic Therapies

Pharmacologic therapy in venous disease is directed toward symptom control in patients with mild to moderate chronic venous disease and the treatment of venous ulcers. Pharmacologic targets have been identified on the basis of advances in the understanding of the pathogenesis of the molecular mechanisms of chronic venous disease, and a substantial number of agents have been developed and studied.[16,54] A cost analysis of severe chronic venous disease in 19,750 German patients showed that 11% had consumed medications designed to treat venous disease in the preceding 12 months; 80% of the purchasers were women, and the majority were older than 50 years.[55] Indications for the medications were varicose veins (58%), leg pain (30%), and various degrees of lower extremity venous disease (30%). A Cochrane database review[56] published in 2005 included 44 prospective randomized trials involving 4413 patients, in which the efficacy of several medications was assessed. Outcomes included edema, venous ulcers, lipodermatosclerosis, subjective symptoms, global assessment measures, and adverse reactions. Among the different medications, phlebotropic drugs, of which the micronized purified flavonoid fraction (MPFF) is the most prominent, showed some degree of benefit (RR, 0.72; 95% CI, 0.65-0.81). The authors concluded, "There is not enough evidence to globally support the efficacy of phlebotonics for chronic venous insufficiency. There is a suggestion of some efficacy of phlebotonics on edema but this is of uncertain clinical relevance. Due to the limitations of current evidence, there is a need for further randomized, controlled clinical trials with greater attention paid to methodologic quality."[56]

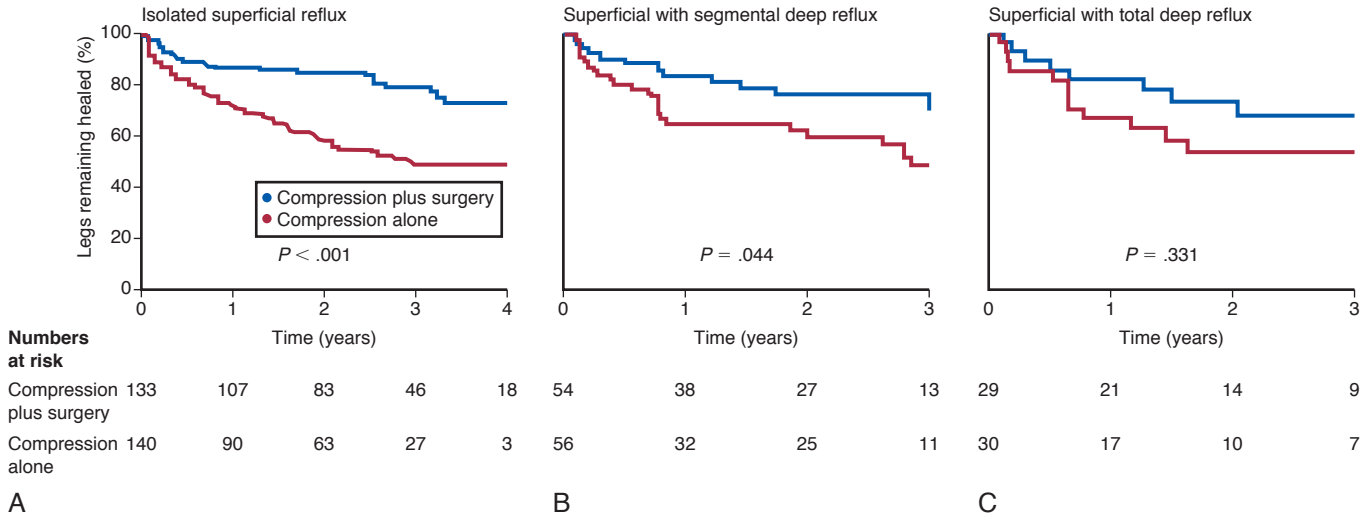


Figure 157.8 Ulcer recurrence rates were significantly reduced in the subgroup of patients with superficial **(A and C)** or segmental deep vein reflux **(B)**. (From Barwell JR, Davies CE, Deacon J, et al. Comparison of surgery and compression with compression alone in chronic venous ulceration (ESCHAR study): randomized controlled trial. *Lancet*. 2004;363:1854–1859.)

Diuretics

The role of diuretics in chronic venous disease is still debated. They may have some benefit in reducing edema in patients with chronic congestive heart failure.

Zinc

Zinc is a trace element and a cofactor of more than 100 enzymatic processes involved in DNA replication, protein synthesis, and cell division. Zinc also plays a key role in the humoral and cell-mediated immunity responses and wound-healing.[57] Despite reports of low zinc levels in patients with venous ulcers and a few reports of a beneficial effect of oral zinc supplementation in the healing of venous ulcers, a Cochrane review from Wilkinson[58] including four trials found no evidence of benefit in oral zinc supplementation on the number of ulcers healed.

Fibrinolytic Agents

In 1982, Burnand et al.[59] observed the presence of fibrin cuffs surrounding the dermal capillaries of 26 lower extremities with lipodermatosclerosis. This finding was confirmed by Falanga et al.[60] in 1987, along with reduced transcutaneous tissue oxygen saturation levels in the skin around the ulcer. Despite these observations, trials involving medications with fibrinolytic activity, such as stanozolol and sulodexide glycosaminoglycan, failed to prove beneficial in ulcer healing.[54]

Pentoxifylline

Pentoxifylline is a competitive nonselective adenylate cyclase inhibitor with several activities, including increase of intracellular cyclic adenosine monophosphate, activation of protein kinase A, inhibition of tumor necrosis factor, and promotion of leukotriene synthesis. The pharmacologic effects of pentoxifylline are related to red blood cell deformability and inhibition of platelet aggregation and thrombus formation.[61] Pentoxifylline also has an antiinflammatory effect that is probably related to the selective depression of tumor necrosis factor expression and the depression of granulocyte phagocytic activity and neutrophil-endothelium adhesion.[61] A prospective randomized trial published in 2007 compared the effectiveness of pentoxifylline, knitted viscose or hydrocolloid dressings, and single-layer or four-layer bandaging for venous ulceration.[62] The study enrolled 245 patients with venous ulcers. The main outcome was time to complete ulcer healing. The dose of pentoxifylline administered was 1200 mg by mouth daily. Initial results showed that pentoxifylline was associated with a statistically nonsignificant improvement in ulcer healing (62% vs. 53%; $P = 0.21$). Further analysis with a Cox regression model resulted in a clinically significant improvement in ulcer healing with pentoxifylline (RR for healing, 1.4; 95% CI, 1.0-2.0).[62]

A Cochrane review, also from 2007, included 12 trials and 864 patients.[63] In 11 trials that compared pentoxifylline (400 mg PO daily) with placebo, a significant benefit in ulcer healing was noted (RR, 1.70; 95% CI, 1.30-2.24). Pentoxifylline plus compression was found to be more effective than compression alone (RR, 1.56; 95% CI, 1.14-2.13). Pentoxifylline alone was more effective than placebo or no treatment (RR, 2.25; 95% CI, 1.49-3.39). Seventy-two percent of patients complained mostly of gastrointestinal adverse reactions. The authors concluded that there is evidence that pentoxifylline may be an effective adjunct to compression therapy in advanced chronic venous disease. The authors also noted the heterogeneity of the trials, which could have resulted in an overall sample bias.[63]

Phlebotropic Agents

Phlebotropic agents are medications with multiple pharmacologic microcirculatory activities that show a unique tropism for veins. The most important phlebotropics are found in the family of the γ-benzopyrone family (flavonoids).[64]

Micronized purified flavonoid fraction (MPFF) consists of 90% micronized diosmin and 10% flavonoids.[65] Although its

mechanism of action has not been fully defined, a number of pharmacologic properties have been identified. In vitro and in vivo animal studies have demonstrated inhibition of granulocytes and macrophage infiltration in the venous parenchyma. This correlates with an overall antiinflammatory pharmacologic activity.[64] Another property of MPFF is phlebotropism, with vein tissue being the most important target. In an animal model of venous hypertension, MPFF was shown to attenuate, in a dose-dependent manner, leukocyte adhesion and migration into the valvular tissue, expression of intercellular adhesion molecule-1 and P-selectin, and apoptosis of endothelial cells.[66] In the same model, venous valve degeneration was attenuated in the treatment group.[67]

A number of prospective randomized trials have been conducted to assess the effectiveness of MPFF. The most recent meta-analysis included 10 prospective randomized trials published between 1975 and 2009, with a total of 1010 patients.[68] The primary outcome was effective treatment of venous edema by ankle diameter reduction. The result was a significant reduction in ankle diameter with MPFF (0.80 ± 0.53), compared with ruscus extract (0.58 ± 0.47), hydroxyethylrutoside (058 ± 0.31), diosmin (0.20 ± 0.42), and placebo (0.11± 0.42). This confirmed 1A level of evidence assigned to MPFF in the management of symptoms and edema.[68]

Another meta-analysis published by Coleridge Smith in 2005[69] included five prospective randomized trials and 723 patients with venous ulcers. MPFF and conventional treatment (local wound care and compression) were compared with conventional treatment plus placebo in two studies ($n = 309$) and conventional treatment alone in three studies ($n = 414$). Primary outcome was ulcer healing at 6 months. At 6 months, ulcer healing was 32% higher in the MPFF group (RR, 32%; 95% CI, 3%-70%). MPFF at a dose of 500 mg twice per day was found to be more beneficial in the group of patients, with ulcers between 5 and 10 cm^2 and in ulcers with a 6 to 12-month duration.[69]

MPFF is effective in control of symptoms and ankle edema in patients with symptomatic uncomplicated chronic venous disease. In association with compression therapy, it is a useful adjunct in large and long-standing ulcers.

Prostaglandins

Prostaglandin E_1 is known to attenuate white blood cell activation and platelet aggregation.[70] In a prospective randomized trial involving 87 patients with venous ulcers, prostaglandin E_1 was administered by intravenous infusion for 20 days in addition to topical therapy. The primary endpoint was ulcer healing at 120 days. The results showed that healing time in the prostaglandin E_1 group was less than 100 days, with more than 75% of patients healing at 75 days. This was statistically significant compared with the placebo (84.2% patients healing at 120 days).[70]

Horse chestnut is an herbal medication with moderate antiinflammatory activity through the release of prostaglandin F.[71] A Cochrane review of seven placebo-controlled randomized trials showed a statistical improvement in leg pain in six trials, which was equivalent to compression therapy in patients with uncomplicated symptomatic varicose veins.[72] In a small prospective triple-blind randomized placebo-controlled trial of 54 patients with venous leg ulcers, oral therapy with horse chestnut did not show evidence of improvement in venous ulcer healing.[73]

Other Medications

Aspirin and ifetrobane (oral thromboxane A_2 receptor antagonist) have failed to demonstrate benefit in either uncomplicated or complicated chronic venous disease.[54]

Calcium dobesilate is a drug that has been shown to reduce capillary permeability. Whereas some benefit has been shown in reducing ankle edema, no advantage has been proved in the care of patients with venous ulcers.[54]

CONCLUSION

High-grade compression therapy is the mainstay of treatment for patients with advanced chronic venous disease (C4-C6). The ESCHAR trial showed that there is a subgroup of patients who may benefit from ablation of refluxing veins, in addition to compression therapy to prevent ulcer recurrence. In patients with uncomplicated C1-C2 chronic venous disease, compression therapy may be beneficial in symptom control, but it is not associated with disease regression.

MPFF is currently the most effective medication in C1-C2 chronic venous disease, and there is level 1A evidence that its use is advantageous, mainly in symptom control. MPFF may be a useful adjunct in the care of patients with C6 disease.

In this meta-analysis of 10 prospective randomized trials, the micronized purified flavonoid fraction was found to be effective in the management of symptoms and edema, compared with other venoactive drugs (ruscus extract, hydroxyethylrutoside, diosmin).

Barwell JR, Davies CE, Deacon J, et al. Comparison of surgery and compression with compression alone in chronic venous ulceration (ESCHAR study): randomized controlled trial. *Lancet*. 2004;363:1854–1859.

In this prospective randomized trial, compression alone was compared with compression plus surgery (high ligation and stripping of the saphenous vein) in patients with C6 disease. At 24 months, the recurrence rate was significantly lower in the compression-surgery group.

Gohel MS, Barwell JR, Taylor M, et al. Long term results of compression therapy alone versus compression plus surgery in chronic venous ulceration (ESCHAR): randomized controlled trial. *BMJ*. 2007;335:83.

The long-term results of the ESCHAR trial are analyzed in this report. Lower ulcer recurrence rate was noted in the compression-surgery group compared with compression therapy only at a 4-year follow-up. The benefit of the combined compression-surgery approach was noted mostly in the subgroup of patients with superficial or segmental deep vein reflux.

Michaels JA, Campbell WB, Brazier JE, et al. Randomized clinical trial, observational study and assessment of cost-effectiveness of the treatment of varicose veins (REACTIV trial). *Health Technol Assess*. 2006;10:1–196, iii-iv.

In this prospective randomized trial, surgery (high ligation of the saphenofemoral junction, great saphenous vein stripping, and phlebectomies) was found to be more cost-effective than conservative therapy (lifestyle modification, leg elevation, and compression stockings) in patients with C2 disease. Injection sclerotherapy also appeared to be cost-effective for patients with superficial venous reflux but was found to produce less benefit compared with surgery.

Nelson EA, Bell-Syer SE. Compression for preventing recurrence of venous ulcers. *Cochrane Database Syst Rev*. 2012;(8):CD002303.

This 2012 update of a Cochrane review emphasizes the importance of compression therapy in preventing ulcer recurrence. No difference was noted between high compression and moderate compression in ulcer recurrence in three trials. Moderate compression stockings were associated with higher compliance to therapy.

Nelson EA, Prescott RJ, Harper DR, et al. A factorial, randomized trial of pentoxifylline or placebo, four-layer or single-layer compression, and knitted viscose or hydrocolloid dressings for venous ulcers. *J Vasc Surg*. 2007;45:134–141.

In this prospective randomized trial, pentoxifylline was associated with a statistically nonsignificant improvement in ulcer healing. However, Cox regression analysis modeling resulted in a clinically significant improvement in ulcer healing with pentoxifylline.

O'Donnell TF Jr, Passman MA, Marston WA, et al. Management of venous leg ulcers: clinical practice guidelines of the Society for Vascular Surgery (R) and the American Venous Forum. *J Vasc Surg*. 2014;60(2 suppl):3S–59S.

Evidence-based clinical practice guidelines for the care of patients with venous ulcers are discussed in this report.

O'Meara S, Tierney J, Cullum N, et al. Four layer bandage compared with short stretch bandage for venous leg ulcers: systematic review and meta-analysis of randomized controlled trials with data from individual patients. *BMJ*. 2009;338:b1344.

In this meta-analysis comparing the effectiveness of four-layer and short stretch single-layer compression bandages, it was noted that four-layer bandages were associated with shorter healing time in larger ulcers. Chronic ulceration and previous ulcerations were found to be independent predictors for delayed ulcer healing.

Pittler MH, Ernst E. Horse chestnut seed extract for chronic venous insufficiency. *Cochrane Database Syst Rev*. 2012;(11):CD003230.

This is the 2012 update of a Cochrane database review first published in 2002. Efficacy and Safety of Horse Chestnut Seed (HCSE) versus placebo are reviewed. Leg pain was assessed in seven placebo-controlled trials. In six trials, a significant reduction of leg pain was observed with HCSE. Leg volume was also noted to be significantly decreased (95% CI 13.49 to 50.72) in the HCSE cohort in six trials. The authors conclude that HCSE is an efficacious and safe short-term treatment for CVI.

Smith PC. Daflon 500 mg and venous leg ulcer: new results from a meta-analysis. *Angiology*. 2005;56(suppl 1):S33–S39.

The micronized purified flavonoid fraction at a dose of 500 mg twice per day was noted to increase ulcer healing, particularly in patients with long-standing large (5 and 10 cm^2) venous ulcers.

Perforating veins (PVs) were not described until drawings by Justus Christian Von Loder were published in 1794.[1] From that time, for more than a century, their role in venous disease remained unappreciated despite the illuminating work of M. Verneuil and subsequent analysis by John Gay.[2] In 1917, John Homans suggested that incompetent perforating veins (IPVs) played a key role in the genesis of venous ulcers.[3] Subsequently, Beecher and Warren formulated the concept of transmission of ambulatory pressure through IPVs into the superficial system, which was supported by the investigations of Cockett and Dodd and provided a physiologic basis for the surgical interruption of IPVs.[4-6] In 1938, Linton described a surgical approach to IPVs in the distal portion of the calf that became the standard in treating venous ulcers for several decades.[7] Multiple modifications of Linton's original technique were proposed to decrease wound complications and to avoid incisions too close to the ulcer. This led to a minimally invasive approach pioneered by DePalma and Edwards and culminated in the use of endoscopy, first described by Hauer.[8] Adding a tourniquet and gas insufflation, Gloviczki and Conrad transformed subfascial endoscopic perforating vein surgery (SEPS) into a reliable procedure that was disseminated around the world and replaced the open surgical approach.[9,10]

The development of endovascular treatment options for reflux in superficial veins has established a new standard for patients with chronic venous insufficiency (CVI), in whom the invasiveness and risk for wound complications associated with SEPS exceed those of the treatment of saphenous veins. As a result, new modalities, such as ultrasound-guided percutaneous ablation of perforating veins (PAPS) with sclerosing solutions or thermal energy, have become the preferable option.[11]

Renewed interest in outcomes following treatment of IPVs and their role in venous pathophysiology uncovered a lack of reliable information related to their impact on the natural history and severity of CVI. Despite a growing body of evidence substantiating decision making in the management of patients with CVI, the indications for eliminating PV reflux remain imprecise.

Abstract

This chapter describes the role of incompetent perforating veins (IPVs) in the pathogenesis and natural history of chronic venous disease (CVD) and its progression to chronic venous insufficiency (CVI), diagnostic techniques for identification of PVs, criteria for assessing their incompetence, and indications and techniques for the interruption of IPVs.

Many aspects of the topic have not been subjected to proper scientific investigation; therefore evidence-based medicine is not always available. In these cases, we have presented material as consensus-based, or even as the author's individual and group experience.

sclerotherapy

In this chapter we describe the role of IPVs in the pathogenesis and natural history of chronic venous disease (CVD) and its progression to CVI, diagnostic techniques for identification of PVs, and criteria for assessing their incompetence. We discuss indications and techniques for the interruption of IPVs as well as the outcomes of these treatment modalities. We have made every attempt to stay within the framework of evidence-based medicine. However, because some or perhaps many aspects of the topic have not been subjected to proper scientific investigation, we refer to our individual and group experience when appropriate. We identify such statements because they introduce substantial bias.

PATHOPHYSIOLOGY

The role of PVs in normal physiology and in the pathogenesis of CVD are discussed in Chapter 156. In this chapter, we review only the relevant aspects of PVs to better understand the rationale for the treatment of IPVs.

Normal Perforating Veins

The venous system of the lower extremity is rich in interconnections between the individual vessels. Because of the numerous collateral circulatory routes established, disruption of venous flow as well as compression of the veins by contracting muscles during locomotion or external pressure is prevented during changes in position of the body and of the extremity itself. By crossing the proper fascia of the extremity, PVs provide a connection between the superficial and deep venous systems in the calf and thigh. There are approximately 60 PVs in a lower extremity,[12] and most if not all of them have valves directing flow from the superficial to the deep veins.

Our understanding of PV anatomy and normal physiology is based mainly on studies conducted during the 1960s and 1970s and on inferences from clinical observations of pathologic conditions. Although some anatomic studies demonstrated that all PVs have valves,[13] others showed that some PVs are avalvular.[12,14] The latter, however, are found in only a minority of extremities and not more frequently than two veins per extremity.[12] These anatomic data are consistent with findings from duplex scans of asymptomatic legs, only 3.6% of which have bidirectional flow in PVs.[15] Whether PVs provide collateral ways for blood flow to bypass areas of obstruction of the superficial veins, such as compression from outside during sitting, or their presence facilitates outflow from superficial veins when pressure in the deep veins drops during walking, or both, it is clear that flow in healthy PVs is directed from the superficial into the deep system. Although the hemodynamic role of PVs in normal circulation has not been addressed by experimental or direct observational studies, it is unlikely that the current theory could be meaningfully challenged.

The role and significance of IPVs are much less obvious. In the absence of functioning valves, blood flow in a PV is governed mainly by the pressure gradient in adjoined segments of the superficial and deep systems. Active contraction of the venous wall and compression by surrounding muscles cannot compensate for the absence of the valve, especially in enlarged PVs with significantly degenerated walls. Therefore knowledge of the hemodynamic function of the deep and superficial systems is critical for understanding the role of IPVs, and this role may differ according to the status of each of the two systems.

Hemodynamic Impact of Perforating Vein Incompetence

IPVs can be found in 40% to 60% of extremities with primary CVD and even more frequently in legs with postthrombotic disease.[16-18] Isolated incompetence of a PV is extremely rare,[19,20] and in most cases IPVs coexist with insufficiency of the superficial veins, deep veins, or both. Although the prevalence of IPVs is slightly higher in legs with both deep and superficial reflux than in limbs with only superficial reflux,[17] the presence of axial superficial reflux appears to be the major factor associated with a higher prevalence of IPVs.[18] More than 60% of extremities with axial reflux in the great saphenous vein (GSV) have incompetent PVs, as opposed to 38% of extremities with only segmental superficial reflux.[16] An association between axial superficial reflux and PV incompetence has been shown during the progression to CVI. About a third of patients with symptomatic varicose veins develop new refluxing segments in 1 year.[21,22] In half of these cases, the new IPVs also develop during the same time.[21,23]

The observation that correction of superficial reflux leads to resolution of perforator incompetence in most limbs supports the concept that superficial reflux causes an "overload" of PVs, resulting in dilation and incompetence.[24] However, treatment of saphenous reflux by either stripping or ablation results in obstruction of the superficial veins to which PVs are connected, or in a significant increase in resistance to outward flow in PVs. Therefore elimination of PV reflux after such treatment does not necessarily mean that the competence of the PV valves will be regained. Rather, it simply means that the blood cannot flow through PVs into (obstructed) superficial veins, even if the PVs themselves remain open. The presence of these incompetent perforators without demonstrated reflux may be a reason that "isolated" IPVs are found in previously treated extremities and cause new symptoms and worsening hemodynamics.[19,25] In addition, surgical treatment of superficial veins often fails to reverse PV incompetence and new IPVs develop in limbs previously treated surgically.[23,26]

The presence of deep reflux further complicates the situation. An IPV may cause reversal of flow in an adjoining segment of deep vein, which is sometimes mistakenly interpreted as deep venous insufficiency but really reflects flow from the segment of deep vein between competent valves through an incompetent perforator into a connected superficial vein. In these cases, correction of superficial insufficiency with or without IPV interruption leads to disappearance of reversed flow in the deep vein segment.[27] When deep reflux is caused by true valvular incompetence, reflux may persist after the treatment of superficial veins.[28] Thus, interpretation of IPV function based on data from clinical studies is not always possible.

Direct measurement of blood flow in IPVs and venous pressure in superficial veins has demonstrated that even when incompetent, a PV can function in a way similar to competent PVs. During standing, there is no blood flow through the IPV, and during walking, the net flow through the IPV is from superficial veins to deep veins despite the bidirectional nature of flow during muscle contractions.[29]

Occlusion of an IPV does not influence venous pressure in superficial veins, whereas occlusion of an incompetent GSV normalizes ambulatory hypertension.[29] In light of these findings, the concept of transmission of the higher blood pressure from deep into superficial veins via IPVs during ambulation becomes questionable. Indirectly, this was confirmed by the demonstration of independent pressure changes in superficial and deep veins during ambulation.[30]

Clinical Correlations of Perforating Vein Incompetence

The presence of IPVs is just one of many factors that determine the progression to advanced stages or affect the functional status and quality of life of CVD patients. The specific role of IPVs in the natural history and pathogenesis of CVD is less clear. The concept that IPVs can cause symptoms such as swelling and skin changes led to the development of more aggressive approaches to treatment and remains the latter's justification.[5] IPVs alone can cause symptoms, affect hemodynamics, and increase the severity of disease.[19,25] Even more convincing is the fact that successful treatment of an "isolated" IPV is associated with the relief of symptoms and improvement of severity scores.[19]

In addition to their role in symptom development and disease progression, IPVs can be a source of recurrent varices after treatment. This concept is supported by consistent findings of a high prevalence of IPVs in extremities with recurrent varices.[31-34] Whether this association is important only in the presence of deep reflux or also plays a role in extremities with a competent deep system remains to be investigated.[33,35]

The relationship between IPVs and skin ulcers in the leg was historically the first to be demonstrated and was consistently confirmed in multiple small case series in which it was shown that surgical interruption of IPVs promotes healing and prevents the recurrence of venous ulcers.[36] This effect is especially prominent in primary CVD and less so in limbs with post-thrombotic disease.[37] Even treating IPVs alone can promote healing of ulcers in the majority of limbs with primary CVD.[19] Large randomized controlled trials, however, have failed to confirm this effect of IPV treatment. The Dutch Ulcer Trial, for example, showed ulcer healing rates of 83% in the surgical group and 73% in the group treated by compression. Ulcer recurrence was almost the same in the two groups: 22% in the surgical group and 23% in the compression group.[38] The results of this and other trials[23,39,40] should be interpreted cautiously because their designs are far from ideal to answer the question of the role of IPVs in ulceration.

In a systematic review of the literature, O'Donnell showed that there is no level 1 evidence that treatment of IPVs alone affects ulcer healing or recurrence; level 1 evidence is available only for ligation of the GSV alone for decreasing recurrence of venous ulcers.[41] He concluded that there is a need for randomized controlled trials to prove the role of IPV treatment for classes C5 and C6 disease in the Clinical, Etiologic, Anatomic, Pathophysiologic (CEAP) classification system.

Given the uncertainty of the physiologic role of IPVs and the lack of high-level evidence of efficacy of IPV interruptions, decision making in the treatment of IPVs can be a challenging task. The relatively low risk of IPV interruption procedures may be the reason that they have been used in the past for the following indications: (1) normalization of venous hemodynamics, (2) prevention of the progression of CVD to more advanced stages, (3) resolution of symptoms and thereby a decrease in disease severity, (4) prevention of recurrent varicose veins, (5) promotion of ulcer healing, and (6) prevention of recurrent venous ulcers. Clear identification of one or more of these six points as a treatment goal in a patient or as an outcome to be measured in a study may facilitate our progress toward better understanding of the role that IPVs play in limbs with CVD.

ANATOMY

As their name suggests, PVs perforate the deep fascia of the leg, which separates the superficial and deep compartments; they can be classified as direct or indirect. Direct perforators connect the superficial to the deep venous systems, whereas indirect perforators join the venous sinuses of the calf muscles. Furthermore, PVs connect to each other via communicating veins above and underneath the deep muscle fascia. The majority of PVs are accompanied by perforating arteries (Fig. 158.1) and nerves that provide blood supply and innervation to the skin.[12,42] Within the fascial orifice the artery is usually located proximal to the vein, but the topography of the subfascial and suprafascial segments of perforator arteries varies significantly. These arteries can be clearly identified by duplex ultrasound, and their position should be taken into account, especially if sclerotherapy is being considered as a treatment option.[43]

The International Interdisciplinary Consensus Committee on Venous Anatomical Terminology recommends classifying PVs into six groups according to the segment of the lower extremity in which they are found[44]:

Perforators of the foot *(venae perforantes pedis)*
Perforators of the ankle *(venae perforantes tarsalis)*
Perforators of the leg *(venae perforantes cruris)*
Perforators of the knee *(venae perforantes genus)*
Perforators of the thigh *(venae perforantes femoris)*
Perforators of the gluteal muscles *(venae perforantes glutealis)*

Each group includes several subgroups (Fig. 158.2). One of the aims of this classification is to allow topographic description of PVs to avoid the use of personal names, which are often historically inaccurate.

Many PVs are small vessels and have little clinical significance. The most important perforators from a clinical standpoint are the direct medial calf perforators, which cross the superficial posterior compartment. The posterior tibial PVs originate from the posterior accessory saphenous vein of the calf (posterior arch vein in the old terminology). The most distal posterior

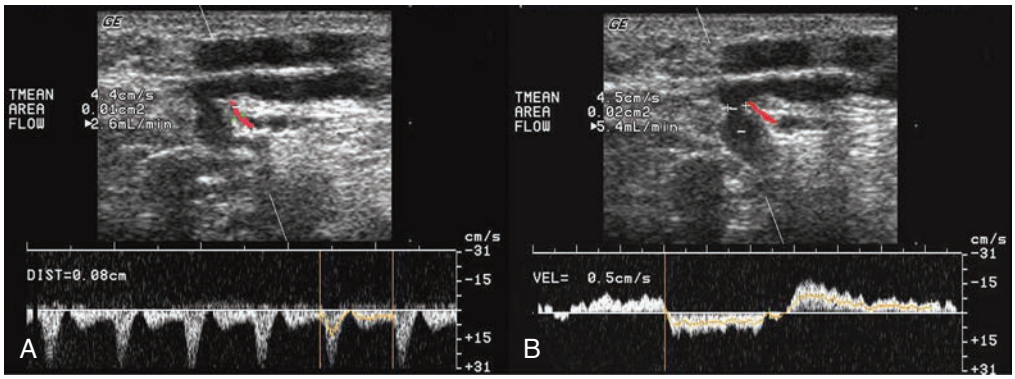

Figure 158.1 (A) A small perforating artery is located next to the perforating vein at the fascial level. Pulsed-wave Doppler confirms arterial flow. (B) Doppler signal from the incompetent perforating vein indicates bidirectional flow.

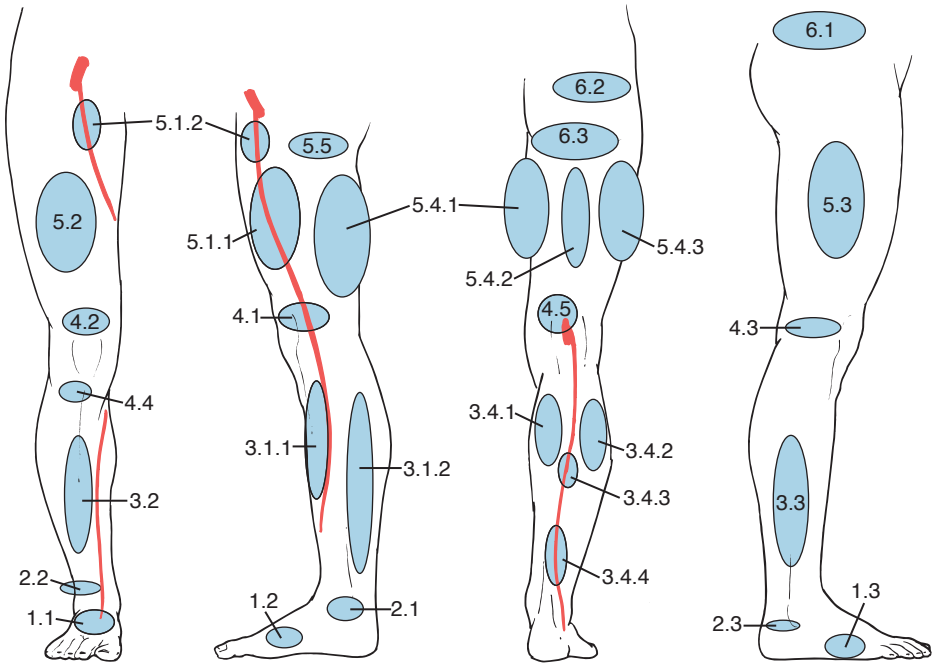

Figure 158.2 Schematic representation of the topography of the main groups of perforating veins (PVs). Foot PVs: 1.1, dorsal foot PV; 1.2, medial foot PV; 1.3, lateral foot PV. Ankle PVs: 2.1, medial ankle PV; 2.2, anterior ankle PV; 2.3, lateral ankle PV. Leg PVs: 3.1.1, paratibial PV; 3.1.2, posterior tibial PV; 3.2, anterior leg PV; 3.3, lateral leg PV; 3.4.1, medial gastrocnemius PV; 3.4.2, lateral gastrocnemius PV; 3.4.3, intergemellar PV; 3.4.4, para-achillean PV. Knee PVs: 4.1, medial knee PV; 4.2, suprapatellar PV; 4.3, lateral knee PV; 4.4, infrapatellar PV; 4.5, popliteal fossa PV. Thigh PVs: 5.1.1, PV of the femoral canal; 5.1.2, inguinal PV; 5.2, anterior thigh PV; 5.3, lateral thigh PV; 5.4.1, posteromedial thigh PV; 5.4.2, sciatic PV; 5.4.3, posterolateral thigh PV; 5.5, pudendal PV. Gluteal PVs: 6.1, superior gluteal PV; 6.2, midgluteal PV; 6.3, lower gluteal PV. (Redrawn from Caggiati A, Bergan JJ, Gloviczki P, et al. Nomenclature of the veins of the lower limbs: an international interdisciplinary consensus statement. *J Vasc Surg*. 2002;36: 416–422.)

tibial perforators are located behind the medial malleolus, whereas the middle and upper posterior tibial perforators are located more proximally in the calf (at 7–9 cm and 10–12 cm from the medial malleolus, respectively) and about 1 inch medial to the tibia; these PVs connect the posterior arch vein to the posterior tibial veins (Cockett perforators). More proximal direct PVs are the paratibial direct perforators or "24-cm perforators," which are located closer to the tibia and 18 to 22 cm from the medial malleolus, as evident in anatomic cadaveric studies (Fig. 158.3). Another group of medial calf perforators, found just below the knee, is known as Boyd's perforators. They connect the GSV and its tributaries to the tibial or popliteal veins. Also of probable clinical importance are the posterolateral or peroneal perforators, which connect tributaries of the short saphenous vein to the peroneal veins. Among these, the most important are Bassi's perforator, located at 5 to 7 cm from the lateral aspect of the ankle, and the "12-cm perforator," located at 12 to 14 cm. Thigh perforators are less developed than calf PVs. The main instances are the Dodd perforators and the Hunterian perforators, which are located in the medial aspect of the thigh and connect the GSV to the popliteal or femoral veins. Other PVs connect the superficial system to the profunda femoris vein.

DIAGNOSTIC EVALUATION

Clinical Investigation (CEAP Level 1)

Large IPVs can be identified by palpation of the fascial defect, especially when varicose veins are located in the same area. By applying gentle pressure against this defect, an investigator can feel retrograde flow when a patient performs the Valsalva maneuver or coughs. Handheld continuous-wave Doppler ultrasonography can be the next diagnostic step, but its sensitivity is insufficient and its specificity is not different from that of physical examination, which is close to zero.[45]

The best test to identify IPVs is duplex ultrasound. This test should be performed in all patients with CVD. The invasive

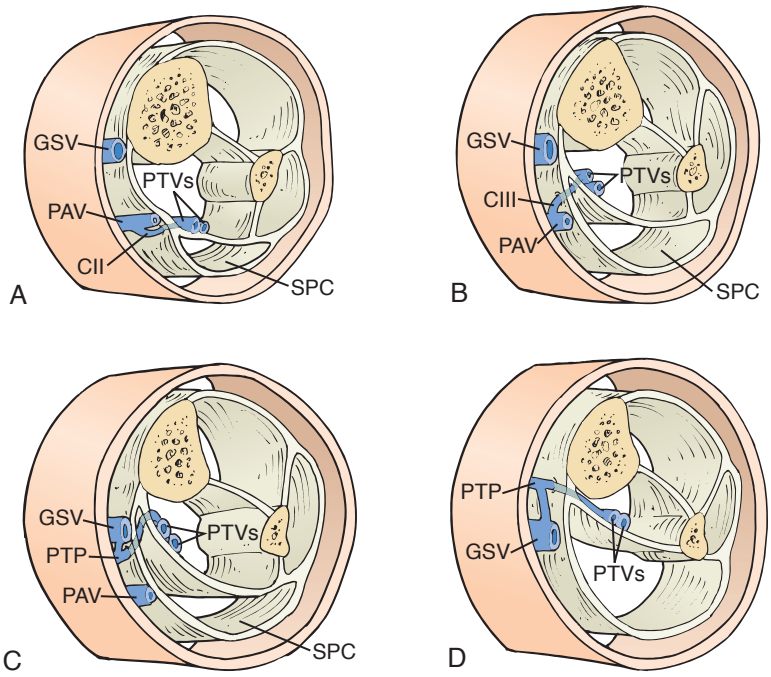

Figure 158.3 Compartments and medial veins of the leg. Cross sections are shown at the level of Cockett II (posterior tibial perforator) (A) Cockett III, (B) "24 cm," and (C) more proximal paratibial (D) Perforating veins. *CII,* Cockett II; *CIII,* Cockett III; *GSV,* great saphenous vein; *PAV,* posterior arch vein; *PTP,* paratibial perforator; *PTVs,* posterior tibial veins; *SPC,* superficial posterior compartment. (From Gloviczki P, Bergan J, eds. *Atlas of Endoscopic Perforator Vein Surgery,* London: Springer-Verlag; 1998.)

nature of venography, its questionable diagnostic properties for identification of IPVs,[45] and its inability to map the exact location of IPVs make its use in CVD limited to selected cases requiring venous reconstruction.

Noninvasive Vascular Investigation (CEAP Level 2)

The size of PVs and their hemodynamic properties are to a great extent affected by the position of the body. It is recommended that duplex scanning be performed while the patient is standing or sitting; however, the 30-degree head-up supine position gives similar results.[46] All surfaces of the extremity should be carefully scanned. The location of IPVs varies, and indirect IPVs can be found at a distance from major axial veins.

Because most PVs are rather short veins, induction of reversed flow in them is a great challenge. To initiate a reversed flow of appropriate duration, the connected superficial vein should be almost empty and the adjoined deep vein should contain a sufficient volume of blood. In many cases this is difficult to achieve, especially when the test is performed on a standing patient. To solve this problem, two sets of criteria for PV incompetence were suggested: a shorter-time cut point of 0.35 second to define the reflux[21] and the use of PV diameter instead of reflux time.[47] Diameter should be measured on a B-mode transverse section at the site where the vein penetrates the fascia (Fig. 158.4). Reflux time should be measured on a longitudinal section using a pulsed-wave mode combined with simultaneous B-mode (duplex) or with the addition of a color Doppler mode (triplex). The site for measurement of reflux time should be the same as that for measurement of diameter—at the level of the fascial orifice (Fig. 158.5).

In our experience, using both approaches simultaneously has proved beneficial. Small PVs less than 2 mm in diameter

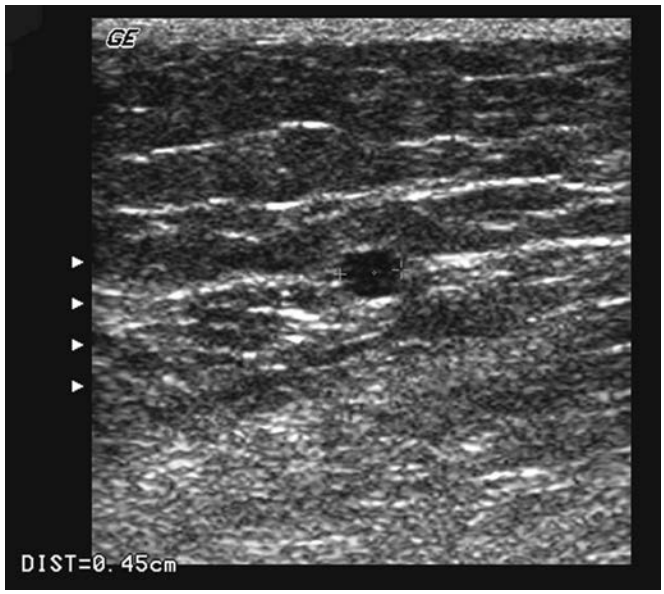

Figure 158.4 Measurement of perforating vein diameter is performed in a B-mode transverse section of the PV at the level of the fascial orifice.

have questionable clinical significance, even when reversed flow through them exceeds the cut point for reflux. They also present a technical challenge for treatment and often undergo spontaneous thrombosis and resolution after ablation of the connected segment of superficial vein. PVs larger than 4 mm in diameter are almost certainly pathologic and may be identified as incompetent even when the reversed flow through them is shorter than the cut point for reflux. Finally, PVs 2 to 4 mm in diameter should be considered incompetent only when they meet the appropriate hemodynamic criteria.

When treatment of an IPV is being considered, duplex scanning should be repeated in the exact position as the patient

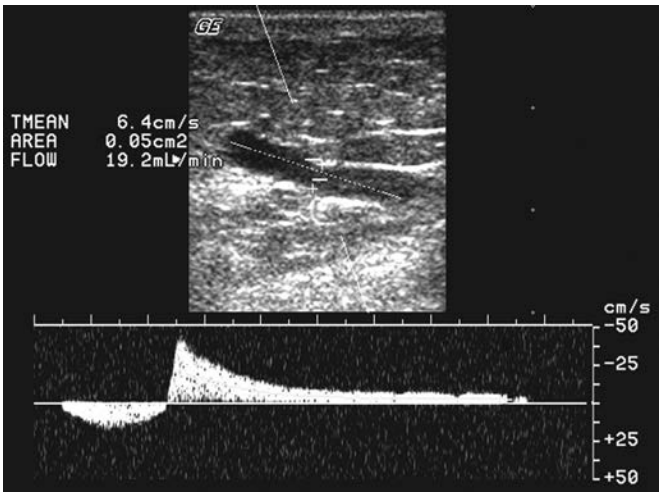

Figure 158.5 Measurement of flow velocity in a perforating vein (PV) is performed in duplex mode in a longitudinal section of the PV at the level of the fascial orifice.

will be in during the treatment. This can be supine, prone, or on the side, depending on the selected access point. Shifting of anatomic structures can markedly affect the topographic relationship between subfascial and suprafascial segments of the IPV and superficial veins, which, in turn, will change the position of a desirable access point.

INDICATIONS FOR INTERRUPTION

Precise definition of the indications for interruption of IPVs is necessary in clinical practice because it provides a basis for assessment of treatment outcomes. It is even more important when research studies are planned and executed. Although definitive studies to identify when IPV interruption should be considered are yet to be conducted, one or more of the following reasons can serve as the indication for treatment of IPVs:

1. Promotion of ulcer healing in extremities with CEAP clinical class C6
2. Prevention of ulcer recurrence in extremities with clinical classes C5 and C6
3. Diminution of the severity of CVD and resolution of symptoms in C2S to C5S extremities
4. Prevention of progression to more advanced stages in C4b extremities

The presence of an IPV alone does not justify interruption. The decision to intervene should be based on clinical judgment and assessment of the role of a specific IPV in the overall hemodynamic picture of the extremity. The benefits of interruption and the risks of leaving this PV untreated should also be considered.

Key suggestions and recommendations from the AVF/SVS guidelines[48] for the treatment of CVD include the following:

- We suggest treatment of pathologic PVs that includes those with outward flow of 500 ms duration and a diameter of 3.5 mm located adjacent to healed or open venous ulcers (class C5–C6, grade 2B).
- We suggest treatment of pathologic perforators in patients with advanced C4 disease, especially in those with pending ulceration (class C4, grade 2C).
- We recommend against selective treatment of incompetent PVs in patients with simple varicose veins (class C2, grade 1B).
- We suggest preferential use of ultrasonographically guided percutaneous techniques (thermal ablation or sclerotherapy) for perforator ablation over subfascial endoscopic perforator surgery (SEPS) or open surgical phlebectomy or perforator ligation (grade 2C).

The most recent AVF/SVS guidelines provide more specific indications for treating limbs with C4b–C6 disease.

These guidelines include the following statements:

- In a patient with a venous leg ulcer (C6) and incompetent superficial veins that have reflux to the ulcer bed in addition to pathologic PVs (outward flow of less than 500 ms duration, with a diameter of >3.5 mm) located beneath or associated with the ulcer bed, we suggest ablation of both the incompetent superficial veins and perforator veins in addition to standard compressive therapy to aid in ulcer healing and prevent recurrence (grade 2; level of evidence, C).
- In a patient with skin changes suggestive of an impending venous ulcer (C4b) or healed venous ulcer (C5) and incompetent superficial veins that have reflux to the ulcer bed in addition to pathologic PVs (outward flow of >500 ms duration and a diameter of >3.5 mm) located beneath or associated with the healed ulcer bed, we suggest ablation of the incompetent superficial veins to prevent the development or recurrence of a venous leg ulcer (grade 2; level of evidence, C). Treatment of the incompetent PVs can be performed simultaneously with correction of axial reflux or can be staged with reevaluation of perforator veins for persistent incompetence after correction of axial reflux (grade 2; level of evidence, C). In a patient with isolated pathologic perforator veins (outward flow >500 ms duration and a diameter of >3.5 mm) located beneath or associated with the healed (C5) or active ulcer (C6) bed regardless of the status of the deep veins, we suggest ablation of the pathologic PVs in addition to standard compression therapy to aid in venous ulcer healing and to prevent recurrence (grade 2; level of evidence, C).

OPERATIVE PLANNING OPTIONS

The timing and technique of IPV interruption are important. Although procedures can be staged, performing simultaneous saphenous vein ablation and perforator ablation has two major advantages. First, all invasive procedures are performed in one session, which is highly desirable for the patient and reduces the cost of treatment. Second, it has been suggested that any remaining incompetent tributaries and IPVs connected to the saphenous veins can increase the chance of recanalization after thermal and chemical ablation.

Thus, treating IPVs at the time of saphenous vein ablation possibly improves the result of the saphenous vein ablation.[77] On the other hand, elimination of saphenous reflux has a

profound effect on the global venous hemodynamics of the leg. Segments not specifically targeted during surgery, such as PVs and deep veins, may partially reverse their incompetence when the total venous "overload" of the leg is reduced. In as many as 58% of IPVs, incompetence will reverse during the 2 years after stripping.[50] Even when IPVs persist after stripping of the GSV, their impact on the clinical status of the extremity is questionable. The ESCHAR (Effect of Surgery and Compression on Healing and Recurrence) study showed that presence of IPVs after stripping does not affect the healing time and rate of ulcers.[51] It has also been observed that adding SEPS to the GSV stripping does not significantly improve patients' quality of life or prevent recurrent symptoms.[52]

When simultaneous treatment of IPVs and incompetent saphenous veins is planned, selection of the IPV interruption technique is very much dependent on the method of treating the saphenous vein. The less invasive options for saphenous ablation limit the use of open surgical interruption because it may increase immediate postoperative morbidity and negate the advantages of minimally invasive procedures. When IPV interruption is performed alone, selecting a minimally invasive option still has the advantage of minimizing immediate postoperative morbidity, thereby allowing early ambulation and reducing impact on quality of life.

OPEN SURGERY

The original open perforator interruption described by Linton in 1938 was subsequently abandoned and should not be considered a choice for IPV interruption unless other options are not available. Interruption of PVs through small stab wounds plus avulsion by a vein hook is now preferred among the open surgical methods because this procedure is significantly less invasive and does not require hospitalization. With this technique, duplex scanning is used for preoperative mapping and the IPVs are marked on the skin, which allows performance of a more precise procedure. Ligation of incompetent perforators can also be done by making a short incision directly over the marked sites and ligating them at the fascia with absorbable sutures. Alternatively, the position of the vein hook can be controlled with the use of intraoperative transcutaneous ultrasound to ensure that a targeted IPV is actually interrupted. Selection of an open perforator interruption technique does not guarantee 100% success; 5% of perforators are usually missed and 32% recur within 3 years, half of them being incompetent.[53]

Subfascial Endoscopic Perforator Surgery

SEPS uses endoscopic instrumentation to achieve interruption of incompetent perforators through small incisions placed remotely from areas of lipodermatosclerosis or ulceration. First described by Hauer in the 1980s,[8] SEPS became the most accepted surgical treatment of CVI because of its minimally invasive nature and safety profile compared with the classic, more extensive Linton procedure. SEPS can be performed through one or two endoscopic ports after exsanguination of the limb with leg elevation and the Esmark bandage, followed by application of a thigh tourniquet inflated to 300 mm Hg (Fig. 158.6). Carbon dioxide is insufflated to enlarge and optimally visualize the subfascial space, with pressure maintained at around 30 mm Hg. On completion of the procedure, the ports and instrumentation are removed, the tourniquet is deflated, and the carbon dioxide is manually expressed from the subfascial space.[54]

Results and Complications

Retrospective data from the North American SEPS registry on 146 patients demonstrated an 88% ulcer healing rate at 1 year, with a median ulcer healing time of 54 days and a complication rate of 6% (Fig. 158.7).[37] Complications encountered were deep venous thrombosis (DVT) (<1%), superficial thrombophlebitis (3%), and saphenous neuralgia (7%).[37] Other complications of SEPS include wound infection, paresthesias, and subfascial space hematoma.[55] The ulcer recurrence rate was 28% at 2 years (Fig. 158.8), significantly better than most published series on nonoperative management. It was evident from the study that a significant number of ulcers did not heal or recurred; however, the recurrent disease after surgery appeared to be less severe in most patients than before surgery. Although this trial was not randomized, it must be noted that ulcers failed to heal in 101 patients until surgery was performed despite an estimated 75% good to excellent compliance with nonoperative care. Subgroup analysis demonstrated a higher recurrence rate in postthrombotic limbs than in those with primary valvular incompetence (46% vs. 20% at 2 years, $P < .05$). Similar results have been reported by several authors, so it is unclear whether SEPS is indicated in postthrombotic limbs. Several other studies have demonstrated a benefit of SEPS in early ulcer healing and decreased recurrence rates (Table 158.1). Nonetheless, other studies did not prove the clinical efficacy of PV reflux ablation, even in patients with ulcerated limbs.[56] For instance, in a report by Scriven and colleagues, combined perforator and superficial vein reflux ablation in ulcerated limbs with associated deep reflux did not result in clinical improvement compared with limbs treated by superficial reflux ablation alone.[57] In a meta-analysis, Tenbrook and coworkers analyzed pooled data of surgical treatment in 1140 limbs with advanced CVD from 20 published series.[58] Ulcers healed in 88% of the limbs treated by SEPS, with or without superficial venous ablation. The recurrence rate was 13% at a mean follow-up period of 21 months. Risk factors for nonhealing and recurrent ulcers included new or recurrent IPVs, postthrombotic syndrome, and ulcers larger than 2 cm in diameter. Surgical complications included wound infection (6%), hematoma (9%), neuralgia (7%), and DVT (1%). All these data from PV surgery trials came from nonrandomized cohorts that almost invariably lacked a comparison group. The Dutch SEPS trial, a randomized, prospective, multicenter study designed to compare SEPS with conservative treatment of venous ulcers, has been performed and published (Table 158.2). Of 200 legs with ulcers included in the study, 94 were treated surgically and 102 were treated conservatively. Healing rates were 83% in the surgical group and 73% in the conservative

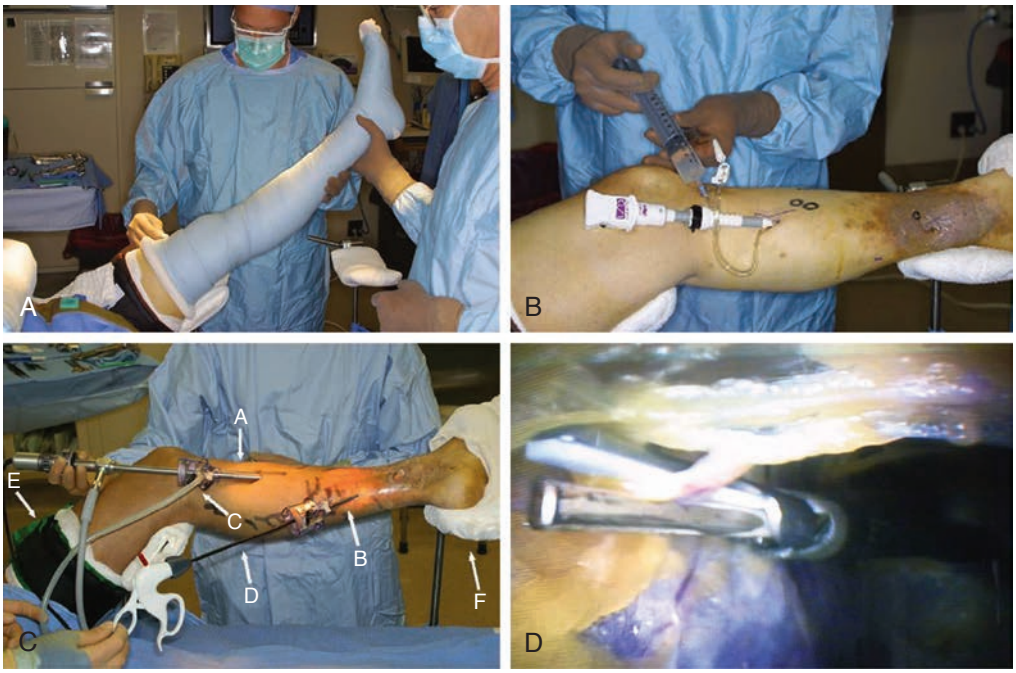

Figure 158.6 (A) Endoscopic division of a perforator is performed in a bloodless field. A pneumatic tourniquet is placed on the thigh, and the extremity is exsanguinated with an Esmark bandage. A tourniquet inflated to 300 mm Hg is used to create a bloodless field. (B) Balloon dissection is used to widen the subfascial space. (C) Subfascial endoscopic perforator vein surgery is performed via two ports: a 10-mm camera port *(A)* and a 5- or 10-mm distal port *(B)* inserted under video control. Carbon dioxide is insufflated through the camera port into the subfascial space to a pressure of 30 mm Hg to improve visualization and access to the perforators *(C)*. A harmonic scalpel *(D)* is inserted through the distal port. The leg is positioned on a holder *(F)*, and the tourniquet is kept inflated *(E)*. (D) The subfascial space is widely explored from the medial border of the tibia to the posterior midline and down to the level of the ankle. Division of the perforator is performed with endoscopic scissors after placement of vascular clips or with a harmonic scalpel placed through the second port. ([A–D] Reproduced with permission of the Mayo Foundation.)

group (difference not significant; median time to healing, 27 months). Recurrence rates were the same in both treatment groups (22% with surgical treatment vs. 23% with conservative treatment). During follow-up at a mean of 29 months in the surgical group and 26 months in the conservative group, the ulcer-free rate was 72% in the surgical group and 53% in the conservative group ($P = .11$). Patients with recurrent ulceration or medially located ulcers in the surgical group had a longer ulcer-free period than those treated in the conservative group ($P = .02$). The trial did not recognize an overall benefit of surgical treatment over compression alone except in selected cases of medial or recurrent ulceration (or both) and in patients who underwent the SEPS procedure in expert venous centers.[38]

Venous ulcers mainly occur at the area of the medial malleolus; however, about 10% develop at the lateral aspect of the ankle. Interruption of lateral calf perforators with SEPS to treat lateral ulcers has been attempted, but clinical outcomes have been unsatisfactory, and perforators were noted to persist postoperatively on duplex scan.[59] It is possible that factors other than PV reflux are behind the pathogenesis of these lesions or that SEPS is inadequate in localizing and interrupting relevant perforators in this particular location. Aside from clinical benefits, one should be able to objectively detect functional improvement after PV interruption to help establish its hemodynamic benefits and correlate it with clinical outcome. Padberg and associates used air plethysmography to assess hemodynamic improvement after perforator and superficial vein surgery and demonstrated a quantifiable improvement up to 2 years after the procedure.[60] Another study from the Mayo Clinic using strain-gauge plethysmography as a diagnostic tool demonstrated improvement in both calf muscle pump function and degree of incompetence in 26 patients 6 months after SEPS and ablation of superficial reflux. These changes correlated with clinical improvement and were significant only in limbs with primary valvular incompetence, as opposed to postthrombotic limbs.[55] Similarly, Ting and colleagues observed significant improvement in both clinical scores and the venous filling index after SEPS; this improvement was maintained at 1-year follow-up.[61] The degree of patient satisfaction was also remarkable, with 74% ± 17% and 90% ± 12% rates of satisfaction at 1-month and 1-year follow-up, respectively.

Until recently, SEPS was considered a minimally invasive alternative to open surgery for the treatment of PV incompetence. Compared with the classic open procedures, the incidence of complications such as wound infection, absence of healing, and nerve injury was significantly lower with SEPS. However, the occurrence of other complications, such as DVT, superficial thrombophlebitis, and neuralgia, as well as the complex learning curve and significant cost, stimulated interest in less invasive methods. Furthermore, the procedure is limited by an inability

to reliably access all incompetent perforator sources and to discriminate between competent and incompetent perforators at the time of treatment.

PERCUTANEOUS ABLATION OF PERFORATING VEINS

The introduction of percutaneous endovenous therapies for superficial venous reflux (thermal and chemical ablation) has established a new standard of office-based procedures that obviate the need for general anesthesia and hospital stay. Thermal and chemical ablation of saphenous veins gained popularity rapidly, thanks to a significant reduction in patient discomfort, fewer complications, and earlier return to work.[62] PAPS combines the precision of a surgical approach with the minimal invasiveness of an injection. PAPS requires a higher level of technical skill than GSV ablation does but offers patients a truly minimally invasive procedure. After PAPS, either as the sole treatment or in conjunction with saphenous ablation, patients can ambulate immediately and experience minimal postoperative pain. PAPS has almost no negative impact on quality of life.[78]

The AVF/SVS clinical practice guidelines recommend PAPS over open surgical techniques. "For those patients who would benefit from pathologic perforator vein ablation, we recommend treatment by percutaneous techniques that include ultrasound guided sclerotherapy or endovenous thermal ablation (radiofrequency or laser) over open venous perforator surgery to eliminate the need for incisions in areas of compromised skin (grade 1; level of evidence, C)."[49]

The two most important technical aspects of PAPS are ultrasound-guided intraluminal access and verification of the

Figure 158.9 Closure RFS (radiofrequency stylet).

initial anatomic success of the treatment. Selection of the access point depends on the technique and instrumentation that will be used. For example, if treatment is planned with the rigid Closure RFS (radiofrequency stylet, Fig. 158.9), an access point should be lined up with the continuation of the subfascial portion of the perforator. More flexible laser fibers allow selection of the entry point to access either the epifascial segment of the IPV or the adjoining superficial vein. A larger and straighter segment of the superficial vein can be selected to provide easier access and a more stable needle position. A guidewire can then be advanced into the perforator and a microintroducer positioned over the wire to secure the precise position for placement of the laser fiber. Alternatively, the fiber can be placed directly through a 21-gauge needle for the 400-μm fiber or through a 16-gauge needle for the 600-μm fiber. If sclerotherapy is planned as the treatment technique, the access selected should be at a safe distance from the perforating artery. If it is not clearly identifiable by duplex scan, the superficial vein connected to the perforator and located a distance of 1 to 2 cm from the fascial orifice should be selected for the access.

For all techniques, successful access and the position of the catheter or needle should be confirmed sonographically. Aspiration of blood is not sufficient because the needle may be in a neighboring vein not connected to the IPV. In the case of thermal ablation, the subfascial position of the catheter should also be verified. The advantage of using the radiofrequency stylet is the ability to measure impedance, which can confirm the intravascular position of the catheter. Sonographic verification, however, is still necessary.

Assessment of initial anatomic success is also based on duplex ultrasound. In addition to verification of the absence of blood flow in the PV, assessment of changes in diameter and echogenicity of the vein wall and lumen is necessary. An increase in echogenicity and thickening of the venous wall, increased echogenicity of the lumen, and absence of spontaneous or induced flow immediately after treatment are signs of successful ablation. An increase in diameter and a decrease in echogenicity with an absence of flow indicate thrombosis in the IPV, which is less desirable because of the risk of propagation in deep veins and the high rate of recanalization. Assessment of success after foam sclerotherapy is most challenging and should be postponed for 24 hours or more because the PV cannot be clearly visualized; flow can be induced by compression of the extremity distal to the PV immediately after successful treatment. As an indirect sign of successful PAPS, we found it helpful to use the dilation and increased flow velocity in the perforating artery accompanying the treated IPV immediately after treatment.[43]

Techniques

Laser Ablation

Several different fibers and kits have been used for endovenous laser ablation of IPVs. The use of lasers with wavelengths of 810-, 940-, and 1320-nm and 980-nm diode lasers has been reported.[63,64]

The patient is placed in the reverse Trendelenburg position and the skin is prepared with sterile technique. Incompetent perforators are visualized and marked on the skin; it is important to document the exact location by measuring its distance from the medial malleolus and tibia for localization during follow-up studies. The target perforator is visualized in transverse view by ultrasound and punctured under vision with a needle; thereafter a stiff introducer and a sheath are advanced over a 0.018-inch guidewire. The laser fiber (600 or 400 μm) is then inserted into the sheath with the tip 0.5 cm or more from the deep system. Tumescent anesthetic (saline solution containing lidocaine, sodium bicarbonate, and epinephrine) is infiltrated into the perivenous tissues to provide anesthesia, reduce dissipation of heat to the surrounding structures, and obtain apposition of the vein walls. Two or three segments of each perforator should be treated, with one of them located subfascially and another epifascially. Each segment should receive between 60 and 100 J or 100 J/cm over the treatable length of the perforator.

Radiofrequency Ablation

The Closure RFS made by Medtronic/Covidien (Mansfield, Mass.) is a rigid device that has two electrodes on the shaft and a removable needle trocar. The vein is punctured either directly with the stylet or with a needle, followed by access over a 0.035-inch guidewire (see Fig. 158.9). Ideally, extrinsic compression should be maintained during treatment (approximately 80 to 90 mm Hg of pressure). After intravascular access has been confirmed by return of blood into the device, tumescent anesthetic is infiltrated around the vein. The vein should be treated in a subfascial segment to ensure the best results, but this should be at least 0.5 cm away from the deep veins. Impedance is maintained between 150 and 350 Ω at a mean temperature of 85°C and a power level of less than 3.5 W. The Closure RFS should be angulated against all four quadrants of the vein wall for 1 minute each, thus requiring 4 minutes of treatment per segment. More segments within the same perforator, ideally two or more, may require treatment to obtain satisfactory closure.

Sclerotherapy

Sclerotherapy can be performed to treat IPVs with a diameter of 4 to 7 mm at the level of the fascia. Smaller veins are seldom incompetent, and larger veins require larger volumes of sclerosant, which can potentially increase the rate of complications. Most

commonly used are sodium tetradecyl sulfate (Sotradecol), sodium morrhuate, and polidocanol (Aethoxysklerol). Larger veins require higher concentrations. In general the patient is placed in the supine position, the skin is prepared by sterile technique, and the vein is punctured under duplex guidance. Venous blood is withdrawn first, just enough to confirm correct needle positioning, and 1 to 2 mL of sclerosing agent is injected. The needle is withdrawn and compression is applied for a few minutes. The vein is reimaged to ascertain the absence of residual flow in the treated perforator. Identification of the accompanying perforating arteries should be attempted to avoid possible skin necrosis, but when this is not possible, it is preferable to inject the perforator in a location well above the fascial opening, where the artery and vein are not so close to each other. Patients with known allergic reactions to sclerotherapy agents, those who are pregnant or lactating, and those with a known or suspected prothrombotic state should not be treated by this technique. The presence of severe arterial occlusive disease or active vasculitis is also a contraindication, because inadvertent intraarterial injection can potentially aggravate preexisting chronic ischemia.

New Treatment Modalities

Similar to thermal ablation techniques that were initially designed for saphenous veins but were adapted to treat IPVs, new technologies are either already being used or likely to be used for this purpose outside their primary indications. Mechanico-chemical ablation (MOCA) has ablation rates similar to those of thermal ablation but does not require tumescent anesthesia.[65-67]

Although the use of other new nontumescent nonthermal ablation modalities for the treatment of IPVs has not yet been reported, it is only a matter of time before technologies such as cyanoacrylate embolization[68,69] will be applied for treatment of IPVs.

Results and Complications

Early success rates with greater than 90% absence of flow within the treated perforator at 6 months have been reported with radiofrequency ablation.[70,71] Unlike GSV closure, skin burns are very rare with the Closure RFS, even when the probe is at a depth of less than 1 cm from the skin.

The early occlusion rate of IPVs treated by laser is reported to be between 85% and 100%.[72,73] Side effects included ecchymosis, induration, and pain (40% to 50%), paresthesias (16%), hyperpigmentation (8%), and phlebitis (4%).[64-68] A 6-month duplex follow-up from a series of 27 perforators treated by laser demonstrated an ablation success rate of greater than 90%.[74] Although detailed documentation of perforator location before treatment is necessary for follow-up comparison, no reliable method exists to determine whether a suspected perforator recurrence is a newly formed perforator or indeed a recanalized perforator.

The early results of duplex-guided sclerotherapy for perforators reported by Guex showed a 90% occlusion rate after three or fewer sessions.[18] In our experience, immediate PV obliteration was achieved in 98% of cases. Skin complications consisting of superficial skin necrosis occurred in 1.5%. Recurrence, defined as the presence of flow in a previously sclerosed PV at duplex follow-up, was present in 23% of cases at a mean follow-up of 17 months. Venous clinical severity scores decreased on average from 11.95 before treatment to 6.5 after treatment ($P < .05$). Likewise, venous disability scores dropped from 1.86 before treatment to 0.81 after treatment ($P < .05$). Perforator recurrence was more common in limbs with ulcerations. Except for the rare occurrence of skin necrosis, cosmetic results were excellent, often with partial reversal of preexisting skin changes and relief of symptoms. Although complications of sclerotherapy are rare, some clinical scenarios should be mentioned. Multiple needle punctures can lead to vasospasm or a hematoma (or both), which may make the procedure technically challenging or technically unsuccessful.

Pain during sclerotherapy injection may be due to intraarterial puncture, in which case the injection should be stopped immediately. Should such pain occur, injection of procaine around the injected artery, local cooling, systemic heparinization, and infusion with low-molecular-weight dextran is recommended. Extravasation in subcutaneous tissues is usually painless unless the sclerosant solution had been mixed with normal saline, which may result in skin necrosis. Another possible serious complication, although rare, is anaphylactic shock. When any sclerotherapy injection is performed, all the necessary equipment to manage this event must be readily available (oxygen, epinephrine, and steroids) because it could be a life-threatening situation.[75,76]

No comparative studies of different PAPS modalities are currently available, but published data suggest that predictors of success differ. A large size of the perforator is more likely to be a risk for failure of sclerotherapy, and a pulsatile flow pattern may cause failure of laser ablation.[64]

Postoperative Management

Immediately after treatment, deep veins should be imaged to rule out DVT, and a compression dressing should be worn continuously for 24 to 48 hours during the day only for the next 5 days. The first follow-up visit should be scheduled within 1 week after the procedure. Duplex scans should be repeated at this time to ensure the absence of DVT and to assess the early anatomic outcome of treatment. The follow-up schedule should be based on other treatment modalities used at the time of treatment of the IPV, but long-term clinical and duplex follow-up is desirable.

Chronic venous insufficiency (CVI) can be well tolerated or advance to a state of chronic venous ulceration. Skin changes such as hyperpigmentation due to CVI of the lower extremity have been reported in 6 to 7 million US citizens, with progression to venous ulceration occurring in up to 2%.[1-3] It is estimated that the cost of venous ulcer care alone in the United States is more than $2.5 billion annually.[4] The excellent early success of ulcer healing with compression is marred by the risk of recurrence in up to 40% of compliant patients and approaches 100% in noncompliant patients.[5,6] Treating all superficial and perforator vein insufficiency can reduce the recurrence risk, but it still occurs in up to 33% of patients with primary deep CVI and 70% of those with the postthrombotic syndrome. These facts demonstrate the importance of deep venous disease in the pathophysiologic process of CVI.[7] Deep venous obstructive lesions in combination with venous reflux have been noted in 55% of patients with chronic venous disease (CVD) in one series, and especially in those with the most severe symptoms.[8] Correcting iliac obstruction without addressing deep venous insufficiency can result in long-term ulcer healing of nearly 60%.[9] The 40% of patients remaining are the select group with chronic deep venous insufficiency who may benefit from valve reconstruction or other open surgical procedures.

PATHOGENESIS

Etiology

Congenital absence of lower extremity venous valves, venous aplasia, or dysplasia is rare.[10] More commonly patients with

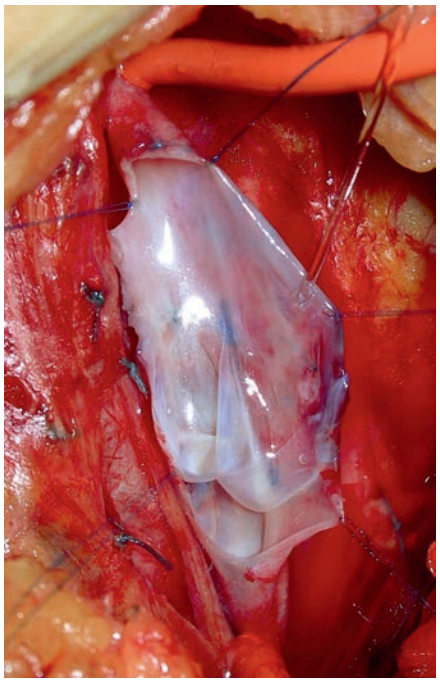

Figure 159.1 Floppy and asymmetrical venous valve leaflets seen after vein opened to reveal the valve cusps.

primary venous insufficiency have floppy, redundant, elongated valve cusps (Fig. 159.1); asymmetrical insertion or development of cusps; or an enlarged venous diameter. All these anomalies prevent normal valve apposition.[11-14] Such cases have no apparent inciting event for the anatomic changes observed, except in cases of clear congenital anomalies. As a consequence of these pathologic changes, reflux occurs in the affected valves either upon standing or with additional stresses. Disregarding aplasia or dysplasia or those with asymmetrical cusp development, in situ tightening of the structurally intact valve can render it competent and functional.

Secondary venous insufficiency is defined as having an apparent inciting event that caused valve damage. The inciting event is often acute deep venous thrombosis (DVT), and in 40% to 70% of all affected patients may be the cause of the deep venous valvular incompetence observed.[11,15-17] The resulting inflammation and scarring with recanalization can cause foreshortening and fibrosis of the valve leaflets, small perforations, or valve adhesion and luminal narrowing (Fig. 159.2).[11] The valves are so damaged that direct repair is not possible. The options remaining to prevent complete system reflux are transplantation of a competent valve from a distant location, transposition of the incompetent venous axis to a position distal to a local competent valve, or the use of less traditional valve techniques such as a neovalve or other valve substitute.

The distinction between "primary" and "secondary" (post-thrombotic) venous disease is not always clear. Diagnostic studies and direct observation at the time of valve surgery have noted both pathologic processes within the same patient.[18,11] Theories proposed to explain a thickened yet functional valve (Fig. 159.3) include potential pathologic changes, resulting simply from sustained hypertension, or from the rapid resolution of deep

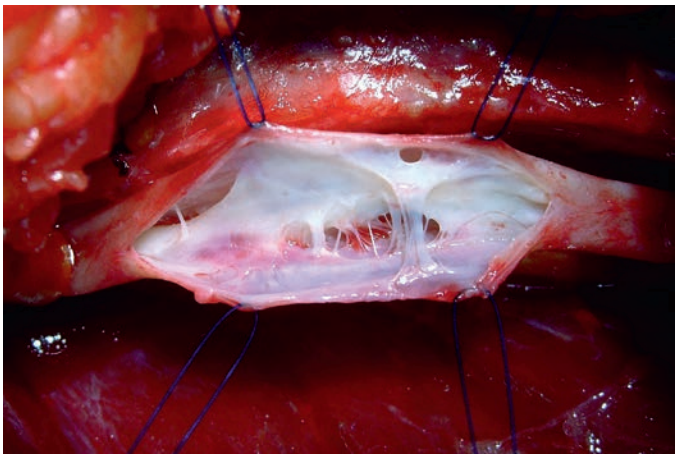

Figure 159.2 Valve destruction resulting from deep vein thrombosis with scarring within the vein, bridges of scar wall to wall, but overall patent vein due to recanalization.

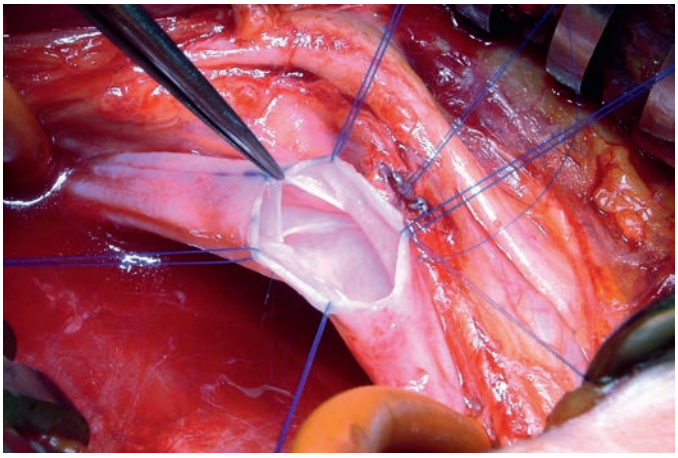

Figure 159.3 Thickened valve in relation to very thin and almost transparent valve noted in Fig. 159.1.

vein thrombus, resulting in minimal damage.[19] Alternatively, the valve itself may not be directly involved in the thrombotic process but affected by thrombotic damage in other locations (proximal or distal).[19-21] Potentially the thickened, noncompliant vein wall resulting from DVT may cause local cusps to become floppy by virtue of a decrease in wall diameter.[11] The valve remains architecturally intact, thin, compliant, and amenable to direct repair.

Hemodynamics

To realize the goal of controlling lower limb venous ambulatory hypertension, correction of deep axial reflux proximal to the calf is required (see Chapters 9 and 156). However, an isolated femoral vein valve reconstruction could be correlated with clinical failure when profunda femoris vein reflux is also present.[22] Conversely, when the profunda system is competent, repair of femoral vein incompetence does improve lower limb venous hemodynamics, since both major collateral pathways are then competent.[22,23] In some cases of femoral vein occlusion, there

is tremendous dilation of the profunda femoris vein such that only correction of reflux in it will be correlated with an improvement in venous hemodynamics (Fig. 159.4).[24] An alternative method of correcting significant axial reflux when both femoral systems are incompetent is to position a competent valve in the popliteal vein (a gatekeeper position).[25-27] At least one investigator has performed multiple tibial vein valve repairs to accomplish the same goal.[28]

DIAGNOSTIC EVALUATION

History and Physical Examination

Patients with CVD due to deep venous incompetence can present with clinical class C0 to C6 (based upon the CEAP classification) with or without associated symptoms.[29] Physical examination and evaluation of venous reflux using a simple handheld Doppler unit are considered the first step in a complete venous patient evaluation (level of investigation I).[29] In those patients with an ulcer, an arterial pulse examination and measurement of ankle-brachial index are critical to rule out the presence of arterial occlusive disease (grade 1, level of evidence B).[30]A careful history should take note of previous episodes of DVT, known hypercoagulable conditions, and any limitations in physical and occupational activity resulting from venous insufficiency. Importantly, the physical examination can eliminate other causes of the patient's symptoms, such as ischemic ulcers, diabetic ulcers, dermatologic disorders, and even skin or soft tissue cancer. A detailed list of potential causes of leg ulcers can be found in a recent review.[30] Each patient should ultimately be stratified according to the CEAP classification to clearly define the venous disease present, which will allow the formation of a focused and appropriate management strategy.[31] Candidates for deep venous valvular reconstruction typically have class C4b to C6 disease, or disabling signs and symptoms such as severe edema (C3). An in-depth extension of the clinical classification (Venous Clinical Severity Score) provides a quantification of disease severity and is a useful evaluation tool to determine a patient's response to treatment.[32] Quality-of-life surveys provide an estimation of the impact of venous disease on the patient's life and the effect that therapy has on the patient's overall well-being.[33] Performance of these evaluations is considered best practice as expressed in the Society for Vascular Surgery guidelines, a grade 1 recommendation for all classes of venous disease and critical to determining treatment success.[30,34]

Figure 159.4 Axial transformation of the profunda femoris vein. Note the remnant of the thrombosed femoral vein in the distal part of the thigh. (From Raju S, Fountain T, Neglén P, Devidas M. Axial transformation of the profunda femoris vein. *J Vasc Surg.* 1998;27:651-659.)

Noninvasive Evaluation

A complete venous duplex evaluation (see Chapter 23) comprises the major component of level of investigation II, which is defined in the CEAP classification as the next step following the basic physical examination and handheld Doppler (level of investigation I). Duplex evaluation is required prior to any interventional procedure (grade 1/level of evidence A/B).[29,30,34] It is essential to clarify the extent and anatomic location of all venous disease, to provide some indication of the etiology (congenital, primary, or secondary), and to aid in determining the pathophysiologic mechanism (reflux, obstruction, or both) of the disease present. The imaging is often so clear in primary deep venous incompetence that venous valve cusps can be seen moving in the venous stream (Fig. 159.5). Insufficiency within any segment of the deep venous system is defined as a prolonged reflux time through the valve after a provocative test. The recommended cutoff value for abnormal reversed flow (reflux) is 1 second in the femoropopliteal veins and 500 milliseconds for the deep femoral and tibial veins.[35,34] Venous obstruction is seen as

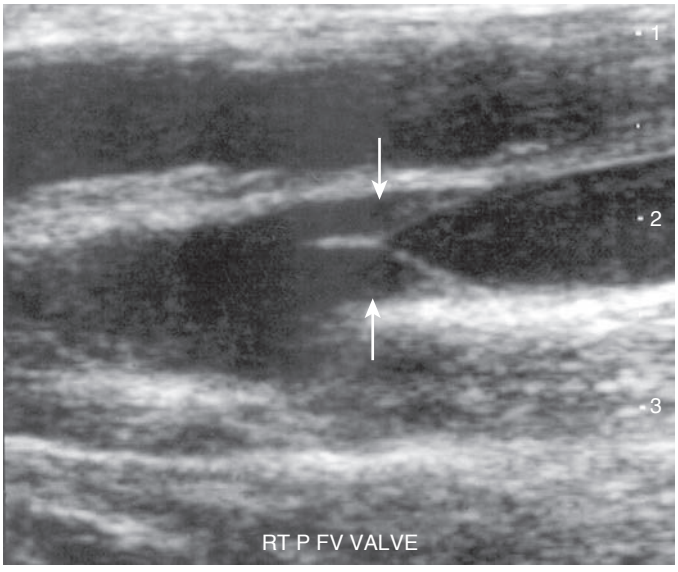

Figure 159.5 Duplex image of a complete and competent valve with both cusps easily identified.

thickened, scarred, and constricted veins or valves with poor flow and diminished augmentation after distal or proximal compression. Respiratory variation can be lost as a consequence of local disease or proximal obstruction or stenosis.

Plethysmography (see Chapter 22) can be utilized to provide an overall quantification of the impact of deep venous insufficiency before deep venous valvular reconstruction and to provide some insight into the effectiveness of treatment. Air plethysmography can quantify the efficiency of the calf muscle pump. The latter represents a crucial factor in deep venous reconstructive surgical outcomes.[36] Plethysmography is used for specific indications in patients with advanced disease or as a research tool (grade 2, level of evidence B) and can be part of a level of investigation II evaluation.[37,34,30] Air plethysmography provides a quantitative estimate of venous insufficiency in the form of venous filling index (abnormal >2 mL/s), and the residual volume fraction (abnormal >35%) has a linear correlation with ambulatory venous pressure measurements. The ejection fraction correlates with the efficiency of the calf muscle pump; a value of less than 60% is considered abnormal.

Invasive Evaluation

For patients being readied for deep venous valvular repair, venography aids in precise operative planning if no other less invasive modality can provide the same detail. Ascending venography (see Chapter 26) defines deep venous system anatomy, eliminates obvious obstruction as a factor, and provides a means of selecting the most disease-free portion of the appropriate venous system when valve transplantation is an option.[11,38] Ambulatory venous pressure with or without thigh tourniquet and venous reflux time can be measured if desired.[11,38,39,40] The importance of significant iliac vein occlusive disease is determined best by the use of intravenous ultrasonography,[40] especially when venography is not diagnostic despite multiplanar imaging. Descending venography (see Chapter 26) is used to determine valve leaflet integrity, anatomic location, and the extent/degree of reflux within the femoral, profunda femoris, popliteal, and tibial veins (Fig. 159.6).[27,41,42,43] It is not uniformly accurate in determining the presence of valvular incompetence, and direct operative inspection remains the "gold standard."[11] However, the combination of venous duplex examination and descending venography provides the best available preoperative determination of valve architecture.

Because they do not assess valve function accurately, magnetic resonance imaging and computer tomography are generally used to evaluate occlusive venous disease rather than candidates for venous valve repair. Each may be useful in detecting extrinsic compression, especially at the iliocaval level. These types of studies constitute those included in level of investigation III and are generally reserved for those with more advanced and complicated venous disorders.[29]

Evaluation of the patient with suspected venous disease follows a standard process in clinical practice. The patient's examination (including handheld Doppler investigation of the lower leg venous system) and history confirms the presence of disease, the clinical classification (C of CEAP), and the potential etiology (E of CEAP). The addition of venous duplex imaging (with or without plethysmography) provides level II diagnostics and confirms the clinical impression. It identifies the location of disease and the types of veins involved (superficial, perforator and/or deep, the A of CEAP), and whether the underlying pathophysiology is due to reflux, obstruction, or both (P of CEAP). The investigation often stops at this point if superficial/perforator disease is a prominent component of the disease process, and the superficial and/or perforator disease is treated. If the patient has recurrent problems, a more in-depth investigation for proximal (iliofemoral) venous occlusive disease is often undertaken, with invasive imaging (venography with intravascular ultrasonography). Investigation has advanced to diagnostic level of investigation III when these studies are chosen. If present and the symptoms are sufficiently severe, angioplasty and stenting of the affected vein is undertaken. If the superficial/perforator and the proximal deep venous occlusive disease has been managed successfully, and deep reflux remains the pathophysiology of the disease process as demonstrated by a combination of dedicated duplex imaging and descending venography, the appropriate valve repair is accomplished as noted in the following text.

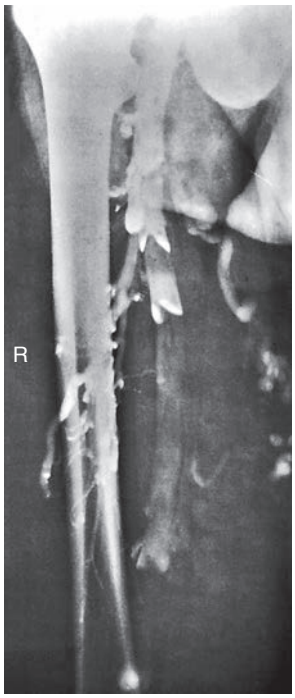

Figure 159.6 Descending venogram demonstrating the presence of valves with architecturally preserved cusps available for in situ repair.

TREATMENT SELECTION

Natural History and Patient Risk Assessment

Patients being considered for deep venous valvular repair have generally undergone previous evaluations and treatment of superficial venous disease that have failed to resolve their signs and symptoms. Thirty-three percent of patients with primary deep venous incompetence and 70% of those with

postthrombotic syndrome will experience ulcer recurrence, suggesting that their deep venous disease should be treated.[7] An algorithm for the surgical care of patients with venous ulcers, which can be extrapolated to all those who might benefit from deep venous valve repair, is found in a recent societal guidelines manuscript (Fig. 159.7).[30] Valvular reconstruction is relegated to later in the algorithm due to an increased risk to benefit ratio.

Patient risk assessment must follow the tenets of any open operative intervention. Hemodynamic instability from the operation is minimal, but because the operative intervention is time-consuming and technically challenging, general anesthesia is typically required. An acceptable cardiac and pulmonary status is required. Systemic infection should be treated before intervention. The presence of systemic disease that may impact healing, such as collagen vascular disease, diabetes, chronic renal insufficiency, or lower extremity arterial occlusive disease, is a relative contraindication to venous intervention unless it is corrected or medically optimized first.

Treatment Options

The treatment options available to correct deep venous valvular reflux are determined by the availability of structurally intact but incompetent venous valves. Selection of the operative technique when the valve cusps are preserved is determined by the degree of cusp prolapse, the surgeon's preference, and the reported long-term success. In the case of valve prolapse secondary to vein wall dilation only, decreasing the vein diameter may reestablish a competent valve. In such cases, external banding

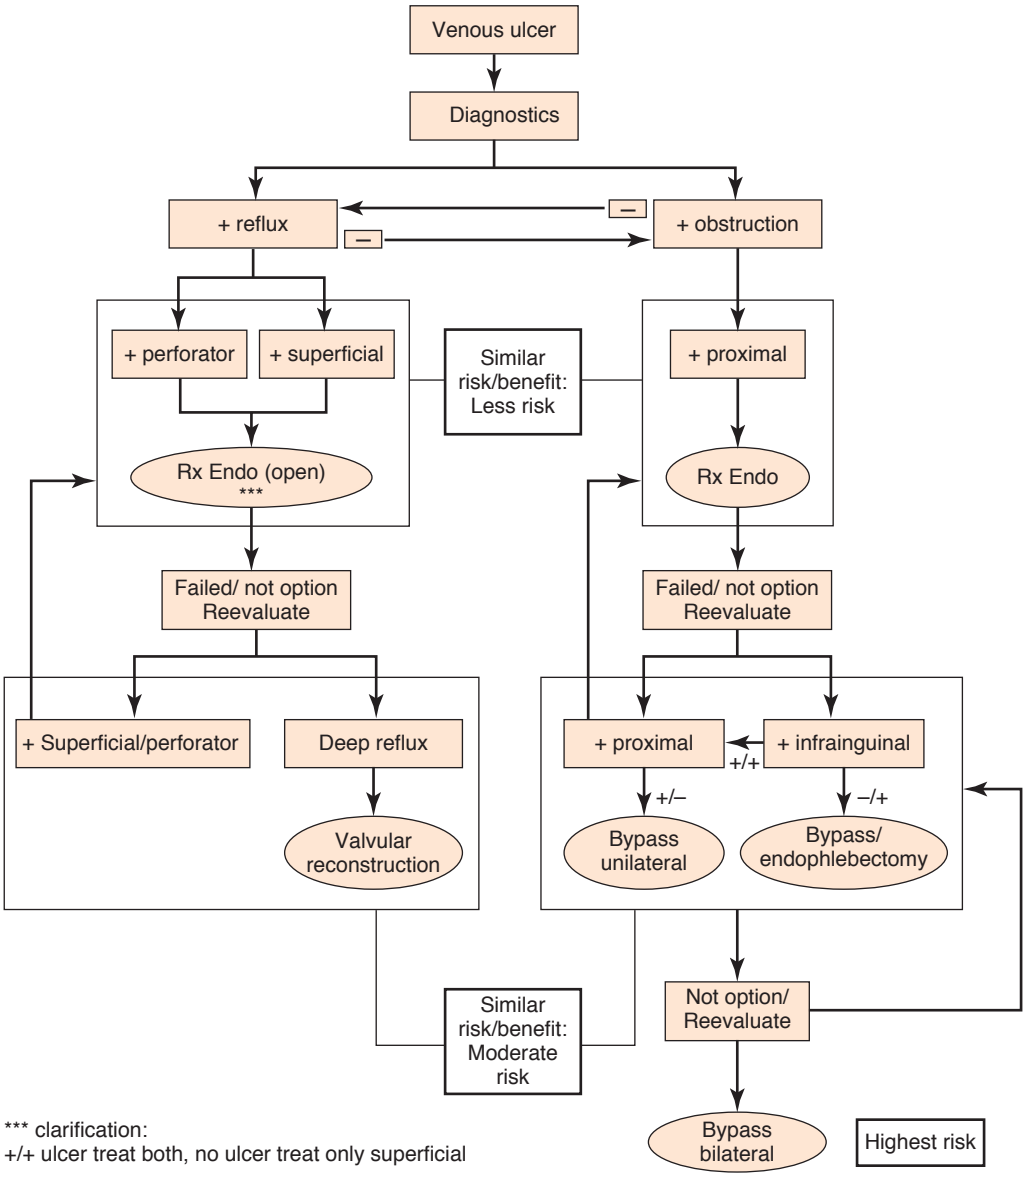

Figure 159.7 Proposed algorithm for operative and endovascular treatment of patients with venous leg ulcer based on involved anatomic venous system and presence of venous reflux or obstruction. The risk-to-benefit ratio is weighed for those procedures with more risk (lower, moderate, higher) considered later in the treatment when the benefit is similar.

of the vein may provide a workable solution to prevent reflux, although there is some question as to long-term success.[44] When wall dilation with more pronounced cusp prolapse is present, external valvuloplasty will provide a way to decrease wall diameter, and techniques are available that can simultaneously enable reefing of the valve cusps. With pronounced valve leaflet prolapse, internal valvuloplasty allows direct cusp leaflet shortening in addition to wall diameter reduction. When there is no identifiable valve structure within an incompetent system, two potential options are available. If a parallel axial system has a competent valve or one that can be made so, a transposition procedure is an option. When this is not feasible, valve transplantation of a competent valve from a distant location remains an option. Valve substitutes using autogenous tissue are a final option. Quests for a percutaneous option or valves made of nonautogenous tissues have not been successful to date. In some instances, intervention in two or more separate axial venous systems (e.g., the femoral and profunda femoris veins) or into the popliteal location will be required to prevent axial reflux into the end-organ, which in this case is the calf and ankle soft tissues/skin. Multiple valve repairs in the same incompetent axial system (e.g., two or more in the femoral vein) are being investigated in the hope of decreasing recurrent reflux and thus symptoms[28,45-47]; however, other surgeons have reported success when only one valve per incompetent system is repaired.

Recent societal guidelines suggest that in select patients with clinical class C4b, C5, and C6 disease, valve repair (internal valvuloplasty, external valvuloplasty, external banding), valve transposition or transplantation, and/or autogenous valve substitutes can aid in venous leg ulcer healing and prevent recurrence in addition to standard compression therapy (grade 2, level of evidence C).[30]

SURGICAL TREATMENT

Relevant Anatomy

The common femoral, profunda femoris, and femoral veins are covered by skin, soft tissue, and fascia in the groin and by the sartorius muscle more distally. Just proximal to the knee, the femoral vein occupies the adductor (Hunter) canal, which places it deep to the sartorius and flanked by the vastus medialis and adductor longus muscles. Distal to the adductor canal, the femoral vein becomes the popliteal vein and lies between the heads of the gastrocnemius muscle distally but is covered only by skin, soft tissue, and fascia directly behind the knee. The anterior tibial veins lie in the anterior calf compartment deep to the anterior tibialis muscle. The posterior tibial and peroneal veins lie in the deep posterior compartment and are covered by the soleus and gastrocnemius muscles, which form the superficial posterior compartment.[48]

Valves are universally present in the paired tibial and peroneal veins, with 3 to 12 valves evenly distributed in each vein.[49] The majority of popliteal veins (>90%) have one to three valves, with a slight trend to be located more caudal in the leg.[49] The femoral veins have one to five valves.[49,50] In about 90% of patients, the most constant valve location is in the proximal femoral vein 1 to 2 cm distal to its confluence with the profunda femoris vein.[49-51] In 88% of patients, the profunda femoris vein has one to four valves.[49] The common femoral vein often has no valve present, but in 30% to 50% of patients it may have one or even two valves within a few centimeters of the inguinal ligament.[49-51]

Operative Planning

In the event that an intact but incompetent valve has been confirmed by preoperative imaging, most experienced surgeons choose the proximal femoral vein for valvuloplasty or to repair both the femoral and profunda femoris valves if both systems are incompetent. This decision is based on the ease of exposure, proximity of the valves, familiarity with the approach, and size of the veins available for repair. When both the proximal femoral and profunda femoris valves are incompetent, some have chosen repair of the popliteal vein valve, which is considered the "gatekeeper" to the lower leg venous system.[25,52] However, mid or distal femoral vein valves can be repaired if they are surgically accessible and amenable to valve repair. As one proceeds more distally in the venous system, vein diameters and valve leaflets become smaller and thus more difficult to repair. Nevertheless, even tibial vein valves have been successfully repaired.[53] If a transposition operation is planned, appropriate imaging must have identified the presence of a competent valve. Valve transplantation requires having identified an architecturally preserved competent valve in the axillary or brachial vein. The vein with the intact valve is removed with proximal and distal ligation of the donor vein, which is well tolerated in the upper extremity venous system. The optimal place for implantation into the lower extremity is into the least damaged vein segment available, which will prevent axial reflux into the calf area. If transposition or transplantation is not an option, an autogenous alternative such as a neovalve may be advisable. The neovalve technique uses autogenous tissue to make a valve structure. The optimal site for this type of surgery is the proximal part of the femoral vein, but the choice depends on the vein's features, such as intraluminal fibrosis, which determines a double channel and can help in creating the neovalve.[54-57]

Prophylactic antibiotics are given during the procedure (e.g., first-generation cephalosporin) and are continued postoperatively for 2 or 3 days by most surgeons.[58,45,59] Intraoperative heparin is commonly given when venous occlusion is required; a typical dose is 2000 to 10,000 units, which is not generally reversed.[41,58,45,59,53,60]

Techniques

Overall Exposure

If reconstruction of the proximal femoral veins (femoral or profunda femoris) is the goal, a groin incision is made in the direction of the vessels to expose the first and second femoral valves.[49] Further dissection through the fascia that lies beneath the sartorius muscle will expose the profunda femoris vein if necessary. After exposure of the targeted valve and sufficient vein proximal and distally to see the valve well, the strip test

should be performed to evaluate for valve competence. This test entails milking blood antegrade past the valve while inflow is occluded, with subsequent application of retrograde pressure against the valve. Reflux is demonstrated by refilling of the vein distally. This incision may also provide exposure for valve transposition, transplantation, or neovalve, if required.

After identification of the valve station to be repaired, careful adventitial dissection to identify the valve attachment lines is useful (Fig. 159.8).[53] This dissection facilitates proper placement of the venotomy, when required, so as not to damage the valve leaflets, and verifies that the valve is present and available for repair. A lack of valve attachment lines requires alternative valvuloplasty techniques, but can also signify destruction of the valve suggesting the need for techniques other than in situ repair.[53]

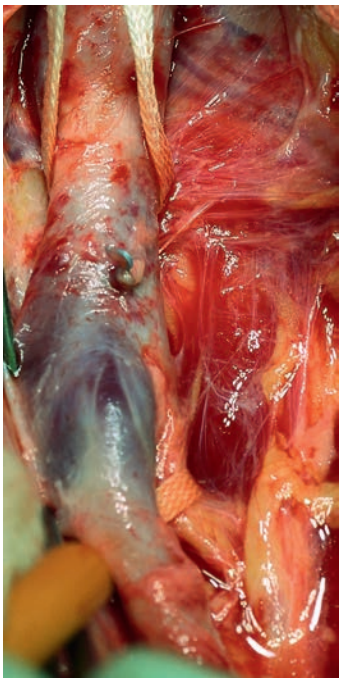

Figure 159.8 The white line clearly visible in this operative photo shows the cusp insertion site prior to opening the vein.

In other situations, a more distal femoral, popliteal, or even tibial vein may be the desired location for valve repair or transplantation. In these situations, the medial exposure is much like that used for exposure of the like-named artery.[48] The popliteal vein can also be exposed through an S-shaped incision in the popliteal fossa, with the transverse portion made in the knee crease to decrease the chance of scar contraction.[48]

Internal Valvuloplasty

The open method of direct valve cusp tightening (reefing) has been the mainstay for correction of primary deep venous valvular reflux. This technique involves venotomy and suturing of the elongated valve leaflets under direct visualization. The redundant valve cusps are plicated to the vein wall with interrupted 6 or 7-0 polypropylene suture to allow proper alignment of the cusps. In 1968, Kistner was the first to report success using a longitudinal venotomy extending through the valve commissure (Figs. 159.9A and 159.10).[61] Raju later described a supracommissural approach in which a transverse venotomy was performed at least 2.5 cm above the valve, staying away from the delicate valve itself (see Figs. 159.9B and 159.11).[62] Sottiurai described a combination approach in which a supravalvular transverse venotomy with distal extension into the valve sinus (a T-shaped venotomy) was used (see Fig. 159.9C).[63] The "trap door" approach of Tripathi and Ktenidis involved two transverse incisions on the vein connected by a single vertical incision (see Fig. 159.9D).[64] Regardless of the approach, suturing of the valve leaflets remains essentially the same (Fig. 159.12). It is estimated that plication of approximately 20% of the length of the valve leaflet can restore valve competency in the majority of cases (Fig. 159.13).[65]

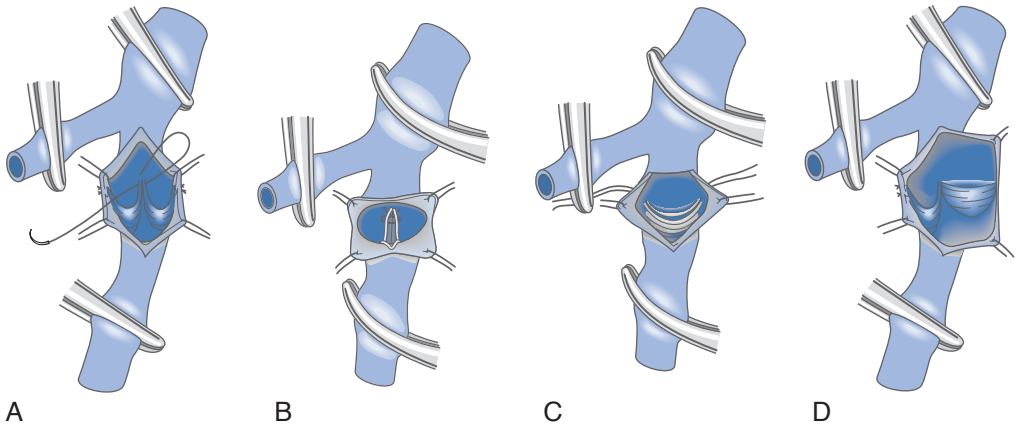

Figure 159.9 Internal valvuloplasty can be accomplished by a variety of techniques used to visualize the incompetent valve leaflets. (A) Artist's representation of the method first proposed by Kistner, in which he opens the vein through the anterior commissure. (B) Representation of the method of Raju, who uses a supravalvular transverse venotomy to view the valve from above without incising through the valve commissural angle. (C) Representation of the method of Sottiurai, who performs a supracommissural incision with extension toward a cusp sinus to improve visualization. (D) Representation of the technique used by Tripathi, who uses a "trap door" incision to provide optimal visualization of the valve cusps for repair. The method of reefing the valve to reestablish a competent valve is essentially the same in each instance.

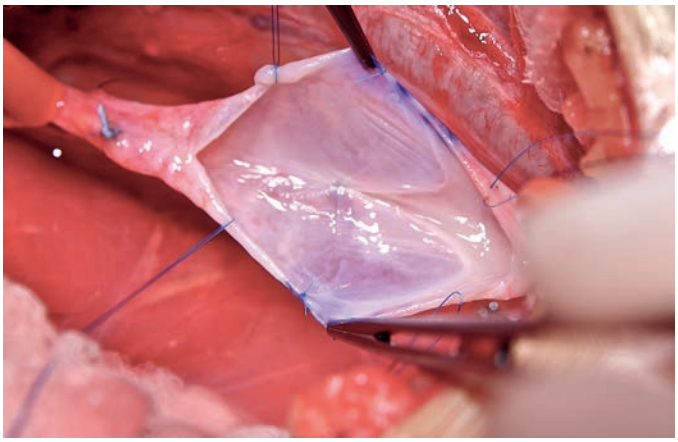

Figure 159.10 This operative photograph shows the vein opened by the technique of Kistner to visualize the valve cusps to be repaired.

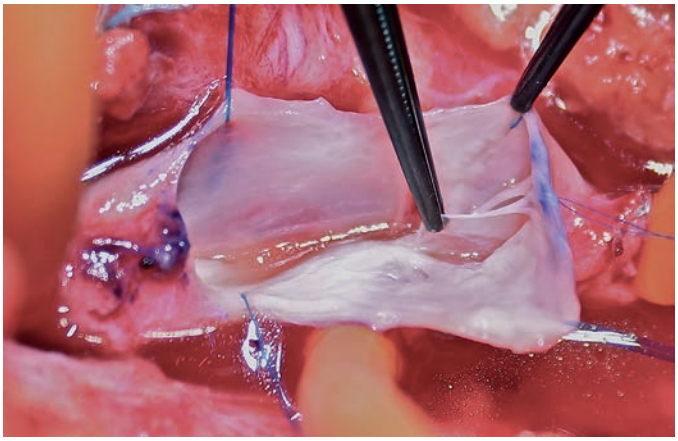

Figure 159.11 This operative photograph demonstrates the vein opened via the technique of Raju, with valves seen below the vein incision.

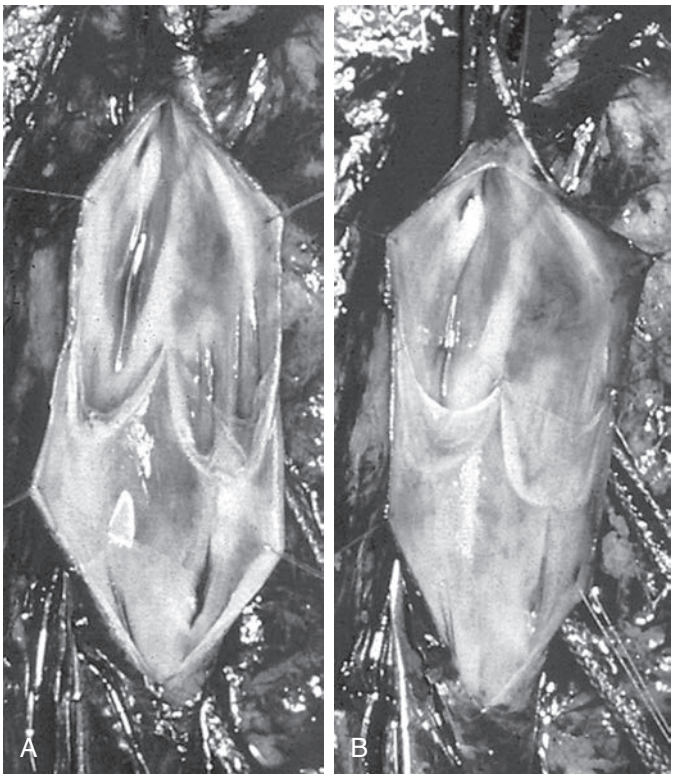

Figure 159.12 The method of Kistner is shown in these operative pictures before valvuloplasty (A) and after valvuloplasty (B). Note the laxity of the incompetent valve before intervention, whereas after reefing of the valve cusps, the normal architecture and tension are reestablished. (Courtesy Dr. Robert Kistner.)

External Valvuloplasty

The technique of external valvuloplasty was pioneered by Kistner and reported in 1990 (Fig. 159.14).[66] This approach offers the advantage of valve repair without a venotomy. It is performed by placing interrupted sutures transmurally through the valve attachment lines, which on tying leaves a decreased commissural angle, competent valve, and reduced vein diameter. Others have used a running suture to accomplish the same effect.[53] Both anterior and posterior plication can be performed. Combining this technique with angioscopy to determine the effect of limited anterior valve plication using interrupted transmural externally placed sutures has demonstrated improvement in clinical symptoms, hemodynamics, and valve competence in a limited number of patients.[60,67] A modification of external valvuloplasty involves the transluminal placement of sutures to reef the valve leaflets and to narrow the vein wall, much like internal valvuloplasty but without opening the vein. Gloviczki and colleagues reported using an angioscope to directly view the valve cusps during repair (Fig. 159.15).[68] A side branch of the great saphenous vein allows introduction of the angioscope, which is then advanced from above for optimal visualization. Interrupted external sutures are seen entering the venous lumen and

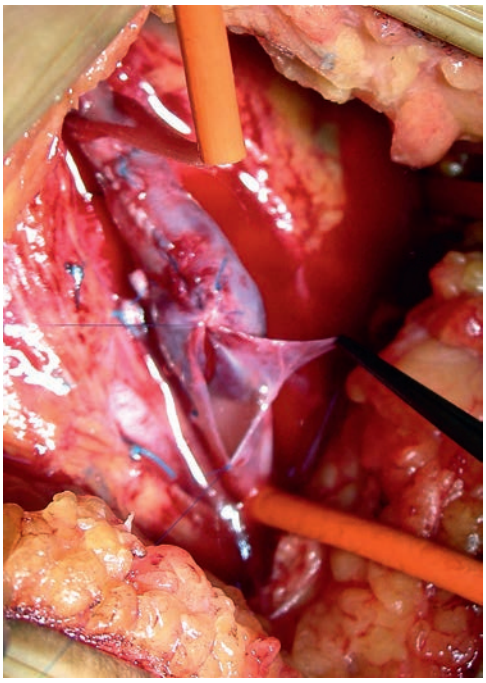

Figure 159.13 This intraoperative photograph confirms valvuloplasty competence; after the proximal extent of the incision has been closed, release of the proximal clamp shows that the valve prevents retrograde flow with no blood visible in the distal open vein.

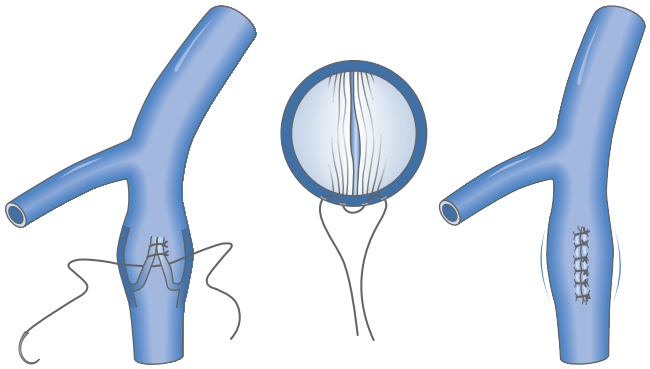

Figure 159.14 Artist's rendition of the method of external valvuloplasty. The enlarged venous diameter results in valve incompetence. Note how the placement of sutures decreases the diameter of the venous wall but protects the valve cusps. The sutures lie outside the vein lumen in this approach.

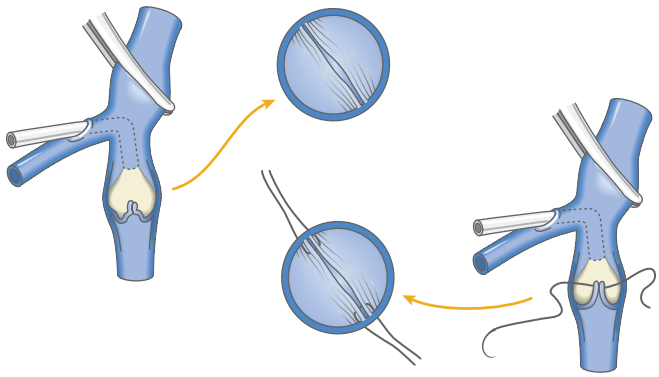

Figure 159.15 As an improvement to "blind" placement of sutures in the method of external valvuloplasty, the use of an angioscope, as suggested by Gloviczki and coworkers, allows precise suture placement within the vein lumen for tightening (reefing) of the valve cusps.

precisely placed to attach the cusps to the vein wall at the attachment line. After a learning curve, the use of the angioscope might not be required to achieve the same effect.[53] However, Raju and colleagues believe that identifying the valve cusp attachment lines externally with the use of adventitial dissection is critical to technical success. Fig. 159.16 demonstrates this technique (transcommissural valvuloplasty).[45] A continuous suture can also be used to accomplish the repair.[58,47] Limited anterior plication, a modification of this method, involves anterior vein dissection and placement of a running mattress suture at the anterior commissure, which runs from a point 3 to 4 mm proximal to the angle of the valve cusp insertion lines up to the angle of the valve cusp insertion.[69] About 3 mm of the vein wall is incorporated into the stitch to adequately approximate the cusps.[69] Limited anterior plication was developed with the aim of decreasing vein dissection and potentially reducing the progressive dilatation of the postrepair vein that occurs after some cases of valvuloplasty.[69] It has been used most commonly in conjunction with saphenous vein stripping and limited to the femoral vein valve.

External Banding

This method has most commonly been used in cases in which dissection vasospasm renders an incompetent valve spontaneously

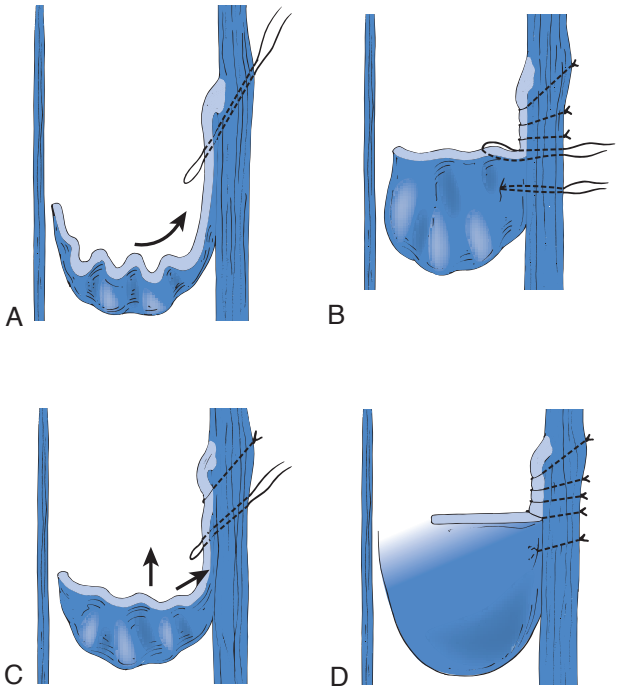

Figure 159.16 The initial through-and-through oblique transluminal suture placed at the commissural apex catches sagging leaflets and resuspends them. (A-D) Transluminal sutures, with each successive suture biting deeper and less oblique than the suture above to pull up the valve, tighten the cusp edges, deepen the sinus, and appose the valve attachment lines. Each suture is tied before the next is placed. One or two of the most caudally placed sutures may pass through the body of the leaflet rather than through the edge, with no subsequent ill effects. (Redrawn from Raju S, Berry MA, Neglén P. Transcommissural valvuloplasty: technique and results. *J Vasc Surg*. 2000;32:969-976.)

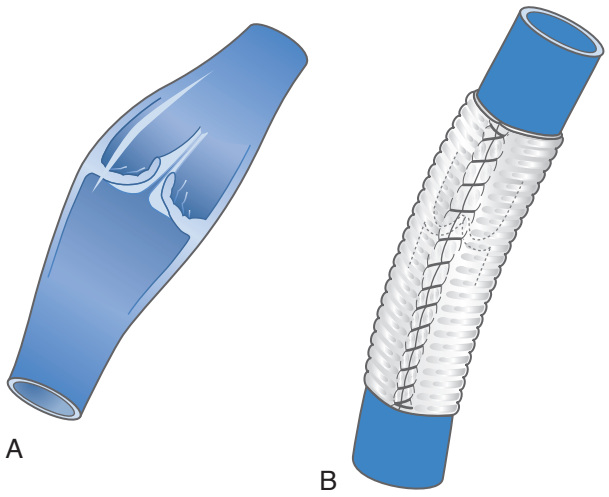

Figure 159.17 Artist's depiction of external banding to prevent venous valvular incompetence in veins that become competent during the vasoconstriction that occurs at the time of operative dissection. Some surgeons use this technique to prevent dilation after valve transplantation or other types of repair. (A) Incompetent valve before banding. (B) After banding, the valve is competent.

competent. An external sleeve made of synthetics is wrapped around the circumference of the vein at the site of the valve. It is tightened to reduce the size of the vein lumen until valve competence is achieved (Fig. 159.17). The sleeve is then anchored in place to the adventitia by sutures to avoid migration. One

investigator uses a specifically designed cuff.[59] One report described the use of a spiral device screwed around the outside of the vein to decrease the diameter until endoscopic confirmation of valve competence.[70]

Several investigators have added an external band at the conclusion of valvuloplasty (any type) to prevent delayed dilation.[58,45,71] Others have abandoned this approach because of concern for scarring with resulting valve failure.[46,72] Alternatively, it may be that modifying the valve sinus shape negatively impacts valvuloplasty outcomes, and this theory may merit future evaluation for all types of venous valve interventions.

Valve Transplantation

Venous valve transplantation provides a technique that can be used when the valve cusps have been destroyed. This procedure was first described clinically by Taheri and colleagues.[73] A 2- to 3-cm segment of upper extremity vein containing a competent valve (or one that can be made competent) is first removed. Other investigators have utilized great or small saphenous veins as the valve donor.[74] The incompetent femoral vein system is approached just distal to its junction with the profunda femoris vein, and the axillary vein segment is sutured in place after removal of an appropriate length of femoral vein. The proximal anastomosis is often accomplished first to confirm valve competency and to allow distention and lengthening of the vein to facilitate the distal anastomosis (Fig. 159.18). In trabeculated postthrombotic veins, Raju and coworkers have described excision of intraluminal synechiae to create a single lumen suitable for implantation.[75] Interrupted sutures are preferred to avoid suture line stenosis.[65] Valve competence is determined by the intraoperative strip test. An external sleeve can then be placed around the segment to prevent later dilation of the segment.[53,65,71] Because approximately 40% of axillary vein valves are incompetent at the time of explantation, bench repair may be required.[53,65] However, more proximal or distal valves in the upper extremity that are de novo competent should be sought before resorting to this added surgical intervention. Should bench repair be necessary, external or internal valvuloplasties have achieved success.[53,76]

Valve Transposition

If a single groin axial venous valve is spared from reflux, a transposition procedure can be performed by placing the incompetent venous system distal to the competent valve. Most commonly, the femoral system is incompetent and the profunda femoris valve remains competent. The incompetent femoral vein can be transected and reimplanted distal to the competent profunda valve (Fig. 159.19). Alternatively, the incompetent femoral system can be placed below a competent valve in the great saphenous vein (Fig. 159.20). When the profunda femoris valves are incompetent, the profunda femoris vein can be placed distal to a competent valve in either the femoral vein or the great saphenous vein. A technique has also been described for transposition of an ipsilateral valve (competent great saphenous vein to the femoral vein and subsequent ligation of the femoral vein proximally [distal to its junction with the profunda femoris vein]) to escape problems with diameter mismatch.[77]

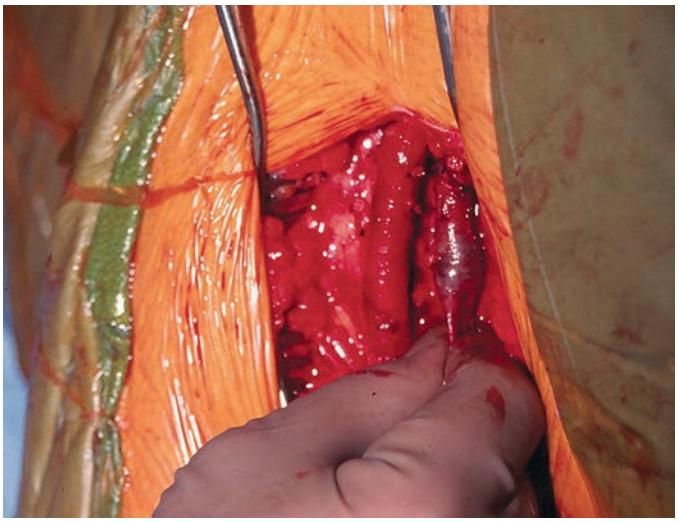

Figure 159.18 This intraoperative picture shows a valve transplant with the proximal anastomosis complete. Any fluid or blood was pushed forward from the distal vein past the valve, and the valve is competent, allowing vein elongation and therefore proper positioning of the distal anastomosis. A similar maneuver is performed when a "strip test" is used to confirm valve competence. During a "strip test" the vein distal to the valve is occluded (in this case by the surgeon's fingers but may be by a vascular clamp or forceps) and the blood is pushed or milked from the vein distal to the valve-containing vein segment. As blood is allowed to refill the vein, if the valve is competent, blood will not reflux and therefore not be present in the vein distal to the valve.

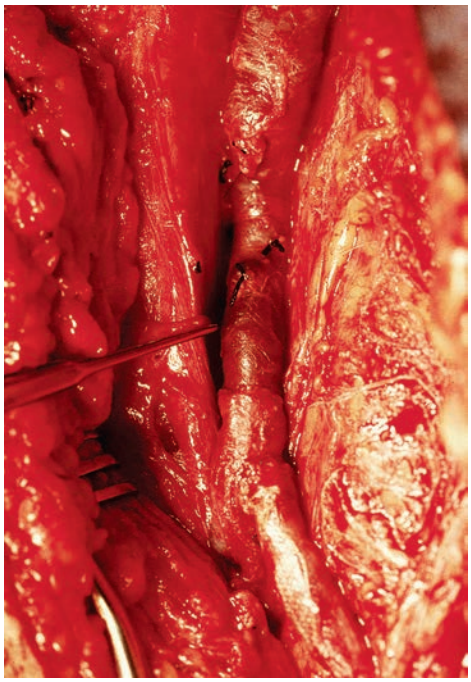

Figure 159.19 Note the competent valve (forceps point to the area) beyond which the incompetent venous system has been placed in this operative picture of valve transposition.

VENOUS VALVE SUBSTITUTES (NEOVALVE)

Valve substitutes could address difficulties in treating patients with deep venous valvular insufficiency that have no autogenous valves available for repair or transplantation. Various attempts using synthetics, xenografts, and allografts have been studied experimentally and, in some cases, reached clinical trials but without success.[78,79,80,81,82,83,84,85,86,87,88,89,90] A more in-depth discussion of these past experiences and some aspects of the endovascular experience can be found in Chapter 60 of the 8th edition of Rutherford's and in a review article.[91]

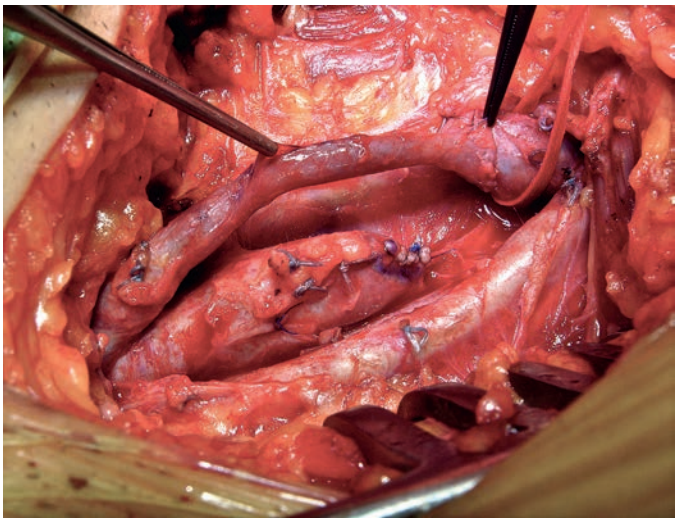

Figure 159.20 This is an operative photograph of a transposition operation using a saphenous vein with a competent valve. The saphenous vein is transposed into the subfascial area, and it is sewn in the distal femoral vein in an end-to-end fashion thereby creating a new competent axis. The suture line to the right in the photo is the oversewn proximal femoral vein. The proximal saphenous vein joins the common femoral vein to the right in this photo.

Valves constructed by invaginating an autogenous vein into itself by the method of Eiseman and Mallette have shown experimental promise but have not been studied clinically.[92,93] However, the use of autogenous tissue to reconstruct valves has been relatively successful in small series.[53] These procedures involve the use of a piece of autogenous vein as a donor. Semilunar cusps were fashioned out of a donor vein after trimming the adventitia and part of the media, and the tissue was sutured into the recipient vein with the nonendothelial surface directed toward the lumen.[53] The study has not been repeated, but good clinical results were noted in this small series. Another attempt to use autogenous vein as a valve substitute has been reported by Plagnol and associates.[94] In this approach, a stump of the great saphenous vein is invaginated into the femoral vein to fashion a bicuspid valve.

Maleti and colleagues reported a technique for constructing a bicuspid or monocuspid venous valve by dissecting the intimal-medial wall of the thickened postphlebitic vein to form the cusp or cusps (Fig. 159.21A and B). An ophthalmic knife was used to divide the vein wall into one or two sheets to fashion the valve cusps. The initial seven cases did well.[54] By 2006, 18 venous valves were constructed in 16 patients with recurrent or nonhealing venous ulcers to treat chronic deep venous insufficiency secondary to the postthrombotic process.[55] The patients received anticoagulation for 6 months. Maleti's most recent improvement has been to place two sutures on the cusp or cusps to hold the valve in the semi-open position and thereby prevent valve collapse (Fig. 159.22) and improve competence (Fig. 159.23).[56] Some excellent intraoperative images and illustrations can be found in a review article by Maleti and Perrin.[57] This interesting work has been verified by at least one investigator to date.[95]

A hybrid approach championed by Opie involves invaginating a cuboidal piece of the vein wall, still attached at its caudal edge, into the vein lumen, with two sutures attached to the cephalad edge to prevent complete reflux of the flap into the distal vein, thereby forming a monocuspid valve. The opening

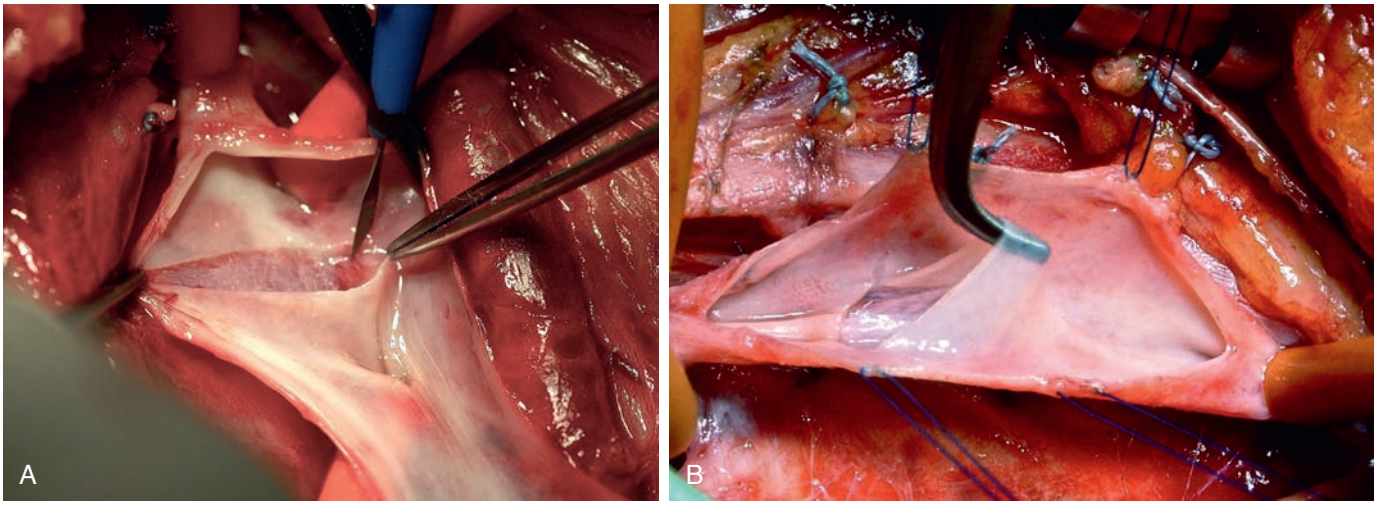

Figure 159.21 This is a neovalve construction being performed by Dr. Maleti with the first photo (A) demonstrating the use of an ophthalmic knife to construct the valve and (B) a bicuspid valve in another patient with the second leaflet yet to be constructed.

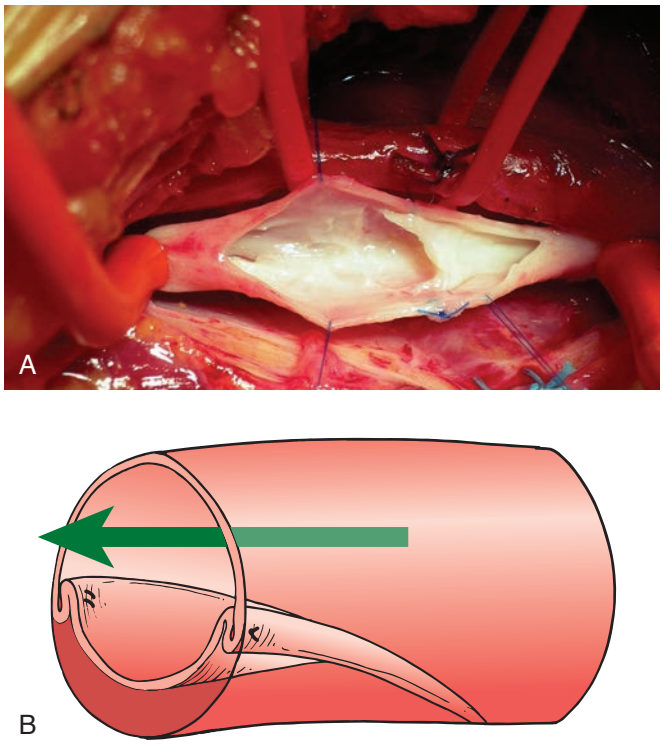

Figure 159.22 (A) This intraoperative photograph shows a monocuspid valve made from the inner wall of a postthrombotic vein with a fine ophthalmic knife. Two sutures *(blue color)* are placed near the outer edges to keep the valve from collapsing while at rest. (B) Artist's depiction of how the monocuspid valve does not completely collapse against the nonluminal wall during antegrade venous flow. The arrow demonstrates the direction of normal venous blood flow toward the heart during exercise.

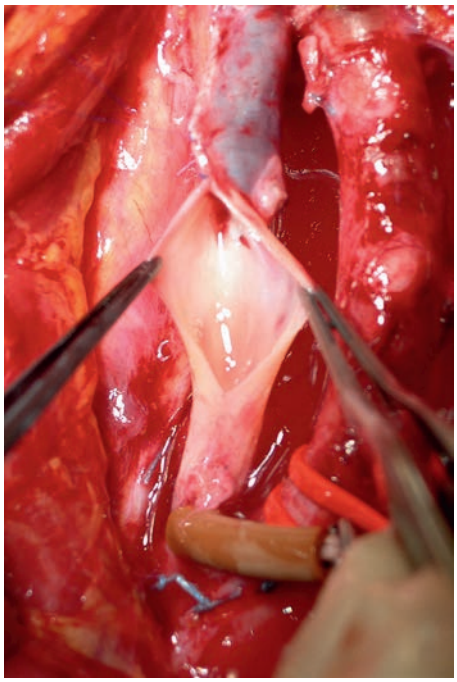

Figure 159.23 Intraoperative photograph demonstrating neovalve competence; the proximal vein is closed past the constructed neovalve; with release of the proximal clamp, the distal vein is free of refluxing blood.

in the vein wall is repaired with a specially designed and flexible expanded polytetrafluoroethylene patch.[96] It is difficult to explain how the valve can prevent all reflux since it is open on both sides, but sufficient reflux must be prevented to produce a clinical effect. Investigators from Russia have reported an 80% clinical improvement and no recurrent reflux at 8 months of follow-up using this technique.[97]

Endovascular Valve Replacements

There is an interest in repair or replacement of venous valves through a minimally invasive percutaneous "endovascular" approach. Attempts to date have been investigated in terms of hemodynamic outcomes in animal models. Some have been tested in clinical use but are currently without published success.[98,99,78,79,100,80,101,102,103,104,105,106,107,108,109,110]

Postoperative Management

Pneumatic compression devices are applied postoperatively to decrease swelling and the risk of DVT.[41,45,60,71,111] This may also increase flow through the valve repair when the patient is sedentary. Because therapeutic or low-dose intravenous heparin or low-molecular-weight heparin is generally administered postoperatively, closed drainage of wounds may avoid hematoma formation. Anticoagulation regimens include (1) warfarin on postoperative day 1 with an initial target international normalized ratio of 2.0 to 2.5 for the first 6 weeks, and then subsequently decreased to 1.7 to 2.0 until 4 months, at which point it is stopped[45]; (2) "minidose" warfarin, 1 to 2.5 mg/day, for long-term anticoagulation[53,112]; (3) warfarin at therapeutic levels for 3 months[41,46,71,111,113] or 6 months[58]; (4) no anticoagulation in procedures other than open valvuloplasty[60,69]; or (5) therapeutic low-molecular-weight heparin for 3 months.[47] Although many surgeons encourage the use of compressive support after venous valve reconstruction, compliance continues to be problematic.[11,18]

Results

Complications and Initial Results

Valve repair procedures have low morbidity and low (<1%) mortality.[114,58,45,46,53,69,71,115] Hematoma and seroma formation are seen in up to 15% of cases, with some expected variation according to the level of anticoagulation necessary.[18,41,45,46,65,71,72,111] DVT occurs in less than 10% of cases in most series.[18,41,45,59,53,65,71,72] However, this clinical experience may underestimate the actual incidence, because in a series using venographic surveillance at 2 days postoperatively, a 20% rate of DVT was noted. The thrombus was often not occlusive or extensive, nor was there a reported clinical impact.[111] An extensive review including most types of valve repair noted a DVT incidence overall of 12.4%, with 6.7% in those with primary disease but 25.4% in patients treated for postthrombotic insufficiency.[46] An aggressive approach using catheter-directed thrombolysis did result in complete resolution of thrombosis in 60% of cases (three of five) and salvage of the involved valve repair in 50% of cases (one of two).[45]

Pulmonary embolism can occur but is rare. In one series utilizing in-depth surveillance, it occurred in 1 of 129 patients.[45] Wound infections have been seen in 1% to 7% of cases.[18,45,46,53,65,71] Patency and valve competency of all types of repairs within the perioperative period (30 days) are reported as excellent by most investigators. A few series report a less than 1% incidence of early failure.[45,53] Valve leaflet trauma can occur, especially early in one's clinical experience during vertical venotomy, with seven cases reported by one investigator.[46] These injuries were successfully repaired with an 8-0 suture, and 57.1% of cases (four of seven) were competent at 2 years.

Late Results

Internal Valvuloplasty

Kistner and colleagues have monitored their patients who required internal valvuloplasty for decades and have reported life-table results of clinical success (Fig. 159.24). Table 159.1 is a compilation of series reporting success with internal valvuloplasty. It confirms excellent clinical results in patients who would otherwise have experienced unrelenting symptoms as a result of chronic deep venous insufficiency. Valves are competent in 60% to 70% of patients at 5 years in most series.[18,22,27,41,46,62,64,111,113,115,116,117,118] In general, a patent and competent valve translates into clinical improvement, whereas recurrent reflux is associated with clinical failure. A similar comment can be made regarding all types of venous valvular reconstruction.

External Valvuloplasty

External valvuloplasty may be a less durable repair than open valvuloplasty.[27] Much of the current work involving isolated deep venous reflux surgery by various techniques of external valvuloplasty has involved the repair of multiple valves within the same axial system, which can confuse interpretation of the results. Raju's group used the transcommissural technique to repair 179 valves in 141 limbs, with a valve competence rate of 63%, clinical improvement in about 70%, and statistically significant improvement in venous hemodynamics at 3 years.[45] Tripathi and colleagues reported an experience in which standard external valvuloplasty was used in the majority of cases. In 12 limbs, 19 repairs were performed, with a competency rate of 31.6% (6 of 19) and an ulcer-free rate of 50% (6 of 12) at 2 years.[46] One would surmise that six valves in six limbs were still functioning. Rosales and colleagues reported on 17 patients with 3- and 5-year competency rates of 64% and 52%, respectively, but many patients had multistation or multilevel repairs, which makes interpretation of individual results difficult.[47]

The addition of femoral vein external valvuloplasty to superficial saphenous surgery has been an interest of several investigators, probably because of the proximity of the proximal femoral valve during open surgery. Limited anterior plication in combination with superficial venous intervention has demonstrated improved venous refilling time and decreased ambulatory venous pressure at 10 years.[69] Standard femoral external valvuloplasty in addition to superficial saphenous stripping have demonstrated statistically significant improved clinical and hemodynamic results over that achieved with superficial surgery alone.[114] At 3 years of follow-up, 90.9% of valves were competent, with improved venous hemodynamics and venous severity scores. In combination with great saphenous vein ablation, the addition of an external band to the repaired femoral vein was more beneficial in preventing recurrent reflux/symptoms than external valvuloplasty alone.[58] More than 50% of patients had clinical class C5 or C6 disease, and at 5 years the competence rate was reported to be 48.5% and 69% ($P = .04$), with an ulcer-free rate of approximately 68% and 96% ($P = .008$). This occurred in addition to improved venous hemodynamics for those with and without external banding.

External Banding

The prosthetic sleeve method of valve repair has achieved acceptable results in selected patients with less advanced disease.[27]

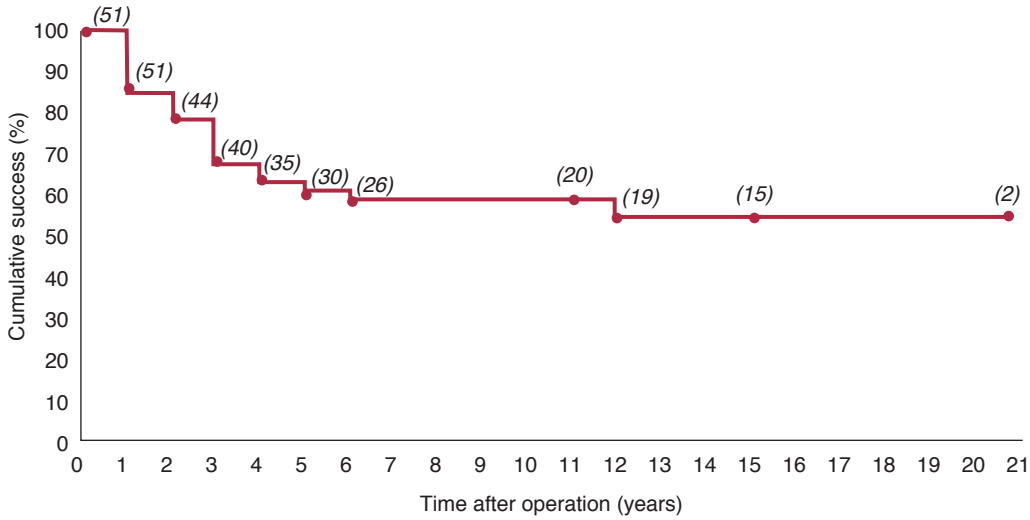

Figure 159.24 Cumulative clinical success rates for all limbs of patients with class 0 or 1 (as defined in the original article but comparable to higher CEAP clinical classifications) disease who underwent a venous valve reconstruction. Numbers in parentheses represent total limbs at risk for each time interval. (Redrawn from Masuda EM, Kistner RL. Long-term results of venous valve reconstruction: a four- to twenty-one-year follow-up. *J Vasc Surg.* 1994;19:394.)

[g]Twelve months after surgery.
[h]More than one valve repair per limb.
FV, Femoral vein.

A more aggressive approach involving the use of banding in patients with advanced disease in which venous constriction did not necessarily result in a competent valve demonstrated the ability to achieve valve competence in a majority of cases.[59] In 42 limbs, 125 valves were repaired, and the repairs were generally in the femoral vein (60) or popliteal vein (53). The investigators reported competence in 90% of patients at 86 months and significantly improved photoplethysmographic estimates of recovery time, but the surgeons did not report competency per valve site. Long-term ulcer healing rates were directly associated with the number of valves repaired: one, 51%; two, 65%; and three, 86%. Another group confined banding to the proximal femoral vein valve in patients with grade 3 or grade 4 reflux, and only in those in whom the profunda femoris vein was competent. They reported a 78% competency rate and symptom relief at 50 months.[119]

Valve Transplantation

Table 159.2 provides a synopsis of the results that one can anticipate when valve transplantation is required to treat chronic deep venous valvular incompetence.[25,26,62,118,120,121,52,122,123] Clinical improvement is seen in about 50% of patients, even at 8 years of follow-up, and it remains an option in cases in which other options are not possible.[15,65,124] The use of great or small saphenous vein valve transplants provide similar results at 3 and 7 years.[74]

Valve Transposition

Table 159.3 tabulates the results of transposition operations.[18,23,77,116,118,125] Good results with the technique of valve transposition have been observed in 40% to 50% of patients after 5 years of follow-up.[18,23,77,116,118,124,125] The method of placing the femoral system below a competent great saphenous valve with ligation to offset the size discrepancy has resulted in 55% of the patients being free of ulcers at 10 years.[77]

Multilevel Valve Reconstruction

There is increasing evidence that multilevel valve reconstruction (more than one valve repair in the same axial system) improves maintenance of valve competence in at least one of the repaired valves and, as a consequence, improves clinical outcome. Raju and his group have been advocates of this approach for many years.[28,45] At 2 years, Tripathi and colleagues found that patients with primary reflux disease undergoing single-level valvuloplasty could expect a 59.4% valve competence rate and 54.7% ulcer healing rate, which was significantly lower ($P < .05$) than results achieved with multilevel repair, which demonstrated rates of 79.7% and 72.9%, respectively.[46] A similar

trend was noted in those requiring valve transplantation; valve competence and ulcer healing rates were 38.9% and 46.1%, respectively, for single-level repairs, versus 55.8% and 57% for multilevel repairs. Rosales and colleagues have accumulated data on external valvuloplasty that suggest improved clinical results, especially in CEAP class 4 patients, with the use of a multilevel (different locations in the same axial system) and multistation (more than one valve in the same location) technique, but statistical significance was not obtained, and clear determination of valve competence was not provided.[47] Lane and associates found that as the number of external banding repairs per axial system increased, so did long-term ulcer healing.[59]

Venous Valve Substitutes

Table 159.4 demonstrates the current state of the art regarding autogenous valve substitutes. The Plagnol type of valve has both experimental and clinical results reported, with 19 of 20 reconstructions being patent and competent at a mean of 10 months.[94] One valve demonstrated reflux because of insufficient valve length at the time of reconstruction. Invagination of an adventitial surface into the venous lumen is of some concern but was not substantiated in this study. The Maleti neovalve initial configuration resulted in early thrombosis below the valve in two patients, and there was one late occlusion shortly after starting oral contraceptives.[55] Therefore 95% of treated

segments remained primarily patent and competent, with significantly improved duplex and air plethysmography results at a mean of 22 months of follow-up. Ulcer healing occurred in 16 cases (88.9%), at a median of 12 weeks with no recurrences. There was no associated mortality.[55] However, at a median follow-up of 54 months, valve competence was demonstrated in 13 of 19, or 68%.[56] The one case added to the 2006 report included an episode of DVT, and the long-term ulcer healing rate was now 84%, with two recurrences. The modification noted in the techniques section was instituted to improve these results. The second group studied (modification included) consisted of 21 operations, with a median of 5 months of surveillance. All valves were competent, and there was a 95% ulcer healing rate and two recurrences (9.5%).[56] Opie reported no incompetent valves in 14 operations at 4 years and excellent clinical improvement.[96]

Overview

In general, patients with postthrombotic reflux tend to experience reduced healing rates and more recurrent venous ulcers than those with a primary cause of reflux, as noted from the results of internal valvuloplasty (generally a primary cause) versus transplantation or a transposition approach. However, Raju and associates found little difference in the results of repair of postthrombotic versus primary disease in their series.[16,27] It is possible that this difference simply reflects a delay in the appearance of ulceration after valve failure. These same investigators reported a difference in valve competence based on the method of repair (Fig. 159.25). It would appear that there is decreasing durability as one progresses from internal valvuloplasty, to external valvuloplasty, and finally to the need for transplantation and other interventions.

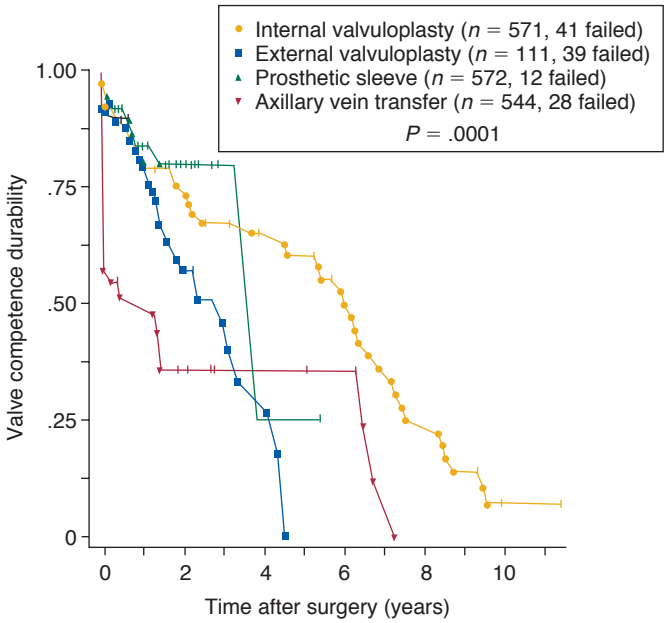

Figure 159.25 Actuarial durability of various valve reconstruction techniques assessed by serial duplex examination for competence. (Redrawn from Raju S, Fredericks RK, Neglen PN, Bass JD. Durability of venous valve reconstruction techniques for "primary" and post-thrombotic reflux. *J Vasc Surg.* 1996;23:363.)

Follow-Up

Monitoring and Management

A typical method of clinical follow-up includes physical examination at 6 weeks, 3 to 9 months, and then annually, but with considerable variability in the exact timing of visits.[41,58,45,46,59,69,111,113,115] During each visit, venous duplex ultrasonography is performed to determine valve site patency and valve competence. Noninvasive testing has generally replaced descending venography, which was often used in earlier series.[18,60] Most surgeons include some type of hemodynamic assessment. Some use a visual analogue pain score or assessment for swelling.[45,69] Reclassification by the CEAP criteria, venous severity scoring, and use of quality-of-life assessment tools are encouraged to provide quantifiable parameters of clinical success.[41,58,45,46,59,71,111,113,119]

Reoperative surgery can be difficult but is sometimes required.[53] The best approach appears to be to use a new incision remote from the original operative site. One choice of site is the femoral vein at the adductor canal, as it is easily accessible. Raju and Hardy[53] have found it difficult to perform popliteal valvuloplasty because of an often thick adventitial coat, which makes adventitial dissection and therefore visualization of the valve commissures difficult.

SURGICAL TREATMENT OF ILIOCAVAL VENOUS OBSTRUCTION

The first successful venous reconstruction in a patient was reported more than 50 years ago by Warren and Thayer[1]; in the past 2 decades improvements in diagnosis, patient selection, surgical technique, and the availability of better graft materials have resulted in more frequent successful implantation of venous bypasses in patients.[2] More recently, endovascular treatment for iliocaval obstruction has progressed rapidly, and currently venous stenting is the primary choice for treatment of benign iliac or iliocaval venous occlusions. However, surgical treatment remains an excellent option in cases in which endovascular techniques have failed or are not possible. The endovascular treatment for iliocaval obstruction is addressed in Chapter 161.

ETIOLOGY

Deep venous thrombosis (DVT) is the most common cause of venous obstruction. Venous occlusion may also be due to trauma, radiation, external compression by retroperitoneal fibrosis or

Abstract

This chapter covers two conditions that affect the lower extremities and pelvis venous drainage: chronic iliocaval venous occlusion (CICVO) and pelvic congestion syndrome (PCS). Etiologies of CICVO are numerous but dominated by the May Thurner syndrome (compression of the left common iliac vein by the right common iliac artery and the lumbar vertebrae) and the post-phlebitic syndrome. Severe symptomatic patients due to CICVO with contraindication or failure of endovascular techniques should be recognized and treated by open surgical therapy. Main cause of pelvic pains in women, the PCS can be authentified by noninvasive explorations and, if necessary, treated by open, laparoscopic or mainly endovascular techniques.

Keywords

iliocaval venous obstruction
pelvic congestion syndrom
May Thurner syndrome

embolisation

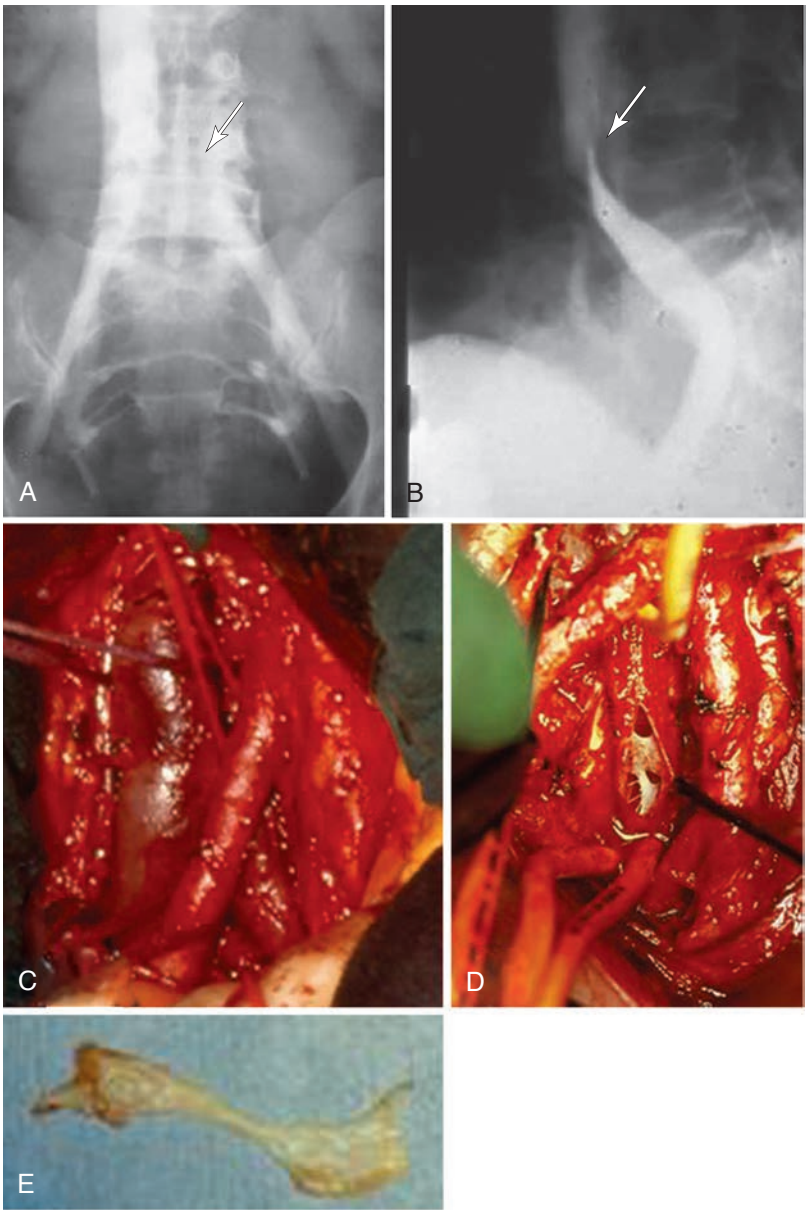

Figure 160.1 Compression of the Left Common Iliac Vein by the Right Common Iliac Artery (May-Thurner Syndrome). Anterior (A) and lateral (B) phlebograms. The *arrow* indicates compression of the vein by overriding artery. C, Intraoperative view. (D) Intraoperative visualization of the webs inside the left common vein. (E) Intraluminal web after removal.

overlying arteries (May-Thurner syndrome),[3,4-7] benign, malignant, primary, or metastatic tumors[8-10]; cysts; aneurysms; abnormally inserted muscle bands (popliteal vein entrapment)[11]; and fibrous bands or ligaments (soleal arch syndrome, femoral vein compression by the inguinal ligament[12]).

Compression of the left common iliac vein by the overriding right common iliac artery (May-Thurner syndrome) (Fig. 160.1) is considered an important cause of left iliofemoral venous thrombosis.[4-7] May and Thurner observed secondary changes, such as intraluminal webs or "spurs," in the proximal left common iliac vein in 20% of 430 autopsies.[3,4-7] Other causes of iliofemoral and caval thrombosis include congenital anomalies, such as membranous occlusion of the suprahepatic inferior vena cava (IVC) with or without associated thrombosis of hepatic veins (Budd-Chiari syndrome),[13] aplasia, and hypoplasia of the iliofemoral veins as in Klippel-Trénaunay syndrome.[14,15]

PREOPERATIVE EVALUATION

Preoperative evaluation in patients with iliofemoral and/or iliocaval venous obstruction should reveal the cause and functional significance of the obstruction and the extent and severity of associated venous incompetence. In at least two-thirds of patients with venous outflow obstruction, distal reflux due to valvular incompetence contributes greatly to development of chronic venous insufficiency (CVI).[16]

History and Physical Examination

The history and physical examination, complemented by examination with a handheld Doppler instrument, should reveal signs and symptoms typical of venous congestion. Patients have lower extremity swelling and experience exercise-induced pain

in the thigh muscles, referred to as venous claudication. This pain is described as a "bursting" pain in the thigh and sometimes the calf which is relieved by rest and leg elevation.[17]

Signs of CVI, such as edema, varicose veins, skin changes, lipodermatosclerosis, eczema, and ulceration, should be noted. Distended varicose veins are present even in the supine patient with CVI, and suprapubic and abdominal wall collaterals develop in patients with pelvic occlusion. Bleeding from high-pressure varicosities is not infrequent. The swollen leg has a cyanotic hue, and bilateral swelling indicates bilateral iliofemoral or vena caval occlusion or systemic disease. In some patients, venous congestion results in hyperhidrosis and significant fluid loss through the skin. Associated chronic high-output or low-output lymphedema may also develop.[18]

Preoperative evaluation should identify risk factors for DVT (see Chapters 145 and 147). Associated chronic arterial occlusive disease and congenital venous malformations (Klippel-Trénaunay syndrome, Parkes Weber syndrome) should be excluded. Patients with membranous occlusion of the vena cava frequently also have evidence of hepatic failure, Budd-Chiari syndrome, and portal hypertension.[13]

Imaging

Duplex ultrasound scanning (DUS) is the first test of choice to identify DVT. However, depending upon factors such as the presence of overlying bowel gas and increased body fat, the IVC and proximal iliac veins may be difficult to image in enough detail to guide further treatment. In these cases, computed tomographic venography (CTV) or magnetic resonance imaging (MRI) can be performed. These tests are also important in identifying causes of iliocaval venous thrombosis, including tumor, cyst, retroperitoneal fibrosis, and iliac venous compression.[19]

Abnormal DUS findings associated with iliocaval occlusion, such as absent flow in the iliac veins and loss of phasicity of flow in the distal veins, are discussed more fully in Chapters 23 and 156.

Ambulatory venous pressure measurements may suggest venous hypertension; measurements of arm-foot pressure differences, as described by Raju et al., can also be used to quantitate venous hypertension. In their study a resting arm-foot pressure differential greater than 4 mm Hg was considered evidence for significant obstruction justifying venous reconstructions.[20] In potential candidates for proximal venous reconstruction, femoral and central venous pressure measurements are required in our practice to document the severity of iliac or iliocaval obstruction. Either a pressure difference of at least 5 mm Hg between the femoral and the central pressures in the supine patient or a twofold increase in femoral vein pressure after exercise indicates hemodynamically significant proximal stenosis or occlusion.

In patients being considered for venous reconstruction, we perform both ascending and descending catheter-based phlebography to evaluate obstruction and associated valvular incompetence.[21,22] Femoral access is useful not only for descending phlebography and iliocavography but also for measuring femoral venous pressures. Iliocavography and abdominal venacavography through a brachial approach may also be necessary in some patients to visualize the vena cava proximal to the occlusion.

INDICATIONS FOR SURGICAL TREATMENT

Prior to the development of endovascular techniques for the treatment of venous disease, surgery was the only option following failures of conservative management. However, with the development and success of advanced endovascular treatments (see also Chapter 161),[23-26] surgery is now generally reserved for cases in which endovascular treatment fails or is deemed inappropriate. The severity of venous stenosis, the location and length of venous occlusion, the age of the thrombus, the nature of any external compression, the presence of underlying malignant disease, and the risks of surgical intervention also play a role in determining whether to attempt endovascular or direct surgical reconstruction. Currently we first attempt endovascular treatment, alone or in combination with thrombolysis, surgical thrombectomy, or excision of old thrombus from the femoral veins, before a surgical bypass is recommended.

Proper patient selection is important; the ideal patient has unilateral iliac occlusion with minimal distal thrombus and valvular incompetence. Patients with severe infrainguinal postthrombotic disease and valvular incompetence may have a decreased chance of success because the distal disease is not treated. In a series published by the Mayo Clinic, there was a trend toward a higher rate of graft occlusion in patients with infrainguinal reflux.[27]

GRAFTS IN THE VENOUS SYSTEM

Grafts placed in the venous system undergo thrombosis more frequently than those implanted for arterial reconstruction, in part because flow in venous grafts is lower. Pressure in the venous system is low, and grafts can collapse under increased abdominal pressure or in tightly confined spaces, such as the area under the inguinal ligament and the retrohepatic space, or when tunneled through the diaphragm. Many patients with previous DVT have hypercoagulable states. The thrombogenic surface of the prosthetic graft also increases the risk of graft failure.[27]

As a result of extensive efforts made in the past decades, patency of grafts implanted in the venous circulation has improved considerably.[28-41] The availability of large-diameter autologous and prosthetic grafts, use of adjuncts such as a distal arteriovenous fistula, rigid external support of the grafts, perioperative and postoperative anticoagulation, the use of perioperative intermittent-compression pumps, and postoperative surveillance with duplex scanning all contribute to improved patency and clinical outcomes.

Venous Graft Materials

Autogenous grafts for the femorofemoral, iliofemoral, and iliocaval locations have the best chance of long-term success. The great saphenous vein, because of its low thrombogenicity

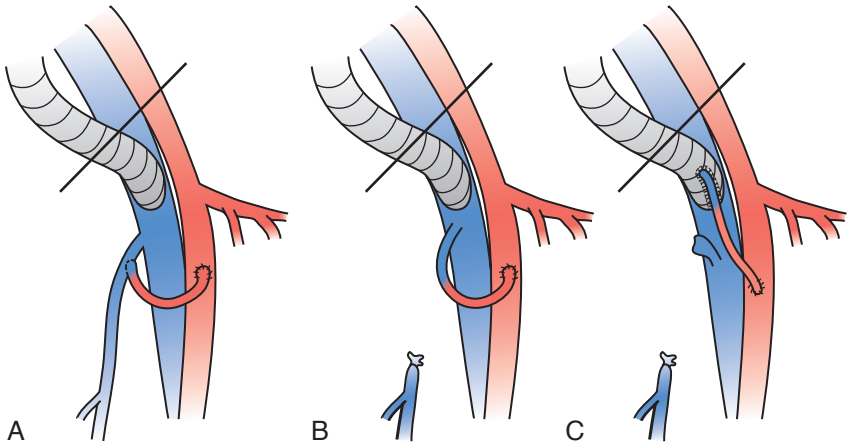

Figure 160.2 Different Types of Arteriovenous Fistulae Placed Distally to a Ringed Expanded Polytetrafluoroethylene (ePTFE) Femoral Venous Graft. The saphenofemoral vein junction is preserved with the use of either a branch of the great saphenous vein (A), or the main trunk of the great saphenous vein (B). (C) The saphenofemoral junction is divided and the main trunk of the great saphenous vein is directly anastomosed to the ePTFE graft.

and suitability in terms of length, is the best choice when available. As a spiral or panel graft, it can be used for the reconstruction of large veins, although in our experience these grafts do not perform as well for iliocaval reconstructions as they do for superior vena caval replacement.[21,22] The contralateral superficial femoral vein, arm veins, and the jugular veins are other potential sources of autogenous grafts. Although harvesting of deep veins was initially believed to result in a high level of CVI in the lower extremity, more recent data suggest it is relatively benign in the majority of patients. The only factors found to be associated with venous morbidity following lower extremity deep vein harvest in a recent study were an ankle-brachial index less than 0.4 and a concurrent great saphenous vein harvest.[42]

The efficacy of cryopreserved vein or arterial grafts in the venous circulation has not been well studied. A few reports exist regarding their use in reconstruction of the superior vena cava and innominate veins.[43] Data at this point are insufficient to support the recommendation of these grafts for routine clinical use.

Of the available prosthetic materials, the expanded polytetrafluoroethylene (ePTFE) graft has been used most frequently for large vein replacement.[a] Because of a large diameter, sufficient length, immediate availability, and external ring or spiral support associated with relatively low thrombogenicity, ePTFE grafts continue to be the best choice for prosthetic replacement of large veins.

Use of Arteriovenous Fistulae

Multiple studies have confirmed that a distal arteriovenous fistula, first suggested by Kunlin and Kunlinin in 1953,[33] improves the patency of grafts placed in the venous system.[b] An arteriovenous fistula increases flow and decreases platelet and fibrin deposition in prosthetic grafts (Fig. 160.2).[36] Prosthetic grafts have significantly higher thrombotic threshold velocities than do autologous grafts and require higher flow to maintain patency.

Disadvantages of an arteriovenous fistula include the longer operating time needed to create the fistula and the inconvenience of additional procedures to close the fistula at a later date. A potential side effect is elevated cardiac output caused by high fistula flow. In addition, high fistula flow can defeat the purpose of the operation by increasing venous pressure at the groin and causing more distal venous outflow obstruction. Experimental work revealed that to avoid deleterious effects on venous outflow from the leg, the optimal ratio between the diameters of the fistula and the graft should not exceed 0.3. Elevated intraoperative pressure in the femoral vein after placement of a fistula should be taken as a warning sign, and fistula diameter should be decreased by banding or other modifications.

The configuration and location of the fistula have also been the subject of much controversy. A large side branch of the great saphenous vein or the saphenous vein itself can be used to perform one anastomosis only. Most recently, we have placed the venous end of the arteriovenous fistula directly onto the hood of the venous graft at the distal anastomosis, using either a 4-mm vein as a free graft (saphenous vein or a large tributary) or a 4-mm ePTFE graft. The advantage of these is that flow can be calibrated with an electromagnetic flowmeter, and large flows (>300 mL/min) can then be avoided. The arterial anastomosis is usually made to the superficial femoral artery. We place a small polymeric silicone (Silastic) sheet around the fistula to prevent healing and to facilitate dissection of the fistula during a second procedure to occlude it. A 2-0 polypropylene suture is also tied loosely around the fistula, and its end is positioned in the subcutaneous tissue close to the incision for later identification. Intraoperative duplex scanning can be used later to identify the fistula. Percutaneous closure of the fistula with transcatheter embolization or a covered stent placed across the arterial side are also options.

At present, for all prosthetic grafts anastomosed to the femoral vein and all longer (>10 cm) iliocaval grafts, a femoral arteriovenous fistula is added to maintain patency (see Fig. 160.2). The fistula is left in place for at least 6 weeks after the operation, and patients without any side effects benefit from long-term fistula flow to prolong patency. For the Palma procedure (described later), we use a fistula selectively and take it down within 2 months after surgery.

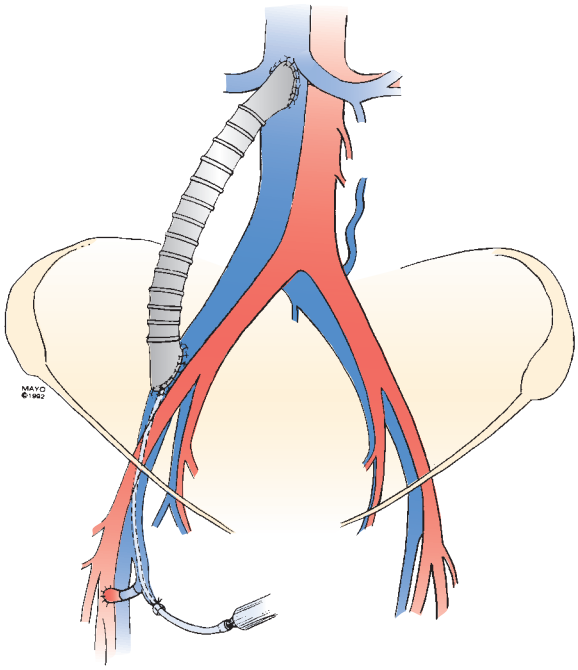

Figure 160.3 Illustration of a right iliac vein/inferior vena caval externally supported polytetrafluoroethylene graft. Note the arteriovenous fistula at the right groin and a 20-gauge catheter, which is introduced through a tributary of the saphenous vein for perioperative heparin infusion. (From Gloviczki P, Pairolero PC, Toomey BJ, et al. Reconstruction of large veins for nonmalignant venous occlusive disease. *J Vasc Surg*. 1992;16:750, with permission of Mayo Foundation.)

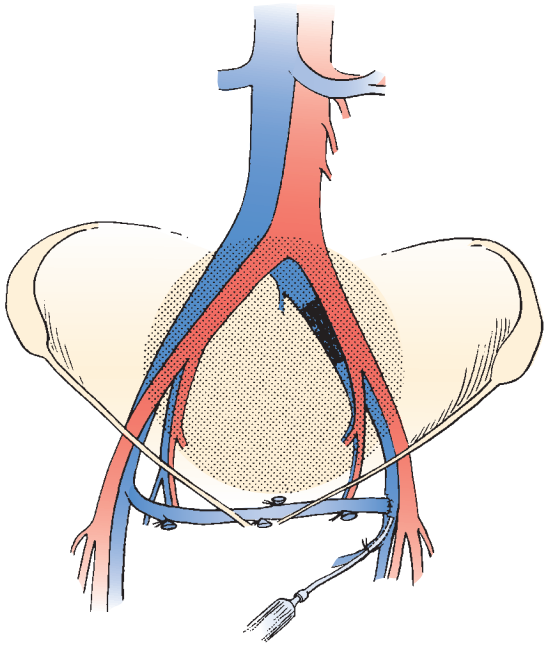

Figure 160.4 Left-to-right femorofemoral venous bypass (Palma procedure) for left common iliac vein obstruction. A small polyethylene catheter can be placed through a side branch of the greater saphenous vein for immediate perioperative heparinization to improve chances of patency. (From Rhee RY, Gloviczki P, Luthra HS, et al. Iliocaval complications of retroperitoneal fibrosis. *Am J Surg*. 1994;168:179.)

Anticoagulation

Intravenous heparin, at a dose of 50 IU/kg, is given in surgery prior to cross-clamping, and anticoagulation is maintained during and after the procedure in most patients. We frequently administer low-dose heparin (500-800 IU/h) locally through a small polyethylene catheter placed just distal to the anastomosis in the perioperative period (Fig. 160.3). This is continued until complete systemic heparinization is achieved by 48 hours after surgery. The catheter is then removed, heparinization is continued intravenously or by using low-molecular-weight heparin, and the patient begins oral anticoagulation therapy with warfarin.

An intermittent pneumatic compression pump, leg elevation, elastic bandages, and early ambulation are also used in the perioperative period to improve the success of venous reconstruction.[55] The patient is fitted with 30- to 40-mm Hg graduated-compression elastic stockings before discharge. Warfarin is continued in patients with autogenous grafts for at least 3 months. In most patients with prosthetic grafts or an underlying coagulation abnormality, oral anticoagulation is maintained indefinitely.

Graft Surveillance

Intraoperative duplex scanning is performed in most patients to ensure patency, good flow, and lack of thrombus deposition. Direct pressure measurements are made before wound closure in every patient to document the hemodynamic benefit. In venous or ePTFE conduits, fistula flow can be measured and calibrated with an electromagnetic flowmeter. If flow is higher than 300 mL/min, banding of the fistula is performed.

On the first postoperative day, we perform contrast phlebography through the catheter positioned at the distal anastomosis of the graft (see Fig. 160.3). Any stenosis or thrombosis detected at this time is revised during a reoperation. Postoperatively, grafts are observed with duplex scanning at 3 and 6 months and then twice yearly afterward. Outflow plethysmography is also performed to document the level of hemodynamic impairment/improvement in the lower extremity. In symptomatic patients, contrast phlebography is usually performed to exclude graft stenosis.

SURGICAL PROCEDURES

Cross-Pubic Venous Bypass (Palma Procedure)

Initially described 40 years ago by Palma and Esperon[56,57] in Uruguay and popularized by Dale[58] in the United States, the Palma procedure has remained a useful technique for venous reconstruction in patients with unilateral iliofemoral outflow obstruction (Figs. 160.4 and 160.5). The operation requires a normal contralateral iliofemoral venous system to ensure venous drainage. Results have been better in patients with intact inflow, when the affected limb has no infrainguinal obstruction or deep venous incompetence.[27,59]

We favor this operation especially in young women who present with residual chronic iliac vein occlusion after acute left iliofemoral venous thrombosis which develops as a result

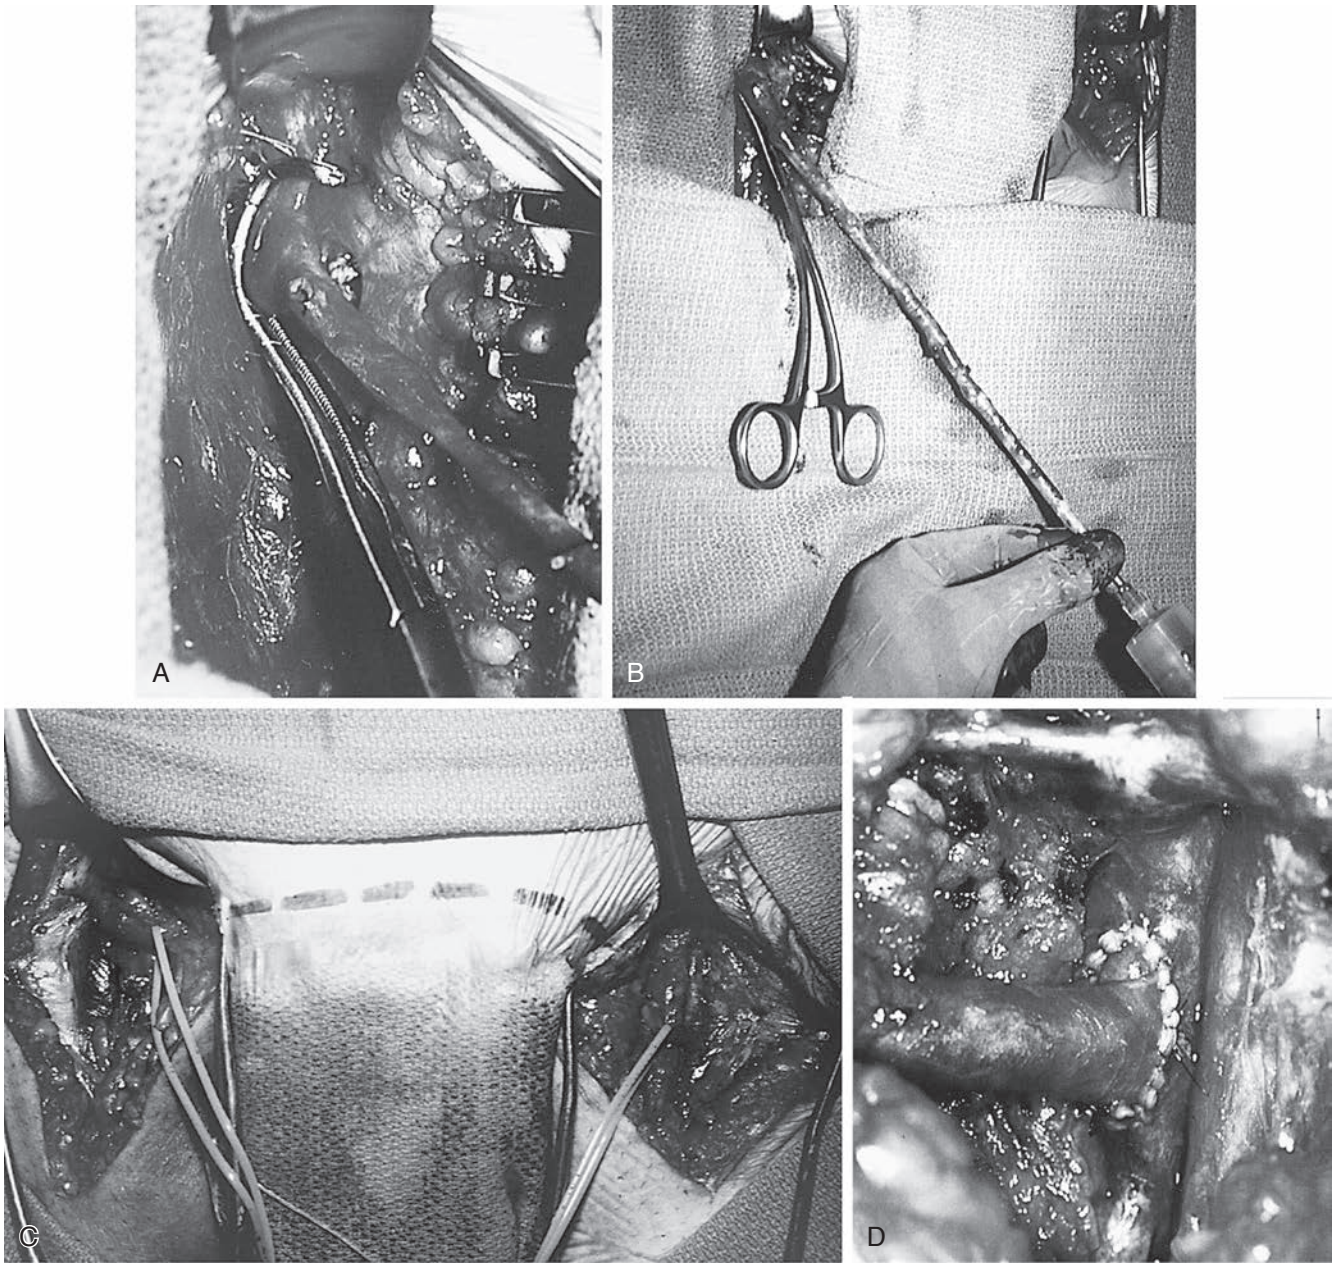

Figure 160.5 (A) Technique of Palma procedure: the contralateral saphenous vein is dissected, and its distal end divided in the thigh; then a vascular clamp is placed on the common femoral vein. (B) The vein is distended with papaverine solution. (C and D) The saphenous vein is tunneled to the left groin and anastomosed end to side to the common femoral vein. A femoral arteriovenous fistula is constructed and encircled with a Silastic sheath for easy identification for takedown 3 months later.

of May-Thurner syndrome. The operation is indicated in patients who are not candidates for iliac vein stenting or in whom previous endovascular procedures have failed.

Technique

The contralateral great saphenous vein is used in the classic Palma procedure (see Fig. 160.5). Preoperative imaging of the potential conduit with duplex scanning is recommended because varicose saphenous veins or veins smaller than 4 mm in diameter have poor chances of long-term success.

Endoscopic harvesting of a 25- to 30-cm segment of the contralateral saphenous vein ensures an excellent cosmetic result; otherwise, the vein can be dissected through two or three small skin incisions. It is divided in the distal thigh or calf and remains attached at the saphenofemoral junction. Tributaries are also ligated and divided.

The graft is gently distended (see Fig. 160.5) and tunneled to the contralateral groin in a suprapubic, subcutaneous position. Dissection of the femoral vein on the affected side should be minimal; usually, only the anterior and lateral vein wall is freed

for proximal and distal clamps or for a side-biting clamp to occlude the vein for the anastomosis. Excision of intraluminal fibrous bands after venotomy may be required. The anastomosis between the saphenous and femoral veins is performed in an end-to-side technique. If the vein is small, interrupted 5-0 or 6-0 sutures are preferred to permit later dilation of the vein and to avoid "purse-stringing" of the venous anastomosis. A small catheter can be placed through a tributary of the ipsilateral saphenous vein for immediate low-dose heparinization and postoperative phlebography (see Fig. 160.5). A temporary arteriovenous fistula can also be placed to improve flow and aid in achieving early patency.

If the traditional transposition results in significant kinking of the saphenous vein at the contralateral groin, free vein grafting should be considered, excising the saphenous vein along with a small rim of the common femoral vein and reimplanting it after a 180-degree turn. For autogenous graft material, the contralateral or even the ipsilateral saphenous vein (with lysis of any competent valves) or an arm vein can be used. When suitable autogenous conduit is not available, an 8- or 10-mm externally supported ePTFE graft is the best alternative (Fig. 160.6).[48,60]

Results

Analysis of results of 433 operations published in 10 series revealed clinical improvement in 63% to 89% of patients (Table 160.1).[c] Reported patency rates ranged from 70% to 85%, but follow-up periods were variable and objective graft assessment with imaging was rarely performed in all patients. The largest series, 85 crossover venous bypasses, was reported by Husni.[61]

[c]References 27, 44, 48, 57, 58, and 61-65.

At the last follow-up visits (6 months to 15 years postoperatively), 47 of 67 grafts were patent. Results in this study were improved when a temporary distal arteriovenous fistula was used. The patency rate of grafts implanted for extrinsic compression of the iliac vein without distal disease was 100%, as opposed to 67% in patients with post-thrombotic syndrome.[61] In a review of 50 consecutive operations performed in 47 patients, Halliday and associates reported a cumulative patency rate of 75% at 5

years confirmed by phlebography. Clinical improvement was seen in 89% of patients.[64] Danza and colleagues reported somewhat better results with use of the saphenous vein as a free graft rather than as a transposition. Of 19 patients who underwent free saphenous vein grafting, 84% experienced either symptomatic relief or improvement versus 75% of 8 patients who underwent transposition.[63] Gruss and Gruss and Hiemer reported "long-term patency" (no time interval reported) in 22 of 26 grafts. On the basis of these results, Gruss recommended using externally supported ePTFE grafts with arteriovenous fistulae for all cross-femoral venous bypasses.[48,66]

Plethysmographic evidence of outflow obstruction was an independent predictor of clinical outcome in a report by AbuRahma and coworkers. Of their patients, 88% undergoing the Palma procedure who had abnormal preoperative maximum venous outflow showed significant clinical improvement, whereas 86% of those with normal preoperative maximum venous outflow had no improvement after surgery.[62]

Prosthetic Femorocaval, Iliocaval, and Inferior Vena Caval Bypasses

Anatomic in-line iliac or iliocaval prosthetic reconstruction can be performed for (1) unilateral disease when autogenous conduit for suprapubic grafting is not available or (2) bilateral iliac, iliocaval, or inferior vena caval occlusion. Extensive iliocaval venous thrombosis secondary to inferior vena caval filters or tumors, as well as retroperitoneal fibrosis not responding to nonoperative therapy, are potential indications. Failure of previous endovascular attempts and occlusion after placement of multiple stents are also indications for bypass.

Technique

The femoral vessels (for the arteriovenous fistula or for the site of the distal anastomosis) are exposed at the groin. The iliac vein or the distal segment of the IVC is exposed with a right oblique flank incision through a retroperitoneal approach. The vena cava at the level of the renal veins is best exposed through a midline or a right subcostal incision. The ascending colon is mobilized medially, and the vena cava is exposed. The infrarenal IVC is reconstructed with a 16- to 20-mm graft, the iliocaval segment usually with a 14-mm graft, and the femorocaval segment with a 10- to 12-mm graft. The arteriovenous fistula is constructed first in patients who undergo an iliocaval bypass (see Figs. 160.3, 160.7 and 160.8).

A short iliocaval bypass with a significant pressure gradient can be performed without an arteriovenous fistula. Reconstruction of the vena cava with a straight ePTFE graft, if inflow is good, is also usually performed without an arteriovenous fistula. In patients who undergo femorocaval bypass, we perform the

proximal and distal anastomoses of the bypass first and then create the arteriovenous fistula before opening the graft. As discussed previously, we generally use a tributary of the great saphenous vein for the fistula. The operation is performed with the patient fully anticoagulated, and prior to closure, a small polyethylene catheter is placed to the level of the distal anastomosis to infuse low-dose heparin (500 IU/h).

Results

Experience with femorocaval or iliocaval bypass is limited; only a few series have been published (Table 160.2).[22,27,46,47,67] In a Mayo Clinic series of 17 such bypasses, primary and secondary patency rates at 5 years were 63% and 86%, respectively.[27]

Alimi and colleagues reported the results of eight iliac vein reconstructions with femorocaval or iliocaval bypasses for both acute and chronic obstructions. In four patients with chronic obstruction, three grafts were patent at last follow-up.[46] Eklof and associates observed only one occlusion in five grafts followed for 14 to 22 months after surgery, in which bypass was combined with venous thrombectomy for acute DVT.[69] In 2003 the Mayo Clinic group published long-term results of femoroilial, femorocaval, and iliocaval prosthetic bypasses. They observed 5-year secondary patency rates of 86% for femoroiliac and iliocaval bypasses and 57% for femorocaval bypasses. The only factor affecting long-term patency was the presence of May-Thurner Syndrome.[59] We believe that all femorocaval or longer iliocaval grafts require the benefit of a distal arteriovenous fistula to maintain patency. Our policy now is to keep the fistula patent as long as possible.[27,54]

Combined Endovascular and Open Reconstructions

The combination of long iliac vein occlusions with chronic thrombosis of the common femoral vein precludes effective venous stenting. In these patients, open surgical thrombectomy of the common femoral vein with excision of old thrombus and recanalized intimal strands can be combined with intraoperative iliac or iliofemoral vein stenting. We perform these procedures in a hybrid operating room. A saphenous vein or bovine pericardial patch can be used to close the defect after thrombectomy in the femoral vein (Figs. 160.9 and 160.10). Two-year patency rates of these hybrid reconstructions were published in a Mayo Clinic series, including four patients with stent placement extending into the common femoral vein patch and five patients with the stent terminated proximal to the common femoral patch. All of the latter experienced early thrombosis; two underwent further stenting into the common femoral vein at the time of revision. Two-year secondary patency in patients with common femoral vein extension ($n = 6$) was 67% compared with 0% without common femoral vein stent ($n = 3$).[59]

Iliac Vein Decompression

Compression of the left iliac vein between the right common iliac artery (see Fig. 160.1) and the fifth lumbar vertebra was described first by McMurrich[67] in 1908 and later in much more detail in a large autopsy study by May and Thurner, who also recognized the clinical implications of the iliac "spurs" leading to acute DVT.[4,70] Cockett and Thomas coined the term *iliac vein compression syndrome* in 1965 and called attention to the obstructive symptoms in affected patients, who are often seen without clinical signs of previous DVT.[5] May-Thurner syndrome is observed more frequently in women between the second and fourth decades of life. Left lower extremity swelling, venous claudication, pain, and skin changes secondary to chronic stasis, including rare ulceration, may develop.[3,5-7]

An acute complication is left iliofemoral DVT. Some surgeons suggest repair of any lesion discovered,[71-78] but we advocate reconstruction only for symptomatic patients with previous iliofemoral DVT. Endovascular techniques with stenting are the first choice of treatment in most patients (see Chapter 161). However, open surgery can be performed in patients in whom endovascular treatment has been unsuccessful or is considered inappropriate.

Technique

The usual procedure is a Palma procedure. In patients with stenosis or short iliac occlusion, direct exploration of the vena caval bifurcation with the use of a variety of techniques to release the iliac venous obstruction has been recommended. The iliac vein is fully mobilized, and any external compressing bands are transected. Excision of intraluminal webs followed by vein or ePTFE patch angioplasty may be performed; other surgeons recommend transposition of the iliac artery behind the

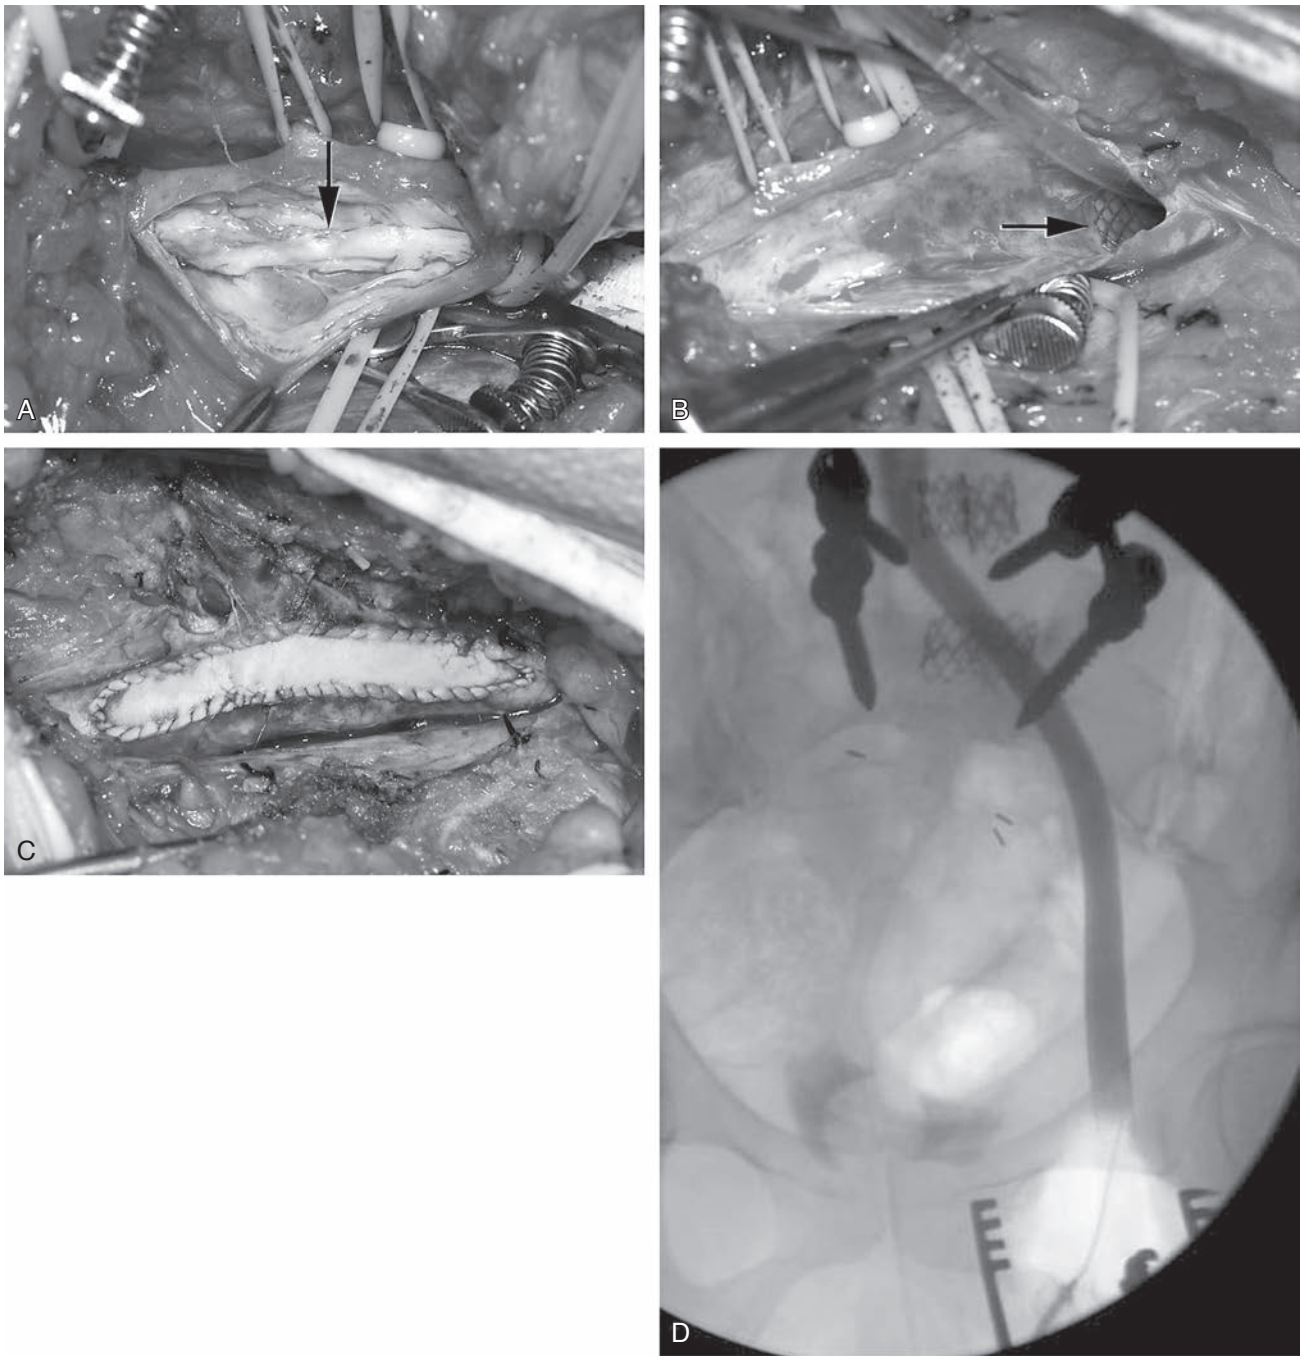

Figure 160.9 Combined Endovascular and Open Reconstruction for Chronic Iliofemoral Venous Occlusion. (A) Note old recanalized thrombus *(arrow)* in the common femoral vein. (B) The old thrombus was excised and the iliofemoral vein was stented with Wallstents *(arrow)*. (C) The femoral vein was closed with bovine pericardial patch. (D) Postoperative venogram confirms widely patent iliofemoral vein.

iliac vein.[53,71] Cormier and coworkers suggested transposition of the right common iliac artery into the left internal iliac artery to decompress the left common iliac vein.[72] Placement of a silicone elastic bridge over the iliac vein to prevent compression by the iliac artery, as suggested earlier, is not recommended.[73]

Results

Akers and colleagues found that of 80 reported patients undergoing iliac vein decompression, 65 (81%) had significant improvement postoperatively.[74]

Suprarenal Inferior Vena Cava Reconstruction

The most common reason to reconstruct the suprarenal IVC for benign disease is membranous occlusion of the IVC, which is frequently associated with occlusion of the hepatic veins (Budd-Chiari syndrome), subsequent portal hypertension, and liver failure (see Chapter 164). Occlusion of the suprahepatic IVC usually does not always cause significant congestion of lower extremity veins, although leg edema and venous claudication may develop. If percutaneous transluminal balloon angioplasty,

Figure 160.10 (A) Preoperative photograph of an 81–year-old patient with severe right lower extremity swelling and massive transudation of fluid due to right common iliac vein obstruction. Patient underwent a combined endovascular (iliac vein stenting) and open (thromboendovenectomy of the common femoral vein). (B) Photograph 9 months after the operation confirmed excellent clinical results.

stenting, or transatrial dilation of the membranous occlusion has not been successful, and portosystemic shunting is not required, venacavoatrial bypass is an effective technique to decompress the IVC. Most surgeons agree that an externally supported ePTFE graft is the best option.[13,45,52,65]

Technique

The retrohepatic segment of the vena cava and the right atrium are exposed through a right anterolateral thoracotomy, with extension of the incision across the costal arch so that the peritoneal cavity is entered through the diaphragm. The liver is retracted anteriorly, and the paravertebral gutter is exposed together with the suprarenal segment of the IVC. The pericardium is opened anterior to the right phrenic nerve, and the right atrium is isolated. The IVC is cross-clamped with a partial-occlusion clamp above the renal vein, and a 16- to 18-mm externally supported ePTFE graft is sutured end to side to the IVC. The graft is then passed parallel to the IVC to the right atrium or the suprahepatic IVC. The central anastomosis is performed after placement of a partial-occlusion clamp on the vena cava or the right atrium. Before completion of the anastomosis, air is carefully flushed from the graft to avoid air embolization.

An anterior approach was suggested by Kieffer and associates, who performed segmental replacement of the suprahepatic IVC using a short externally supported PTFE graft. Tunneling of a long cavoatrial graft anterior to the bile duct and under the left lobe of the liver was also reported (Fig. 160.11).[52]

Results

Wang and colleagues reported on 100 patients with Budd-Chiari syndrome, 12 of whom underwent cavoatrial bypasses. Clinical improvement with patent grafts was noted in 10 patients at a median follow-up period of 1.5 years after surgery.[13] In another series, Victor and colleagues reported patent grafts at 21 months to 6 years after the operation in five patients.[65]

Three cavoatrial grafts placed for nonmalignant disease were reported by the Mayo Clinic group: one patient with an ePTFE graft was asymptomatic at 10 years, a long Dacron graft became occluded at 3 years, and a spiral vein graft occluded within 1 year.[27,59]

SUMMARY

Progress in endovascular techniques has decreased the number of patients who are candidates for open surgical reconstruction for chronic occlusion of the iliofemoral veins or the IVC. Proper patient selection, attention to technical details during surgery, selection of the appropriate graft, perioperative thrombosis prophylaxis, and close follow-up are important to achieve long-term success. The Palma procedure using the great saphenous vein provides predictable long-term success for patients with unilateral iliac vein occlusion. ePTFE grafting for iliac vein or IVC occlusion is also an effective tool in the treatment of carefully selected patients with advanced, symptomatic venous disease. Combined endovascular and open procedures will likely increase the success of reconstruction of the large veins in the future.

PELVIC CONGESTION SYNDROME

The development of valvular incompetence and/or obstruction in the pelvic and gonadal veins may cause disabling symptoms, mainly in women of childbearing age; the disease is known as

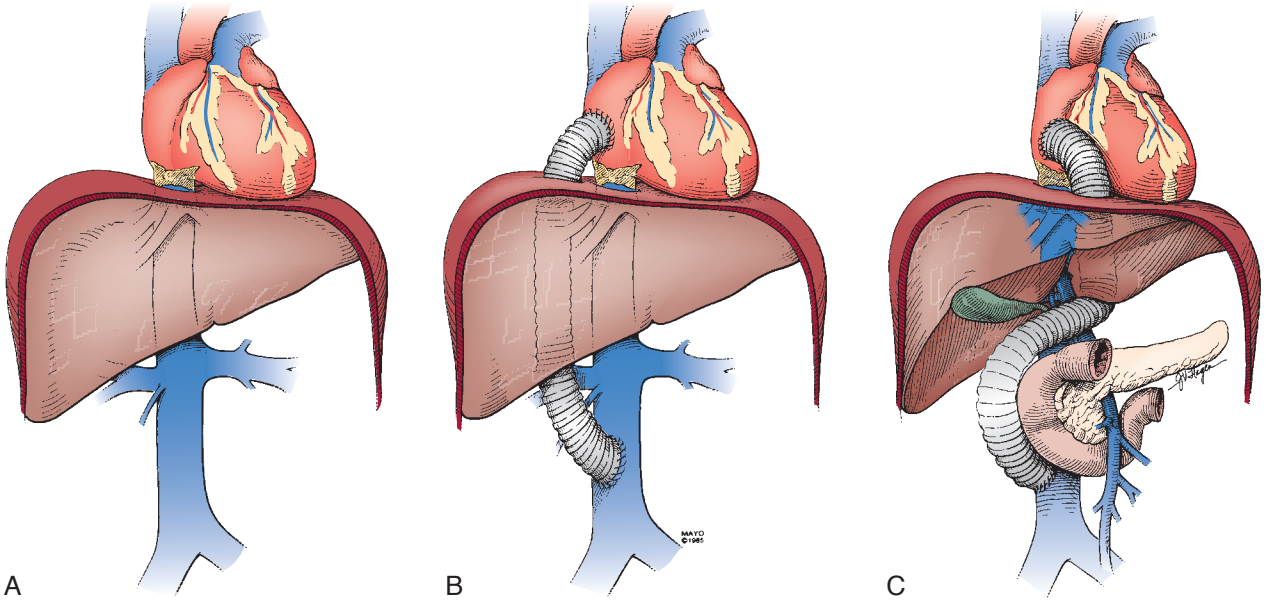

Figure 160.11 Different configurations of cavoatrial bypass performed for membranous occlusion of the inferior vena cava. Reinforced polytetrafluoroethylene graft can originate from the infrarenal (B) inferior vena cava and be routed behind the right lobe of the liver. Another potential position of the graft is behind the left lobe of the liver (C). (With permission of Mayo Foundation.)

pelvic congestion syndrome (PCS). Although first described in 1857 by Richet[79] and given its name in 1949 by Taylor,[80] this pathology was recognized only recently as a frequent cause of chronic pelvic pain.

INCIDENCE

Pelvic venous incompetence and varicose veins are found in 10% of women, and 15% of women between the ages of 18 and 50 years suffer from pelvic pain.[81] In a cohort of 148 patients with chronic pelvic pain, Soysal and coworkers noted that the incidence of PCS was 30%.[82] Belenky and colleagues found ovarian vein incompetence and varicosities in 9.9% of the general female population, with 59% of this group experiencing symptoms of PCS.[83] However, because many of these symptoms can be caused by other pelvic diseases (endometriosis, uterine fibroma, pelvic cancer, etc.), initial gynecologic examinations are mandatory before reaching the diagnosis of PCS, even in the presence of pelvic varicose veins. PCS can also cause lower limb varicose veins in atypical locations or recurrence after surgical treatment.[84]

ANATOMY OF THE PELVIC VENOUS SYSTEM

Pelvic structures are drained by both the internal iliac (hypogastric) and genital veins (Fig. 160.12).[85] The internal iliac vein rises near the upper part of the sciatic foramen, passes cranially posterior and medial to the internal iliac artery, and at the brim of the pelvis joins the external iliac to form the common iliac vein. Its tributaries correspond to branches of the internal iliac artery and are divided into parietal and visceral veins. Parietal tributaries are the superior and inferior gluteal, sciatic, sacral, ascending lumbar, and obturator veins. Visceral tributaries are the internal pudendal, middle hemorrhoidal, and vesicoprostatic plexuses in men and the uterine, gonadal, and vesicovaginal plexuses in women. Lepage and associates showed that in 27% of cases the internal iliac vein drains by means of two separated trunks.[86] In exceptional cases it can drain directly into the IVC. Valves are found infrequently in the internal iliac veins: 10% of cases in the main trunk and 9% in its tributaries.[86]

The ovarian veins form a plexus in the broad ligament near the ovary and uterine tube and communicate with the uterine plexus. They drain to the IVC on the right at an acute angle and on the left side to the LRV at a right angle. Anatomic variations can be present (see Fig. 160.12B). Multiple trunks can be present.[87] Observations based on vaginal ultrasound have revealed that the normal average diameter of ovarian veins is less than 5 mm.[88] According to Stancati and coauthors, valves are present in these veins, mainly in the distal third.[89] However, Ahlberg and collaborators found no ovarian vein valves on the left side in 15% and on the right side in 6%.[90] The ovarian veins are connected with the utero-ovarian and salpingo-ovarian veins through the broad ligament and with the rectal, vaginal, and vesical veins.

PATHOPHYSIOLOGY

According to Greiner,[91] pelvic varicose veins can be due to three different mechanisms:

- Type 1: reflux secondary to pelvic and genital (ovarian) vein incompetence. It is the most frequent etiology and of

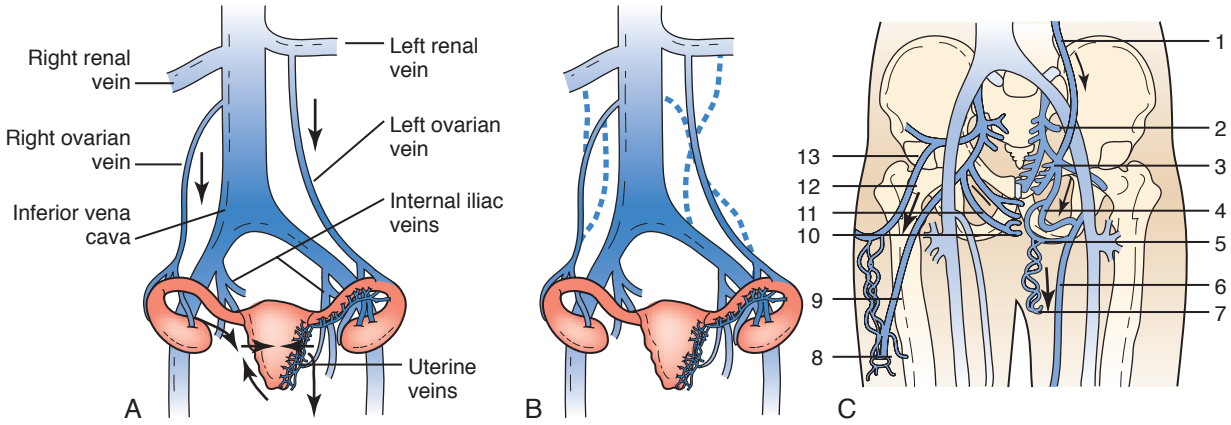

Figure 160.12 Anatomy and Reflux of the Pelvic Veins. (A) Anatomy. *Black arrows* indicate pathologic reflux in the bilateral ovarian veins and around the uterus, with varicosities developing on the left side of the uterus. (B) Anatomic variations of the ovarian veins, shown by *dashed lines*. (C) Internal iliac veins and their communications with the utero-ovarian plexus and thigh superficial veins: *1*, ovarian vein; *2*, internal iliac vein; *3*, uterine vein; *4*, obturator vein; *5*, external pudendal vein; *6*, great saphenous vein; *7*, varicosity of the anteromedial aspect of the thigh; *8*, varicosity of the posterolateral aspect of the thigh; *9*, sciatic vein; *10*, vulvar varicosity; *11*, internal pudendal vein; *12*, cystic and vaginal veins; *13*, buttock veins. Multiple collaterals are present.

uncertain cause. However, it has been shown that hormonal factors contribute to varicose veins, and that these veins are exposed to high levels of hormones. Estradiol inhibits the reflex vasoconstriction of vessels and induces uterine enlargement with selective dilation of the ovarian and uterine veins mainly during pregnancy.[92] In one study, intravenous injection of dihydroergotamine in women with pelvic congestion and pain produced a 35% reduction in vein diameters veins associated with a decrease in pelvic blood flow that resulted in pain relief.[93] Moreover, cystic ovaries are frequently associated with pelvic varicose veins.[93,94]

- Type 2: secondary to obstruction of outflow. May-Thurner syndrome,[95-97] nutcracker syndrome,[97,98] left renal vein thrombosis, post-thrombotic disease involving the common iliac veins or the IVC (or both), and Budd-Chiari syndrome can all lead to the development of pelvic varicose veins via collateral pathways.
- Type 3: secondary to a local compression phenomenon. The main cause is endometriosis, but it can also be due to tumors, posttraumatic lesions, and sequelae of infections.

CLINICAL FINDINGS

PCS often develops in young women (late 20s to early 30s) who are multiparous,[99] but treatment occurs at a mean age of 41 years.[100] The condition often disappears after menopause.[99] These lesions are rare in men except in cases of varicocele and are often due to venous obstructive disease. PCS can be described as a highly variable combination of chronic (up to 6 months) pelvic pain (heaviness that increases during the day, mostly if the patient stays sitting or standing and when lifting, and can be relieved by the supine position), dyspareunia, dysmenorrhea, and urinary (dysuria, pollakiuria, bladder urgency), and rectal (constipation) symptoms. Symptoms occur predominantly on one side but can be bilateral. Hemorrhoids are frequently found in these patients.[100]

Clinical examination can reveal cervical motion; retrocervical, paracervical, uterine, and ovarian tenderness; uterine enlargement; and uterine retroversion. According to Beard and colleagues, the combination of tenderness on abdominal palpation over the ovarian point and a history of pain after sexual activity was 94% sensitive and 77% specific for discriminating pelvic congestion from other causes of pelvic pain.[99] Perineal (mainly vulvar) varicose veins can be associated with PCS. Lower extremity findings include superficial venous insufficiency, atypical varicose veins (buttock, posterior and lateral aspect of the thigh, etc.), and recurrence after procedures for varicose veins.[100]

DIAGNOSIS

Noninvasive Investigations

Duplex Scanning

A pelvic color DUS is performed with transparietal 5-MHz and transvaginal probes after 3 days of a no-residue diet and an empty stomach.[95] Both the internal iliac and genital veins should be imaged to identify dilation and reflux, including imaging with the Valsalva maneuver. Pelvic varicose veins are defined as multiple dilated tubular structures around the uterus and ovary with venous Doppler signals and diameters larger than 5 mm.[95] The positive predictive value of a 6-mm-diameter ovarian vein for the diagnosis of PCS has been reported as 83.3%.[101] The obturator, sciatic, and internal pudendal veins should also be imaged. Collateral pathways, such as enlarged veins crossing the uterine myometrium, are often present. The common iliac veins, IVC, and renal veins should be imaged to search for venous obstruction. A lower extremity DUS can be

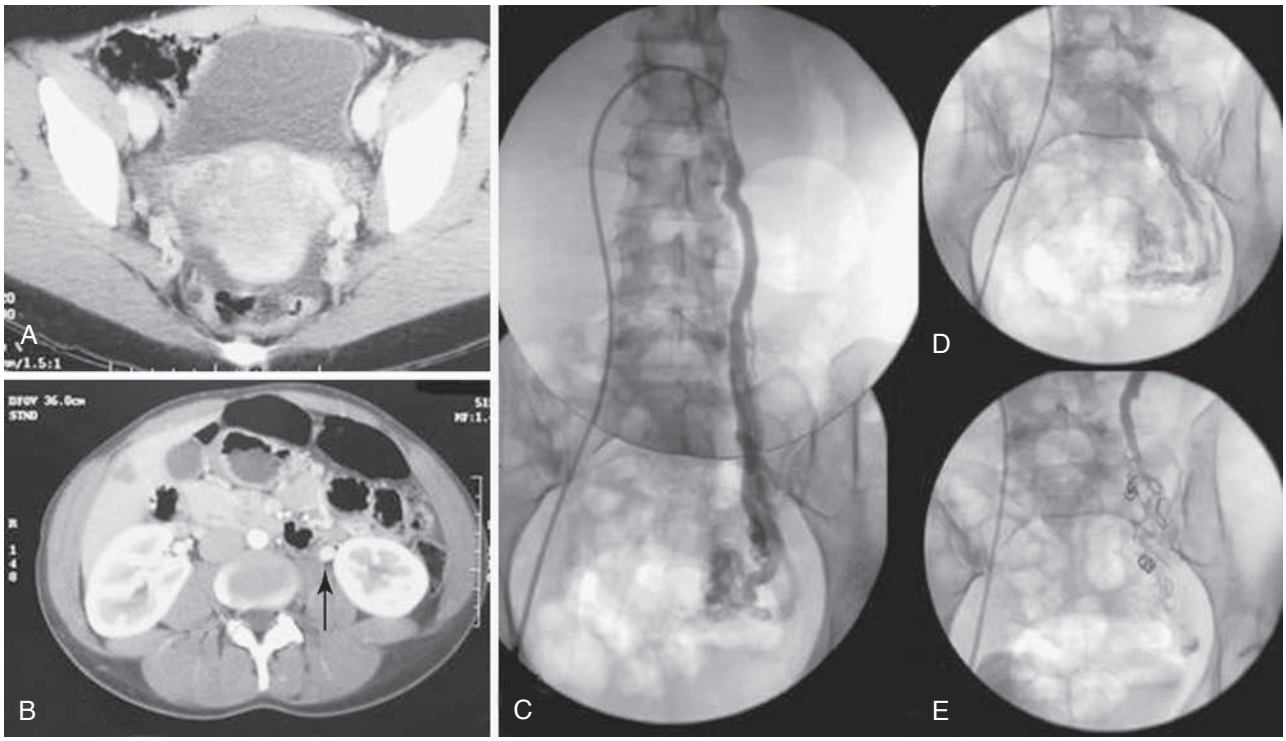

Figure 160.13 Woman With Pelvic Congestion Syndrome Secondary to Left Ovarian Vein Incompetence. (A) Pelvic varicose veins on computed tomography (CT) angiography. (B) CT angiogram showing left ovarian vein reflux. The vein is dilated and opacified early *(arrow)*. (C) Selective phlebography of an incompetent left ovarian vein with periovarian varices. (D) Delayed phlebographic imaging showing the left internal and common iliac veins. (E) Results after embolization with foam and coils.

obtained to search for valvular incompetence, which can be secondary to pelvic incompetence.

Computed Tomographic and Magnetic Resonance Venography

CTV or MR venography can be performed to confirm the presence of pelvic and genital varicose veins.[102] CTV should be timed for evaluation of the portal, genital, and renal veins, and separate imaging should be performed at later times for evaluation of the pelvic and iliocaval veins. Pelvic varices are imaged as dilated, tortuous, enhanced tubular structures around the uterus and ovary, with possible extension into the broad ligament and pelvic sidewall (Fig. 160.13A). They can also involve the paravaginal venous plexus. Rozenblit and associates define ovarian vein incompetence as opacification during the arterial phase of CT angiography and 7 mm or greater in maximum diameter (see Fig. 160.13B).[103]

On T1-weighted MRI, pelvic varicose veins have no signal intensity because of the flow void artifact; on gradient-echo MRI, varicose veins have high signal intensity. On T2-weighted MRI, they usually appear as an area of low signal intensity, although hyperintensity or mixed signal intensity may also be noted, possibly because of the relatively slow flow through the vessels. Two and three-dimensional, T1-weighted gradient-echo sequences performed after the intravenous administration of gadolinium are the most effective sequences for demonstrating pelvic varicose veins.[102,104,105]

CT and MR venography examinations can also identify other sources of pelvic pain, mainly endometriosis. Images should be evaluated for venous obstructive disease. However, because these tests are performed in the supine position, they can underestimate venous pathology.

Contrast Phlebography

This imaging technique is considered the "gold standard" for diagnosis and can be combined with interventions for treatment.[106] It is performed under local anesthesia via the common femoral or brachial vein approach.[106,107] It should image the four veins responsible for venous return from the pelvis: both internal iliac veins and both gonadal veins. The study should be performed with and without a Valsalva maneuver. A 4F or 5F Cobra 2 catheter is commonly used to catheterize and perform selective venography (see Figs. 160.13C, 160.14A and 160.15A). In some cases a Simmons catheter is required for imaging of the right gonadal vein (Fig. 160.16A). In cases of a brachial approach, a multipurpose or a vertebral catheter can be helpful. Either approach can be used, but catheterization of the right ovarian vein is more often successful from the brachial approach (18% failure for brachial approach[106] vs. 58% failure through femoral approach[107]). Kim and associates advocate the use of balloon occlusion venography to image the internal iliac veins (7F Berman wedge catheter [Arrow International, Reading, Pennsylvania] inflated in the trunk of the internal iliac vein).[108]

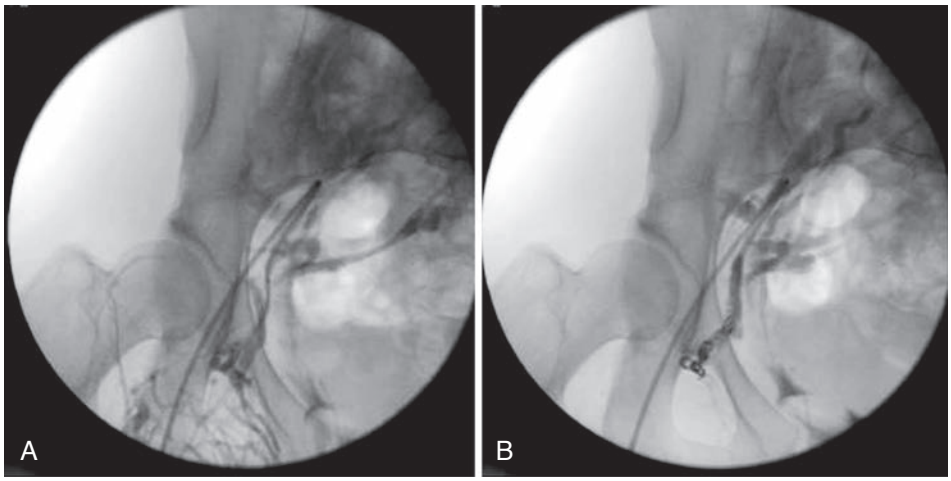

Figure 160.14 Patient With Varicose Vein Recurrence After Right Great Saphenous Vein Stripping. (A) Selective phlebography of the right obturator vein. (B) Results after treatment with foam and coils.

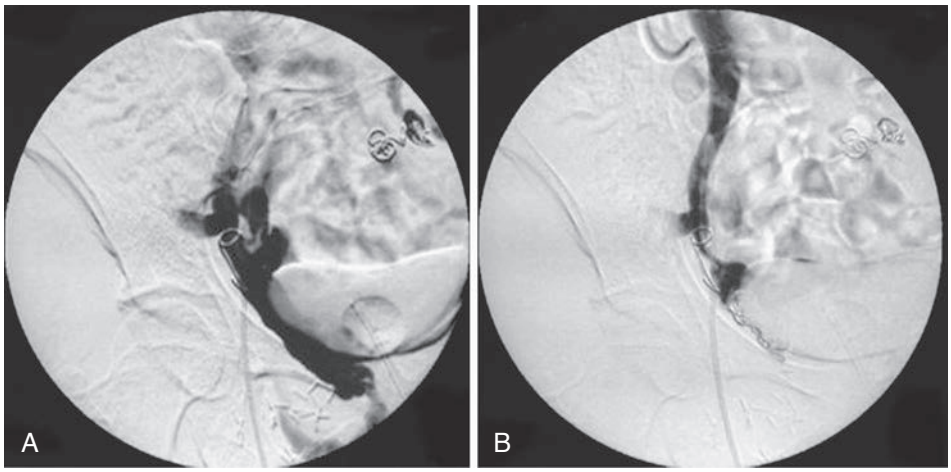

Figure 160.15 Woman With Pelvic Congestion Syndrome. (A) Phlebography showing right vesicovaginal varicose veins. (B) Completion phlebography after treatment with foam and coils.

According to Chung and Huh, criteria used for the phlebographic diagnosis of PCS caused by ovarian vein valvular incompetence are the following: ovarian vein larger than 5 mm in diameter (see Figs. 160.13C and 160.16A), retention of contrast medium in the ovarian vein for longer than 20 seconds, existence of congestion in the pelvic venous plexus, opacification of the internal iliac vein (see Fig. 160.13D), and/or filling of vulvovaginal and thigh varicosities. Each variable is assigned a value between 1 and 3, depending on the degree of abnormality, and a venogram score of 5 or higher indicates the presence of PCS.[109]

Differential Diagnosis

As suggested earlier, it is important to rule out nonvascular causes of pelvic pain, such as endometriosis, uterine fibroma, pelvic cancer, or pudendal nerve compression. The diagnosis relies on analysis of the symptoms and on investigations. Pelvic ultrasound, CT, and MRI can be of considerable help, but sometimes a more extensive evaluation is required. Laparoscopy reveals pelvic varicose veins if performed in a feet-down position while limiting the pressure of peritoneal insufflation, and it may help to eliminate other pathologies.

TREATMENT

Medical Treatment

Medroxyprogesterone acetate (Provera, Upjohn Ltd, Kalamazoo, Michigan), 30 mg/day for 6 months, was shown to be effective in relieving the symptoms of PCS by Faquhar and coworkers, with 73% of women reporting at least 50% improvement, versus 33% of those treated with placebo.[110] However, this positive effect was not maintained 9 months after discontinuation of treatment. In a prospective randomized trial, Soysal and colleagues compared the efficacy of goserelin acetate (3.6 mg/month for 6 months) and medroxyprogesterone (30 mg/day for 6 months).[82] One year after treatment, goserelin had achieved a statistically significantly better result. Micronized purified flavonoid fraction (Daflon, Servier), 500 mg twice a day for 6 months, resulted in statistical improvement at the end of

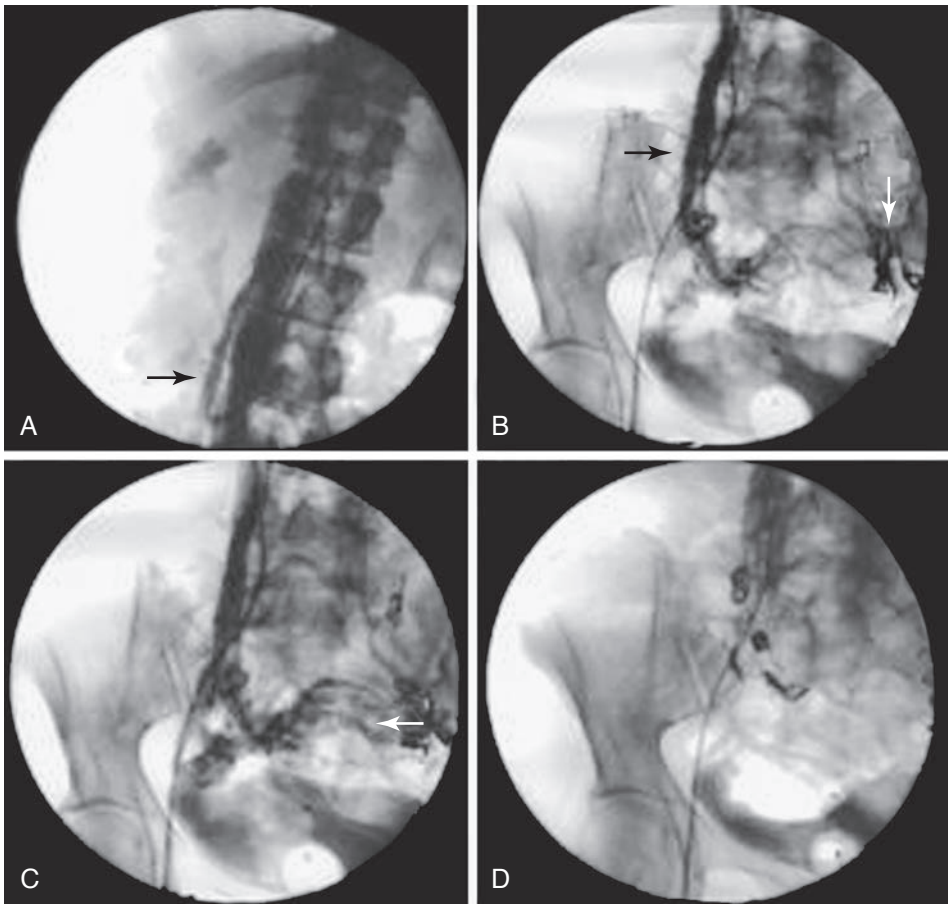

Figure 160.16 Woman With Pelvic Congestion Syndrome Caused by Bilateral Ovarian Vein Reflux. (A) Selective phlebography of a large refluxing right ovarian vein with a Simmons catheter. (B) Result after sclerotherapy and embolization with foam and coils. (C) Late pelvic view showing periovarian varices *(arrow)*. (D) Result after sclerotherapy and embolization with foam and coils.

treatment in a prospective randomized study.[111] Although these medications provide symptom relief, none have permanent effects once discontinued.

Conventional and Laparoscopic Surgery

Different surgical techniques have been reported for the treatment of PCS, including ovarian and/or internal iliac vein ligation, ovarian and uterine artery and vein ligation, oophorectomy, and even total hysterectomy with bilateral salpingo-oophorectomy. Some of these techniques can be performed laparoscopically, but they remain invasive.[112] Despite the observation that bilateral oophorectomy combined with hysterectomy and hormone replacement therapy have been shown to be effective in patients who fail medical therapy,[94] this is an invasive option, which is not acceptable for women who want to become pregnant.

Endovascular Treatment

Techniques

Endovascular therapy with embolization is now considered the first line treatment for PCS in most patients. The procedure is performed under local anesthesia either together with diagnostic phlebography or as a separate procedure. After selective catheterization and contrast-enhanced study of the refluxing vein or veins, embolization is performed. "Rules" of the embolization technique include the following: (1) the entire internal iliac vein should not be embolized, and (2) regarding the gonadal veins, embolization must be performed proximal to the last collateral to prevent recurrences. Embolization is mainly performed using coils (0.035 inch for 4F or 5F catheter and 0.018 inch for microcatheters, pushable or detachable, fibred or not). Vascular plugs (Amplatzer) can be used in cases of very large veins.[113] The number of devices used and the rate of recurrence can be reduced by the addition of foam sclerotherapy to embolization. Foam is prepared from sodium tetradecyl sulfate (Trombovar or Sotradecol) or Aetoxisclerol (polidocanol) and can be injected either before coiling or by using the sandwich technique (see Figs. 160.13E, 160.14B, 160.15B, and 160.16B). Foam is created using air or a 50/50 mixture of CO_2 and O_2 according to the Tessari method (see Chapter 155).[113a] With 3% polidocanol, we use up to 30 mL of foam. Other agents which have been used include n-butyl cyanoacrylate, ethylene vinyl alcohol copolymer, and sodium morrhuate combined with Gelfoam.[108]

When treating the internal iliac vein, Kim and coauthors recommended using balloon occlusion and avoiding embolization of the main trunk.[108] In addition, care must be taken to avoid embolization of the external iliac and common femoral veins.

In a prospective randomized study of 164 women with PCS, Chung and Huh compared ovarian vein embolization, hysterectomy with bilateral oophorectomy and hormone replacement

therapy, and hysterectomy with unilateral oophorectomy.[109] They showed that embolization was significantly more effective than the other two techniques. Asciutto showed that using embolization, untreated patients had no improvement, whereas treated patients improved.[114] Regarding the technique, Monedero and coauthors reported 1186 cases of embolization for recurrent lower limb varicose veins caused by pelvic disease; they had better results with coils and the sandwich technique (coils plus 2% polidocanol or hydroxypolyethoxydodecane foam) than with the use of coils alone (95.6% rate of improvement vs. 76% at 6 months).[106] Literature review shows better results in series reporting embolization of all incompetent veins.

Complications of embolization with or without sclerotherapy are rare and include hematoma at the access site, extravasation of contrast corresponding to vein perforation, coil or glue embolization, DVT and pulmonary embolism, and transient cardiac arrhythmia.

PCS linked to iliocaval obstructive disease (mainly May-Thurner Syndrome) should be treated by stenting of the obstructive lesions (the left common iliac vein).[97,115]

Clinical guidelines including recommendations for the treatment of PCS were recently published by the Society for Vascular Surgery and the American Venous Forum. These recommend that PCS and pelvic varices due to pelvic vein incompetence should be treated using coil embolization, plugs, or transcatheter sclerotherapy, used alone or together (grade 2B) (Table 160.3).[116]

INTRODUCTION

A web-like lesion at the iliocaval junction was described by McMurrich, a Canadian physician, in 1908.[1] Recognition of the lesion now commonly known as May-Thurner syndrome (MTS), or iliac compression syndrome, evoked a series of controversies from the start. Initial debate involved the origin of the lesion: was it ontogenic or acquired? Based upon the rarity of the lesion in embryos and infants, an acquired etiology is now generally accepted, although a few lesions occur at known fusion planes and could be classified as ontogenic.[2,3] Since neovascularization is absent, postthrombotic etiology is not likely. May and Thurner proposed that the lesions, which can range from increased wall thickness to intraluminal membranes, webs, and fibrous strands, result from the trauma of the repeated pulsations of the closely related artery. The name "iliac compression syndrome" is incomplete as compression is but one element of a complex lesion.

Later controversies arose concerning the high prevalence of MTS in the general population in silent form. Cockett reported that the lesion can be highly symptomatic in a select group, often young women of child-bearing age with preferential involvement of the left lower extremity.[4] In some patients, the lesion appeared to precipitate deep venous thrombosis of the extremity. Lea Thomas, a radiologist, developed specialized techniques to visualize the lesions with contrast, while recognizing that venographic sensitivity was only about 50%.[5] Modern imaging techniques have confirmed that iliac vein compression posterior to the crossing right common iliac artery is present in as much as two-thirds of the general population.[6] Recent use of intravascular ultrasound (IVUS) has shown the lesion to be present at more diverse locations in the pelvic venous anatomy (Fig. 161.1), and that it affects a much broader demographic than the narrow band recognized by Cockett and colleagues.[7] IVUS has a sensitivity of ≈80% for the lesion. Most lesions are silent, but symptoms, ranging from swelling to venous ulcerations, may be present. The lesion is best viewed as a permissive pathology, precipitating symptoms when a secondary insult to the limb, such as trauma, infection, or deep venous thrombosis (DVT), is superimposed. Postthrombotic iliac vein

Abstract

The last two decades have witnessed a paradigm shift in the management of femoroiliocaval venous lesions. Endovenous interventions have supplanted open surgery as the treatment of choice, with the latter reserved for patients who are not candidates for endovenous interventions or who have failed such interventions. This chapter reviews the diagnosis and endovenous treatment of femoroiliocaval lesions.

Keywords

Iliac stent
May-Thurner syndrome
Iliac vein compression syndrome
Post thrombotic syndrome
iliocaval chronic total occlusions
occluded inferior vena caval filter

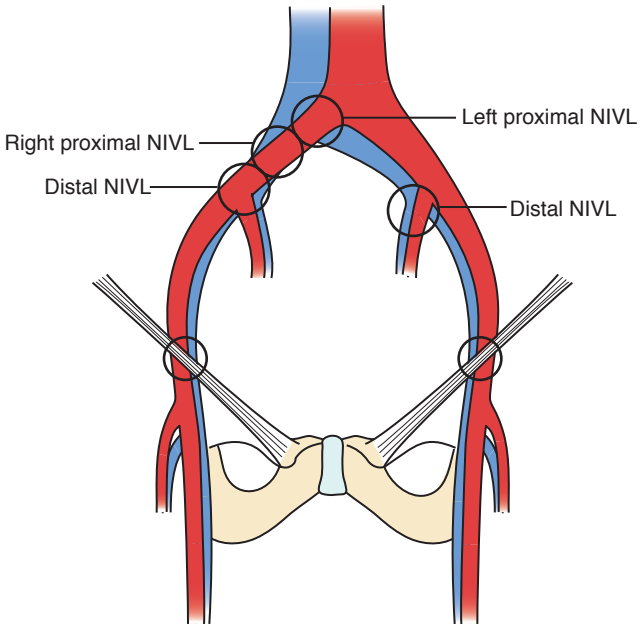

Figure 161.1 Common Sites of Iliac Vein Stenosis Seen on Intravascular Ultrasound Examination. The "classic'" proximal nonthrombotic iliac vein lesions (NIVL) lesion occurs in the left common iliac vein posterior to where it is crossed by the right common iliac artery. The distal lesion on the left side occurs posterior to the left hypogastric artery crossing. On the right side, both proximal and distal lesions underlie the right common iliac artery. Compression by the inguinal ligament is also a source of stenosis.

stenoses resulting from DVT, either precipitated by a May-Thurner type of lesion or occurring de novo, are increasingly recognized. Specific relief of symptoms after percutaneous stent placement has largely silenced earlier critics who argued that the obstructive lesion, even when associated with collaterals, is a "natural anatomic variant" not requiring specific correction. Percutaneous iliac vein stenting has rendered earlier veno-venous bypass techniques obsolete, and these techniques are now reserved only for stent failures. Stent technology has also exposed venous obstruction at the iliac level as a major cause of chronic venous disease (CVD). The safety and efficacy of venous stenting have dramatically broadened the spectrum of CVD patients who can undergo treatment for this disease with clear clinical improvement. This represents a major treatment paradigm change. An unexpected finding in recent stent experience is the observation that patients with combined obstruction and reflux appear to benefit clinically even if the associated reflux remains untreated.[8]

PATHOLOGY

Two major types of iliocaval venous obstruction are recognized, nonthrombotic iliac vein lesions (NIVL), synonymous with MTS, and postthrombotic iliac vein stenosis (PTS) resulting from a prior episode of DVT.[9] The relative incidence in major centers is roughly 50/50 but trending higher in favor of the postthrombotic variety because of improved diagnosis of iliac vein DVT with modern imaging modalities. About 10% of cases are of the mixed type, as NIVL can precipitate thrombosis, and thrombus tends to add fibrosis to compression points in the vein during organization. NIVL lesions are typically subsegmental and focal, occurring in areas where compression by the overlying artery or ligament occurs (see Fig. 161.1). PTS lesions are longer, involving one or more vein segments, with focal elements. A special form of long diffuse stenosis caused by a postthrombotic fibrous envelope surrounding the vein was first recognized by Rokitansky in autopsy studies. Milder forms of this type may not be recognizable in venograms without luminal measurements (Fig. 161.2). A focal lesion occurring in association with a Rokitansky stenosis will be underestimated as the adjacent reference segment for calculation of the stenosis is not normal but stenotic.

The majority of limbs with iliac vein obstruction will also have reflux below the inguinal ligament,[10] resulting in peripheral venous hypertension. Both the obstructive and reflux pathologies cause microvascular injury, which is sustained by the peripheral venous hypertension.[11]

Venous collateralization is poorly understood. In many venous territories, alternative pathways already exist. They normally remain dormant as flow preferentially takes the course of the lower resistance main pathway. When the main channel is stenosed or occluded and the venous pressure rises, flow is diverted through these alternative routes. When the axial stenosis is stented, flow once again takes the lower resistance pathway and the collaterals "disappear." Venographic collaterals can be demonstrated in about 30% of iliac vein stenoses.[7,9] Because of the geometric factor (r^4/L) in the Poiseuille equation, an exponential number of collaterals are needed to equal the conductance of the normal iliac vein. For example, 256 collaterals, each 4 mm in size, are required to equal the conductance of a 16-mm common iliac vein. For this reason it is rare for iliac vein lesions to be fully compensated by adequate collateralization. The exponential power of the geometric factor plays a role in venous resistance. The magnitude of its effects can be surprising. For example, a luminal stenosis of a mere 12% in the common iliac vein (16 ≥14 mm) will nearly double the resistance, and hence, the pressure with the same flow.

Using isotope lymphangiography, lymphatic dysfunction can be demonstrated in ≈30% of limbs with CVD.[12,13] The injury occurs at the pre-collector level, presumably in association with the microcirculatory injury of CVD. Normalization of these scintigraphic abnormalities occurs in about 25% of limbs following iliac stenting (Fig. 161.3).

INDICATIONS AND PATIENT SELECTION FOR ILIOCAVAL VENOUS STENTING

CVD in general is a nonlethal disease and loss of limb is a rarity. There is no role for prophylactic treatment of silent lesions. If symptoms resulting from iliocaval stenosis or occlusion are present, conservative treatment with compression is the initial treatment modality. This modality will fail in 50% or more patients because of inefficacy or, more often, noncompliance with compression regimens.[14] The nature and cause of noncompliance

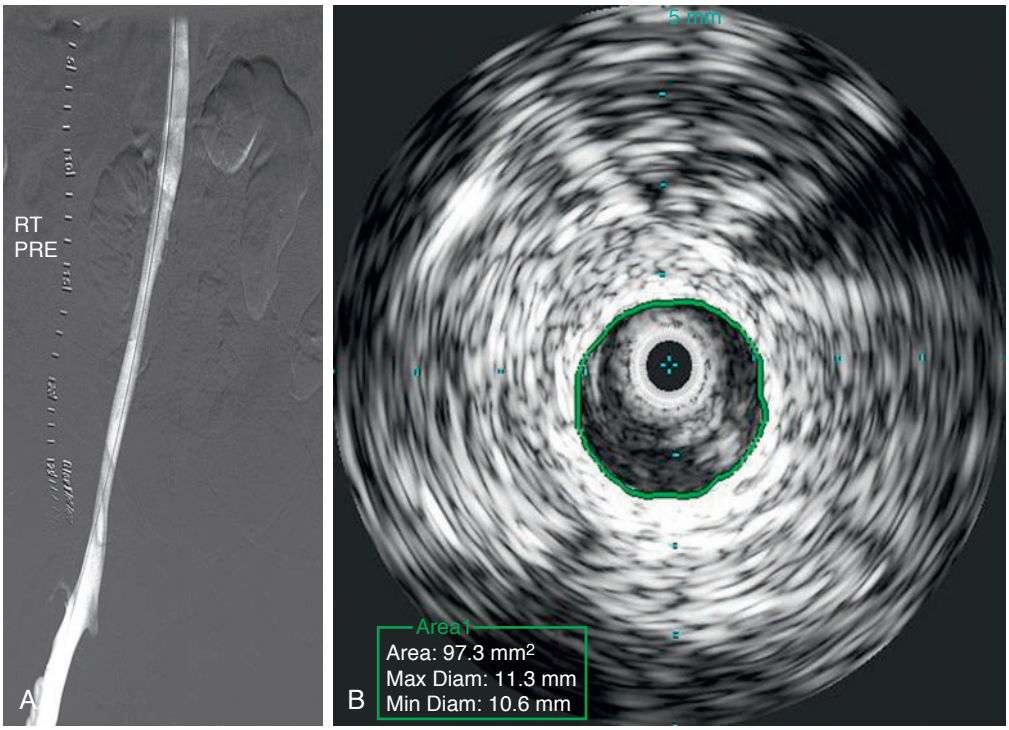

Figure 161.2 Rokitansky Stenosis. The long diffuse stenosis is not readily apparent on venography, which lacks an internal scale (A). On intravascular ultrasound examination (B) the maximum common iliac vein diameter is 11 mm with an area of 97 mm^2, constituting a 50% area stenosis.

is poorly understood. Intensive monitoring, education, and supervision have had no effect on the problem.[15,16] Iliac vein stenting may be carefully considered after failure of conservative treatment. Patients should be advised that this is not a "circulation problem" of the type that affects arteries, but a disease that usually manifests with only quality-of-life issues. Patients are often relieved by this information alone and are then able to make an informed decision regarding intervention.

In general, only patients with CEAP classes 3 to 6 are candidates for correction of iliocaval stenosis. Lesser clinical classes can occasionally be considered if they are thought to have venous claudication or the "venous hypertension syndrome." Patients with venous hypertension syndrome have diffuse limb pain (not to be confused with local pain over varices) relieved by elevation of the limb and compression stockings. Some patients have learned that ambulation can provide pain relief due to lowering of the venous pressure by calf pump action. Atypical pain syndromes include venous claudication (particularly when climbing up stairs), nocturnal leg cramps, restless legs, and dull, diffuse, achy limb pain at night even with the leg elevated. Life-style limitations and sleep deprivation from these atypical pain syndromes are appropriate indications for corrective intervention. Pain severity should be assessed by the visual analog scale (VAS). Venous clinical severity score (VCSS) is the current standard for complete clinical assessment (see Chapter 19).

Special patient subsets who may benefit from stent correction of iliocaval venous stenosis include geriatric patients who cannot self-apply compression due to arthritis or frailty, obese patients with severe venous manifestations who are not candidates for weight reduction surgery, patients with recurrent cellulitis of the limb secondary to the obstructive lesions, and cases of acute iliac vein thrombosis caused by an underlying stenosis. Lysis of the acute thrombus will initially be required in combined acute/chronic lesions. The stenosis can be stented as soon as the thrombus has cleared.

In another special category are limbs with swelling diagnosed as lymphedema. Too often, this diagnosis is based only on clinical impression without the benefit of isotope lymphangiography. "Classic" clinical features of lymphedema, such as dorsal foot hump, squaring of toes, and Stemmer sign, can be present in venous swelling as well, with or without associated lymphatic damage/dysfunction. Considering the huge prevalence of CVD in western populations and the high incidence of associated lymphatic abnormalities, it is likely that lymphedema associated with CVD ("venous lymphedema") is the most common type of secondary lymphedema in the Unites States, with a prevalence far exceeding either primary lymphedema or other secondary causes.

A diagnosis of lymphedema may consign the patient to lifelong, often ineffective conservative therapy. It is recommended that a correctible iliac vein stenosis be ruled out in individuals before a diagnosis of lymphedema is established. After stent correction of a stenosis discovered by this approach, improvement in swelling can be expected, although to a lesser degree than in obstructed limbs without lymphatic abnormalities (see Fig. 161.3).

Associated reflux is often present in patients diagnosed with iliac vein obstruction. If the reflux is in the superficial system, saphenous ablation can be performed before iliac vein stenting, or it can be accomplished concurrently.[17] Patients with deep reflux should undergo iliac vein stenting first, as good results can be anticipated despite the residual reflux.[18] Deep reflux

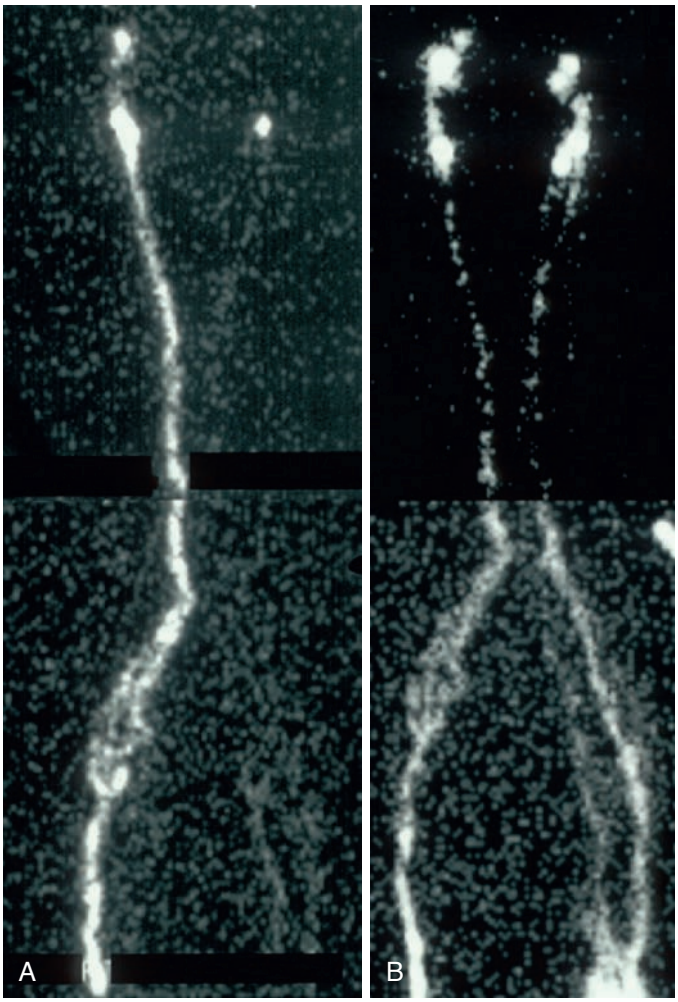

Figure 161.3 Venous Lymphedema. Note the absence of lymphatic activity in the left lower limb on lymphoscintigraphy (A). Activity recovers (B) after the underlying iliac venous stenosis is corrected with a stent.

corrective procedures which currently require complex open techniques are reserved for the salvage of nonresponders to initial stenting.

DIAGNOSIS

Venography has been the main imaging modality to diagnose iliac vein lesions. Transfemoral injection of contrast is required as adequate opacification of pelvic venous anatomy is often not obtained by pedal injection. Because iliac vein lesions are manifested as compression in the coronal (proximal lesion) or the sagittal plane (distal lesion), single plane views can be misleading (Fig. 161.4). However, subtle signs are often present to alert the astute observer (Fig. 161.5).

In a blinded comparison of IVUS and transfemoral venography in 162 limbs at our institution, the presence of a stenosis in the iliofemoral segments was altogether missed by venography in 25%.[19] Among those lesions visible with contrast, the degree of stenosis was significantly underestimated compared to IVUS ($P < .001$). In addition, the level of the iliac confluence as determined by venography varied by as much as one vertebral body length compared to that identified using IVUS. The ideal upper and lower landing zones determined by venography agreed with IVUS guidance in only 29% of limbs. Therefore IVUS guidance during stent placement is preferred. These procedural elements are crucial for technical success and outcome.

Imaging techniques (computed tomography venography, magnetic resonance venography, or duplex ultrasound) can be more definitive than venography for diagnosis, as lumen size at stenotic points can be measured by the intrinsic scale, which is not possible with venography. The diagnostic accuracy of these imaging techniques in detecting iliac vein stenosis has not been determined. At present, we consider IVUS the gold standard in the morphologic diagnosis of iliac vein lesions.

TREATMENT

Technique[20]

A mid-thigh ipsilateral femoral vein access under ultrasound guidance is preferred. Access at superficial locations over bony points, as in arterial practice, is not necessary. Low venous pressure facilitates even deep access with few hematomas or other complications. A large sheath, typically 11 Fr, is preferred for easy manipulation of inserted devices. The mid-thigh access allows enough room for the sheath to deploy stents below the inguinal ligament if needed. This approach has the advantages of the supine position, short distance to the lesion, and antegrade manipulation. Popliteal and internal jugular access are somewhat inferior, but can be used as backup sites. An optional on-table venogram may be performed for diagnostic and road-mapping purposes. The procedure can be performed solely with fluoroscopy and IVUS control without using contrast in the event of contrast allergy or renal dysfunction. IVUS examinations of the inferior vena cava (IVC), common iliac vein (CIV), external iliac vein (EIV), and common femoral vein (CFV) are carried out to identify lesions and appropriate landing sites. IVUS planimetry is used to measure areas. The degree of stenosis is best calculated using the expected normal area for the location (Table 161.1). Using the adjacent or contralateral lumen as a reference may result in underestimation of the stenosis; long diffuse narrowing of the lumen is present in an estimated 20% to 50% of cases. Most symptomatic limbs will have >50% area stenosis or greater, although some lesser lesions can be symptomatic in individual patients with PTS due to severe compliance changes. Predilation using large-caliber (16 to 18 mm) high-pressure balloons (14 to 16 atm) is routine. Because of the fibrous nature of iliac vein lesions, angioplasty alone is seldom effective as recoil is the rule. Large-caliber stents approximating the normal size of the iliofemoral segments should be used. The use of undersized stents is among the most common causes of iatrogenic stenosis with persistent symptoms (Fig. 161.6).

Treating the entire diseased segment or lesion in continuity with landing sites clear of disease is essential for successful outcomes. Skipping short segments of apparently normal vein is a source of potential recurrence. It appears that metal load is a lesser cause of stent thrombosis than uncovered lesions. From this perspective, a philosophy of liberal stent coverage

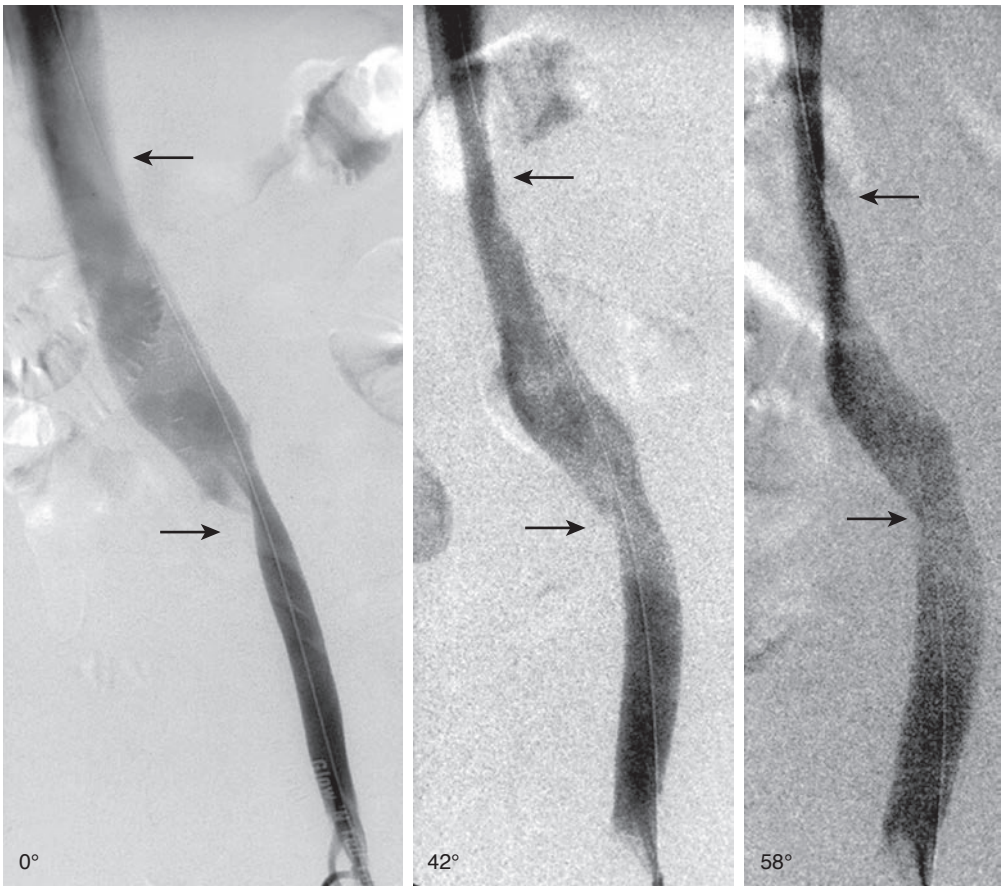

Figure 161.4 Nonthrombotic iliac vein lesions are often two-dimensional rather than circumferential. In the example shown, the proximal lesion is not apparent on frontal projection (0°) but is revealed on lateral projections (←). The distal lesion apparent in the frontal view becomes hidden in oblique and lateral projections (→). The level of iliac confluence is not readily apparent in the frontal view.

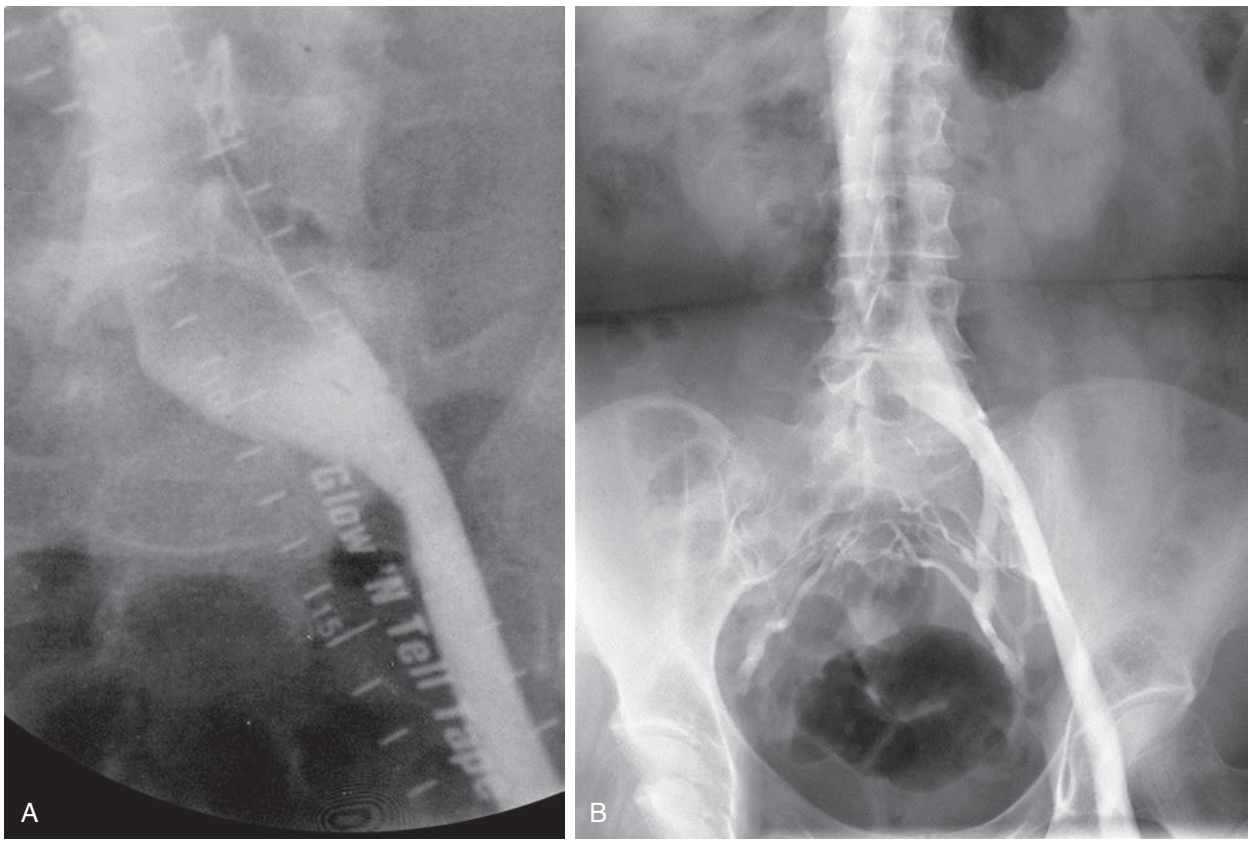

Figure 161.5 Venographic appearance of nonthrombotic iliac vein lesion: "island"-like appearance of the terminal common iliac vein (A). "Pancaking" (B) with collaterals.

TABLE 161.1 Optimal Iliofemoral Venous Segment Diameters/Areas

Vein	Diameter (mm)	Luminal Area (mm^2)
CFV	12	125
EIV	14	150
CIV	16	200

CFV, Common femoral vein; *CIV*, common iliac vein; *EIV*, external iliac vein.

Figure 161.6 An undersized 8-mm diameter stent (optimum 16 to 18 mm) was placed in the iliac vein *(proximal arrow)*. Note the caliber of the stent is smaller than the common femoral vein *(distal arrow)*. Placing an undersized stent results in an iatrogenic stenosis, which is difficult to correct.

rather than one of limited use should govern. Most limbs with postthrombotic disease will require extension of the stent below the inguinal ligament into the common femoral vein. The stent end should remain above the orifice of the deep femoral vein, which provides adequate inflow in most instances to sustain the stent. Occasionally, the stent can be delivered into the deep femoral vein (via jugular, popliteal, or direct deep femoral access) if its ostium is involved in the postthrombotic process. Stent fractures and erosions have been rare with stents crossing the joint crease, unlike arterial applications.

Since the proximal lesion at the iliocaval confluence is spiral, incomplete stent coverage in this area is a common cause of residual symptoms. This tends to occur in procedures that are totally reliant on venographic control without the use of IVUS. The best upper and lower landing sites are chosen on IVUS views using the vertebral bodies and the femoral head as fluoroscopic markers. Extension of the iliac stent for a few centimeters into the IVC is generally required to traverse the proximal lesion in its entirety. Wallstents have been used most often. An 18 or 20 mm stent dilated with 16 and 18 mm balloons, respectively, will accommodate most adults and provide a 2-mm reserve for extra dilation later if required. A Z-stent may be used proximally (within the Wallstent) for added radial strength under the artery, and to minimize jailing of the contralateral iliac outflow (Fig. 161.7). The IVC Z-stent extension greatly simplifies bilateral simultaneous or sequential stenting by eliminating the need for difficult fenestration techniques to reconstruct the iliac confluence.[21] A significant reduction in contralateral DVT has been observed with the Z-stent extension compared to the Wallstent extension.[22] Stenting the iliocaval confluence, particularly when there is bilateral disease, is an unsolved problem.[23] An ideal stent for the confluence is yet to be developed.

Postdilation is carried out after stent deployment. IVUS planimetry is used to confirm that the stenosis has been corrected to achieve the recommended caliber shown in Table 161.1.[24] If not, a larger balloon up to the maximum-rated diameter of the stent is used to achieve the desired caliber. A completion venogram is performed to confirm patency and flow.

The sheath is withdrawn slowly under ultrasound view until the tip exits the vein. A slight to-and-fro movement of the sheath confirms that it is outside the vein. A plug of Surgicel Fibrillar (Ethicon, Somerville, New Jersey) is loaded into the cylindrical plastic guard of the Seldinger needle. Using the obturator with the tip cut off, the hemostatic plug can be pushed into the sheath and delivered over the venotomy site before complete withdrawal of the sheath.

Recanalization of Chronic Total Occlusions[25,19]

Once the province of complex open surgical procedures, chronic total occlusion (CTO) lesions have been found to be surprisingly amenable to percutaneous recanalization in an outpatient setting. Procedure success rates are in the range of about 85% for both iliac and IVC lesions.[19,25] Percutaneous recanalization of extensive occlusions involving both iliac veins and the IVC up to the right atrium have been reported in large case series (Fig. 161.8).[19] Most of these will have chronically occluded renal and hepatic drainage with alternate outflow already established. Few hepatic or renal complications after successful recanalization have been reported.

The recanalization process involves blind threading of a glidewire through the trabeculated vein. Passage with the tip of the glidewire rather than a loop is more often successful. Unlike in arterial CTO, no subendothelial or deeper dissection is performed. Venography, at least in the initial stages, is necessary to define the anatomy and provide a road map. Some CTO lesions that appear daunting on venography can be traversed with surprising ease. This is because contrast may not reach loosely trabeculated segments (often appearing as a "blush")

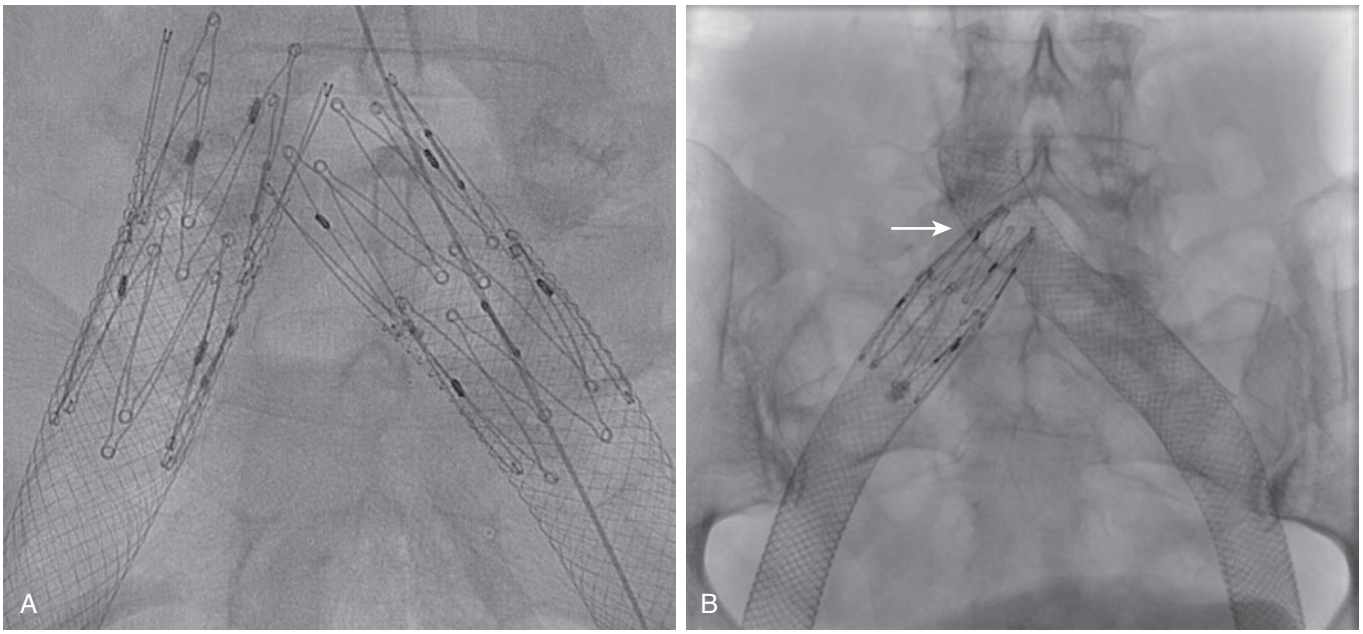

Figure 161.7 Z Stent Inferior Vena Cava Extension of the Wallstent Stack. The widely spaced struts of the Z stent minimize jailing of the contralateral iliac vein and allow easy bilateral sequential or staged iliac stenting (A). Fenestration techniques (B) are technically more demanding. In the example shown, a Z stent has been used to scaffold the fenestrum created in the contralateral Wallstent *(arrow)*. (From Raju S, Ward M, Jr., Kirk O. A modification of iliac vein stent technique. *Ann Vasc Surg*. 2014;28:1485-1492.)

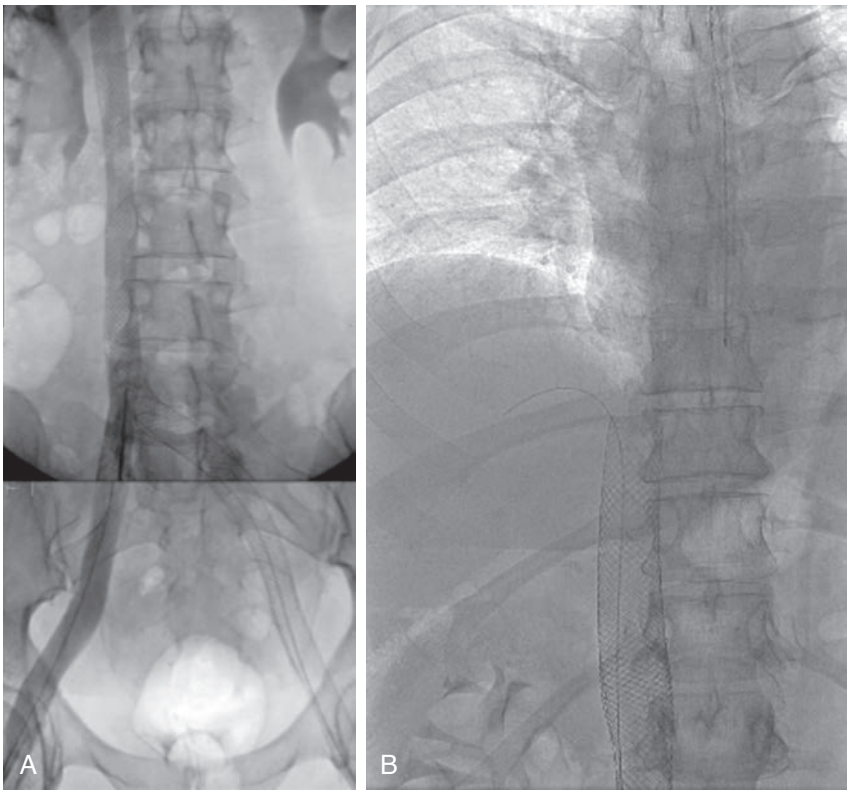

Figure 161.8 Extensive recanalization of chronic total occlusions involving the inferior vena cava and both iliacs. The stent stack extends to the common femoral vein below the inguinal ligament bilaterally (A). Stent erosions and fractures involving the Wallstent crossing joint creases are rare in venous applications. In the (B) panel, the Wallstent stack extends to the atrium.

above short segments of more densely trabeculated vein. The use of angled-tip guiding catheters is standard. Specialized catheters for CTO crossing are helpful. The recanalization course should conform to the normal anatomic course of the occluded vessel. Off-course passage into collaterals or perforations is easily recognized. Because of the low venous pressure and dense fibrous cover over CTO veins, free hemorrhage is rare. In case of perforation, the wire can simply be withdrawn and redirected without aborting the procedure. The passage of the wire into the vertebral canal through collaterals is a hazard if not recognized before balloon dilation. Since the abdominal IVC lies to the right of the vertebral column, passage of the wire in the midline is a clue to vertebral canal entry. This can be checked by oblique or lateral fluoroscopic views. Once the entire CTO lesion is traversed, proper reentry into the open upper IVC or right atrium should be confirmed by venography or IVUS. Occasionally the wire passage may require predilation to allow passage of the 6 Fr IVUS catheter. Normally, the wire tract can be dilated to the desired caliber in a single pass. Stepwise dilation is not necessary as rupture/hemorrhage is very rare.[26] We recommend dilation to 24, 18, 16, and 14 mm for IVC, CIV, EIV, and CFV segments, respectively. To conserve supplies we use 18 mm balloons for all iliofemoral segments and have not encountered problems. Wallstents of corresponding size are then deployed. Small leaks and contrast extravasations are self-limiting once the low-resistance main pathway has been established by stent placement. Completion venography and IVUS planimetry are essential to ensure that a recanalized passage of adequate caliber without conduit defects has been established.

Inadequate inflow into stents is both a short-term and long-term threat to stent viability. There is presently no reliable way to assess inflow. Some stents with rapid washout of contrast have occluded, and others with sluggish flow have surprisingly remained patent. Intraoperative flow may be affected by extraneous factors, including the presence of the sheath obstructing inflow. Preoperative venographic assessments have not been reliable as more inflow channels become visible once a low-resistance channel has been established by the stent. In extreme cases in which all the major named inflow pathways have become occluded and only multiple "twiggy" collaterals provide inflow, a temporary A-V fistula may be considered.

Inferior Vena Cava Filters[19]

Because of the recent liberal use of "retrievable" IVC filters, together with low retrieval rates, an increasing number of complications are currently seen with filter use. One of the more common complications is stenosis or thrombosis of the IVC near the filter. CTO of the IVC and one or both iliac veins produces swelling and pain of the extremities, which can be quite severe. Removal of the filter before recanalization is desirable, but retrieval of a filter encased in fibrous tissue is often impossible. In such instances, the IVC filter can be crushed by balloon angioplasty and stented across using the recanalization technique described earlier (Fig. 161.9). Filters of many types (with the exception of the Mobin Uddin filter) have been successfully treated in this fashion without malsequelae.[19]

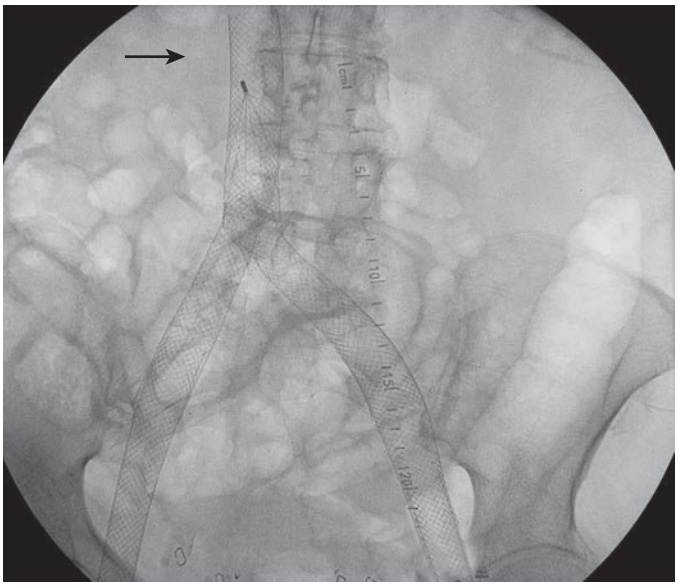

Figure 161.9 Recanalization and stenting of the inferior vena cava (IVC) and both iliac veins following thrombosis associated with an IVC filter *(arrow)* which has been compacted and stented across. Cumulative patency is excellent despite the extensive metal load.

Permanent anticoagulation is desirable after stent exclusion of the filter as thromboembolic protection is lost. Migration of the compacted filter and viscous perforations remain a potential threat in these patients, and patients should be adequately warned during informed consent discussion.

Anticoagulation

Perioperative anticoagulation is used for routine prophylaxis and because of intraoperative endothelial injury. Endothelial healing is complete by 6 weeks after injury.[27] It is believed that deployed stents are covered by pseudo endothelium or are incorporated into the vein wall within this time frame. This means thrombogenicity of the stented segments will be governed by inherent risk factors and not the presence of a stent, per se. Thrombophilia does not appear to influence long-term stent patency with proper anticoagulation.[26]

Stent anticoagulation protocols vary widely among centers. In our practice, patients receive low-molecular-weight heparin (LMWH) in prophylactic dosage before the procedure and intravenous heparin (5000 to 10,000 units) or bivalrudin (75 mg single dose) intraoperatively. Some centers use more rigorous anticoagulation using activated clotting time per cardiac protocols. Post procedure, LMWH is continued at a prophylactic dosage for 48 hours. Patients with NIVLs are discharged on aspirin 325 mg daily if there is no prior history of DVT. Stent thrombosis is extremely rare in this subset. PTS patients are discharged on aspirin as well, if the original DVT was provoked by an event that is no longer present. Long-term anticoagulation with warfarin or one of the new generation oral agents is instituted if there is thrombophilia, recurrent thrombosis, previous unprovoked thrombosis, or extensive stenting.

Reinterventions

Acute thrombosis of stents (<30 days) is rare (≈1%) and occurs almost exclusively in PTS limbs, particularly following CTO recanalizations.[20,25] Thrombolysis usually restores durable patency. In other cases, a lesion at the stent inflow is responsible, as identified by IVUS. Stent extension to cover the inflow obstruction is required in addition to thrombolysis. In our experience, late occlusions (>30 days) occur in 3.5% of stented limbs, overwhelmingly (87%) in postthrombotic limbs.[28] Both early and late occlusions in nonthrombotic disease are quite rare.[20]

Chronic Stent Malfunction[29]

Chronic stent malfunction presents with residual or recurrent symptoms. Like any bypass conduit, stent malfunction is due to problems with inflow, outflow, the conduit itself, or a combination. There are some features unique to the venous stent.[29] Inflow/outflow problems are due to either missed or new lesions obstructing stent flow. Inadequate or partial coverage of the "classic" lesion at the iliocaval confluence during the original procedure is a common problem. This can be exacerbated by downward stent migration or foreshortening of the stent by the squeezing action of the partially covered lesion. A short (<2 cm) extension into the IVC beyond the lesion can lead to coning of the upper end of the stent from compression by the nearby lesion. A small-caliber postthrombotic IVC that was missed during the original procedure is an infrequent cause of stent malfunction, usually when IVUS planimetry was not used. Small-caliber IVC is not as well appreciated on venography as it lacks an internal scale. A normal adult infrarenal IVC has a transverse diameter of 17 to 24 mm on IVUS (smaller range in women). Area planimetry is not useful as the IVC is partially collapsed in most individuals.[30]

Inflow problems can occur when the distal lesion of the MTS (see Fig. 161.1) is missed during the initial procedure. This lesion is often not visible on venography or even IVUS and requires "balloon-sizing" for detection.[18] New or missed postthrombotic lesions can occur at the common femoral vein. When a short stent is used in the common iliac vein, extending only partially or not at all into the external iliac vein, a late stenosis (denovo stenosis) of unknown cause may develop in the external iliac vein after some years.

By far the most frequent causes of chronic stent malfunction are problems associated with the stent conduit itself. There are two major types: stent compression and in-stent restenosis (ISR) (Fig. 161.10).[31] Stent compression is unique to the venous system, wherein the stent is compressed from the outside, squeezing the lumen smaller than the original deployed caliber. The outside force is focal or diffuse fibrosis/restenosis of the stented segment. Stent compression is more resistant to balloon dilation than is ISR.

In-stent restenosis occurring after iliac vein stenting is likely a different process from that affecting arterial stents. ISR that occurs early (<30 days) is probably mostly thrombus (thrombus lining/soft ISR) without cellular elements (Fig. 161.11). The thrombus lining is likely a result of sluggish flow in the now enlarged segment as the flow channel tends to modulate its caliber to correspond to the velocity of inflow. Anecdotal observation suggests that the thrombus lining may be cleared or reduced by instituting anticoagulation. It is also easily cleared at this stage by balloon maceration. After several months, this lining appears to be invested with fibrous elements (hard ISR)

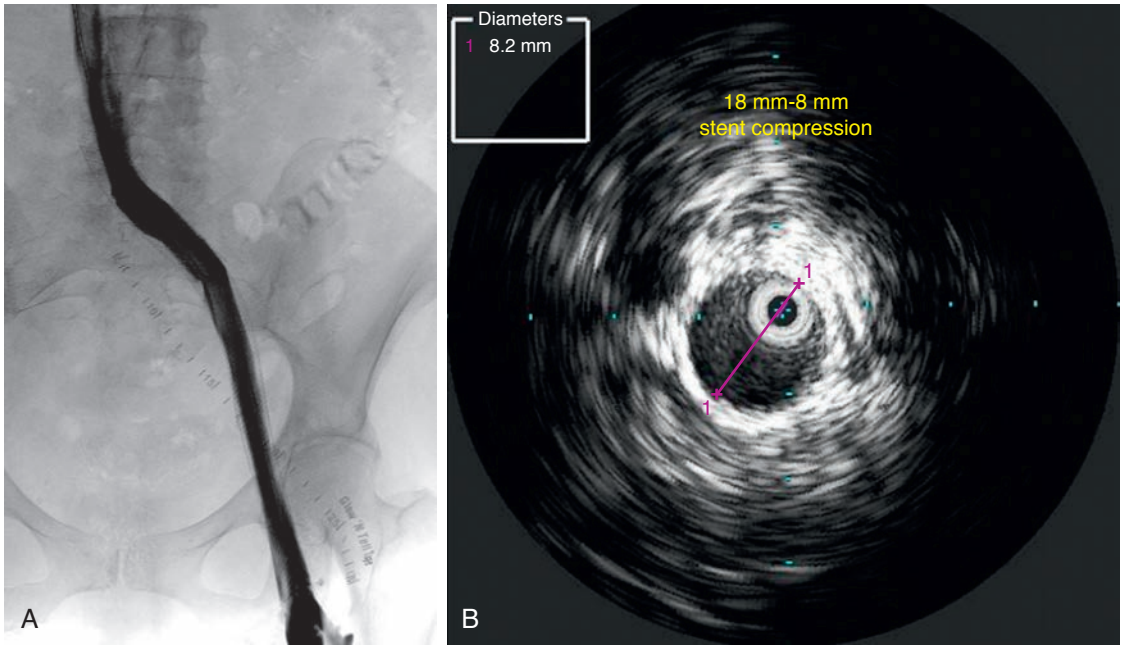

Figure 161.10 Stent compression is unique to venous stents. Compression is difficult to appreciate on venography (A). Using intravascular ultrasound, a 16-mm stent can be seen to have been compressed to 8 mm (B).

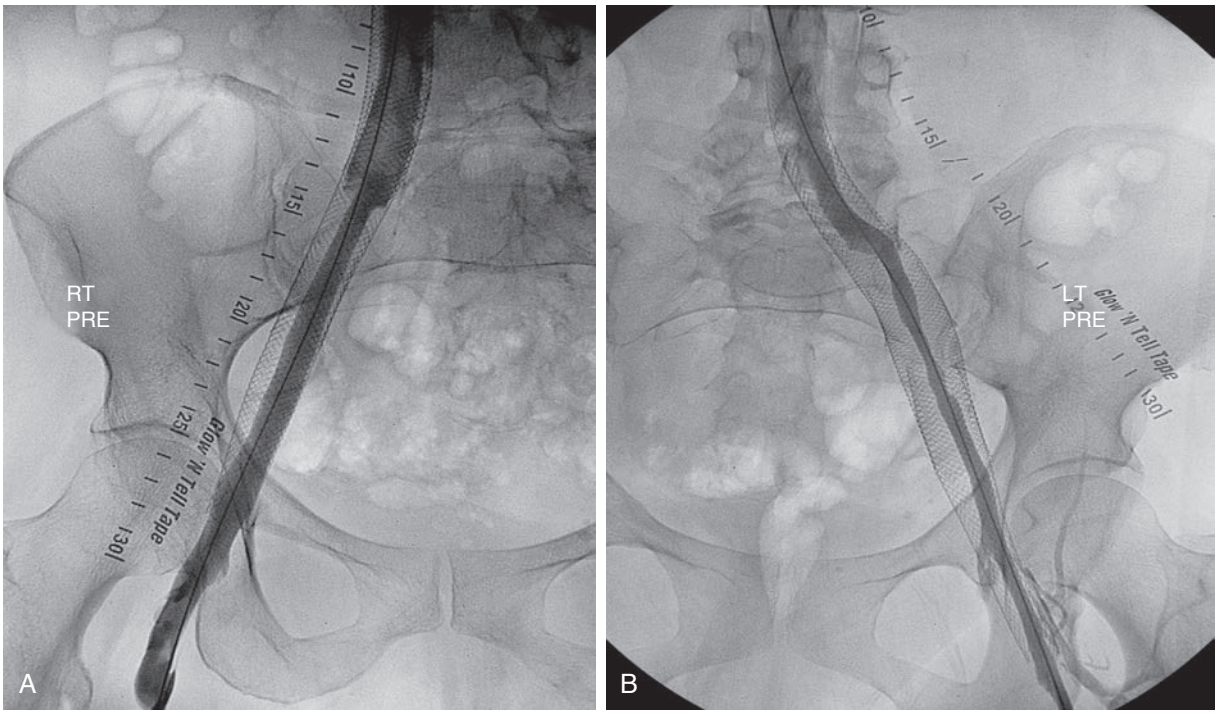

Figure 161.11 Venogram of an early in-stent restenosis (ISR) in an iliac stent (A). This likely occurs from thrombus build-up in the newly placed stent. The external iliac segment is commonly affected. Panel B shows a venogram demonstrating late ISR in a severely postthrombotic limb. The incidence and severity of ISR is higher in postthrombotic limbs and is usually of the hard variety.

and is more difficult to clear by balloon dilation. Nonetheless, the majority can be cleared using aggressive high-pressure (14 to 16 atm) balloons.

Both stent compression and hard ISR are more common in PTS limbs, particularly after CTO recanalizations.[32] Progression of hard ISR from partial to total stent occlusion appears to develop slowly over a period of years rather than in weeks or months. Most stent occlusions appear to be acute DVT events involving the stent, and differ from gradual progression of hard ISR to occlusion.[28]

Stent Surveillance

The above description of stent malfunction makes it clear that routine stent surveillance protocols will improve outcomes. Our practice is duplex screening of the stent the day after placement, followed by another ultrasound 4 to 6 weeks later to assess for acute stent occlusions and early thrombus lining (soft ISR). Later duplex surveillance intervals vary depending upon the original pathology. Lesions resulting from MTS are considered at low risk for occlusion and can be surveilled at 3- to 6-month intervals during the first year and less frequently thereafter. PTS lesions are more susceptible to stent malfunction and require quarterly surveillance during the first year and at least every 6 months thereafter. CTO recanalizations require even more intensive surveillance during the first year.

If symptoms fail to resolve or new symptoms develop, surveillance frequency should be modulated accordingly. Stent surveillance tends to promote follow-up continuity and probably reduces the number of patients "lost to follow-up." The timing of reintervention in these cases of stent malfunction is based primarily on residual/recurrent symptoms except in rare instances in which stent occlusion appears to be imminent. We place patients with hard ISR on cilostazol and optionally on prophylactic or therapeutic anticoagulation. The efficacy of these agents in venous stenting is undetermined.

OUTCOMES

Morbidity and Mortality

Endovenous correction of iliac and caval venous pathology can be done with minimal morbidity and mortality. In one large series of 982 stented limbs, access complications occurred in 0.4% despite the use of deep access sites. No procedure-related mortality occurred (30 days). DVT incidence was 3% over the 22 months of mean follow-up.[20] A recent review of worldwide experience found femoroiliocaval stenting to be a safe and effective procedure with low morbidity across multiple procedures, including recanalization for chronic total venous occlusions (Tables 161.2 and 161.3).[26]

Patency

Stent patency varies depending on underlying pathology. NIVL have excellent stent patency with very few failures compared to stenting carried out for postthrombotic (PTS) lesions. Stent placement for the correction of stenosis has better secondary

TABLE 161.2 Patencies and Procedural Complications Following Iliocaval Stenting

First Author, Year	Case Mix: n (%)	CUMULATIVE PATENCY			Procedure Complications—n (%)

patency than do those performed for CTO. Neglen et al. noted primary and secondary cumulative stent patency of 79% and 100% for NIVL limbs, and 57% and 86%, respectively, for PTS limbs at the 6-year follow-up (Fig. 161.12). For CTO recanalization of iliocaval segments, cumulative primary and secondary patencies were 54% and 74%, respectively, at 48 months.[20] Murphy and colleagues from the same institution recently reported results of recanalization of CTO lesions involving the IVC and one or both iliac veins in 71 patients; primary and secondary patencies were 52% and 93%, respectively, at 60 months.[19] Worldwide results generally parallel these surprisingly good secondary stent patency rates for treatment of stenosis as well as CTO recanalization, as shown in Table 161.2. The lower primary patency reflects the need for re-interventional correction in postthrombotic limbs to maintain performance.

Clinical Results

Clinical results generally mirror the excellent patency of iliac vein stents (see Table 161.3). Results reported by Neglen et al. are broadly representative. Cumulative rates of complete relief of pain and swelling were 65% and 32% with significant improvement (VAS ≥3; swelling ≥1 Gr.) seen in 74% and 62%, respectively, at 5 years. Surprisingly, clinical results after iliac vein stenting appear to be good even if co-existing reflux is left uncorrected.[8] Recently, Raju and colleagues evaluated ulcer healing with iliac vein stenting in 192 limbs with and without reflux. The overall cumulative ulcer healing rate was 75% at 5 years (Fig. 161.13). Healing was better in limbs with NIVL (87%) compared to thrombotic limbs (66%). Ulcers <1 inch diameter had better healing rates than those with >1 inch diameter. Interestingly, the presence of axial deep reflux did not necessarily affect healing. However, limbs with reflux segment scores ≥3 had lower cumulative ulcer healing compared to limbs with reflux segment scores <3.[18]

Geriatric Group

Iliac vein stenting is a safe and effective option in the elderly (>80 years).[33] Many elderly patients are unable to apply compression because of frailty or arthritis. Ulceration or recurrent cellulitis requires frequent hospitalizations, often ending in institutionalization. On the other hand, percutaneous stent

TABLE 161.3 Clinical Outcomes and Complications Following Iliocaval Stenting

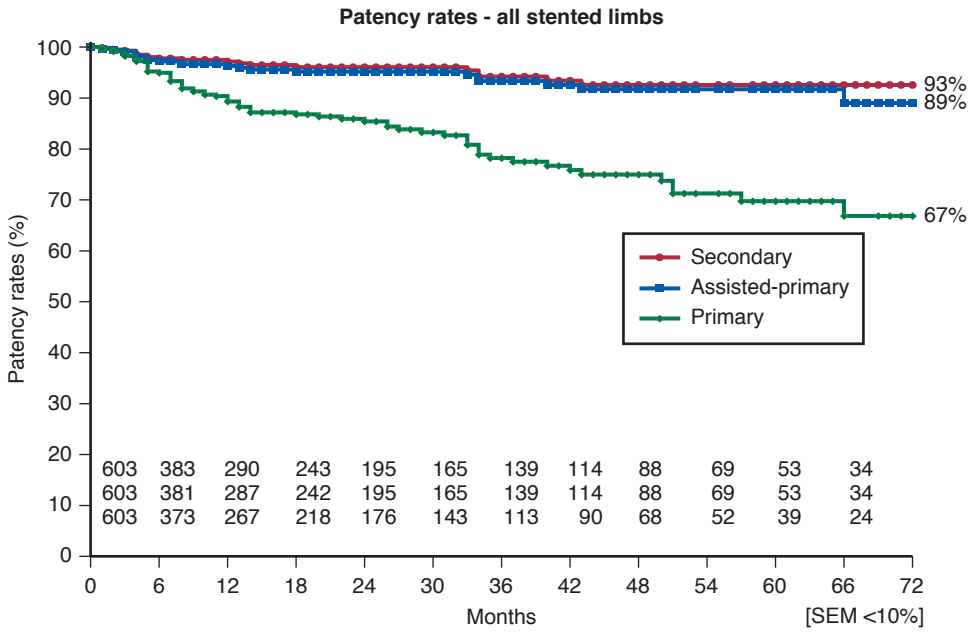

Figure 161.12 Cumulative patency rates of iliac vein stents (thrombotic and nonthrombotic limbs). All of the stent occlusions occurred in postthrombotic limbs and none in nonthrombotic limbs (NIVL) in this series. The secondary patency of NIVL in this series was a remarkable 100% (curve not shown). (From Neglen P, Hollis KC, Olivier J, Raju S. Stenting of the venous outflow in chronic venous disease: long-term stent-related outcome, clinical, and hemodynamic result. *J Vasc Surg*. 2007;46:979-990.)

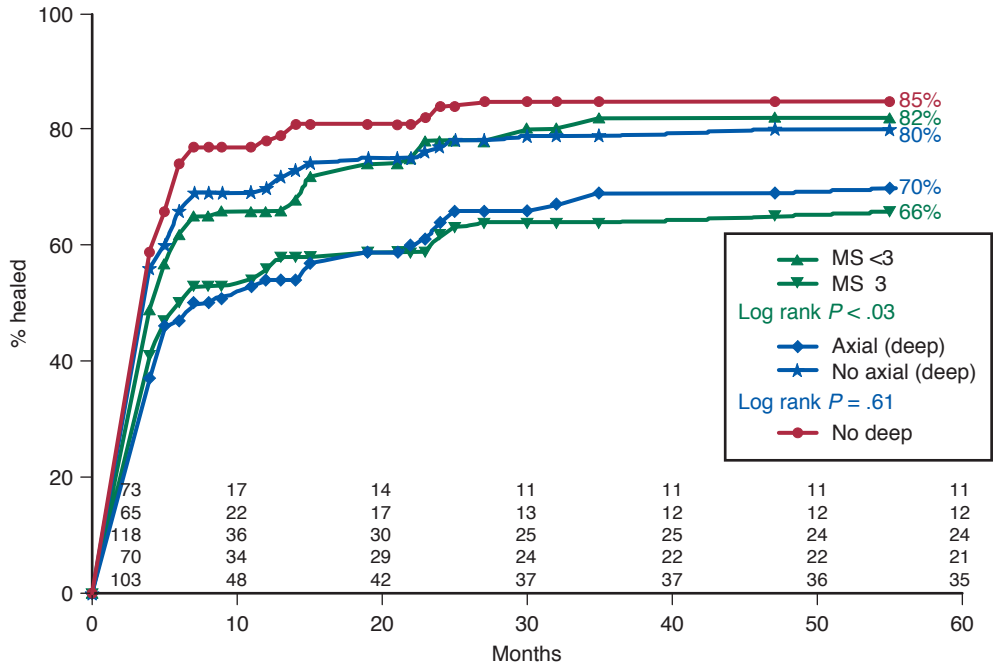

Figure 161.13 Cumulative Ulcer Healing in Limbs With and Without Deep Reflux. Note stable curve (few recurrences) after initial healing. There is no difference between limbs with and without axial reflux *(blue)*. Cumulative healing *(green)* was lower ($P < .03$) in limbs with three or more refluxing deep segments compared to those with less than 3 refluxing deep segments. The *red curve* represents limbs with isolated saphenous reflux treated by ablation. (From Raju S, Kirk OK, Jones TL. Endovenous management of venous leg ulcers. *J Vasc Surg Venous Lymphat Disord.* 2013;1:165-173.)

placement is relatively well tolerated. In a report of iliac vein stenting in 107 limbs in patients over the age of 80, there was no mortality; there was significant improvement of pain and swelling in 73% and 63%, respectively, at 6 years (cumulative data). Complete relief of pain and swelling was observed in 43% and 25%, respectively. This study also noted relief from recurrent cellulitis in 70% of limbs, and 61% (cumulative) of ulcers healed at 6 years. Stockings were able to be discarded in 31% of patients.[33]

Obese Patients

Iliocaval stenting has demonstrated benefit in CVD patients with a body mass index (BMI) >30. The incidence of bilateral CVD has been noted to be double in this subset in comparison to patients with BMI <30 (28% vs. 14%; $P < .01$).[34] Most have NIVL or PTS pathology, but venous compression can be caused by increased intra-abdominal pressure from obesity.[35] Stenting in this group has been performed with good patency (86% secondary patency at 66 months). The clinical relief of pain, plus swelling and ulcer healing, is similar to nonobese patients.[34] The main treatment choice in these patients remains bariatric surgery; venous stenting can be considered if it is declined for medical or other reasons.

Lymphedema

Secondary "venous lymphedema" can be seen in 16% to 30% of patients with CVD.[12,13] Careful attention must be paid to the diagnosis of obstructive venous lesions in this group as they may benefit from stent correction. Patients with secondary venous lymphedema have been noted to experience pain relief poststenting in a manner similar to their counterparts without lymphedema (83% vs. 87% at 40 months follow-up; P = .03). Relief of swelling is somewhat less and occurs in 45% of limbs with lymphedema compared to 66% of limbs without ($P < .01$).[13]

Iliac Vein Stenosis With Tandem Femoral Vein Occlusions

Femoral vein occlusions are easily detected in CVD patients complaining of leg symptoms. The lesion often becomes the focus in contemplating treatment. Less obvious are associated iliac vein lesions that are not as easily detected. The occult iliac stenosis is often more severe, as recanalization/collateralization in femoral occlusions is often satisfactory.[36] IVUS examination and iliac vein stenting may be considered in symptomatic limbs with tandem lesions. Good clinical relief has been reported with this approach.[37]

Thrombosed Inferior Vena Cava Filter

Murphy and colleagues reported on their experience with stent recanalization of IVC CTO with occluded IVC filters with a mean follow-up of 4 years. There was no mortality or filter-related complications. Cumulative patency of the IVC stent ($n = 34$) was 86% at 5 years, with good clinical relief (Fig. 161.14).[19]

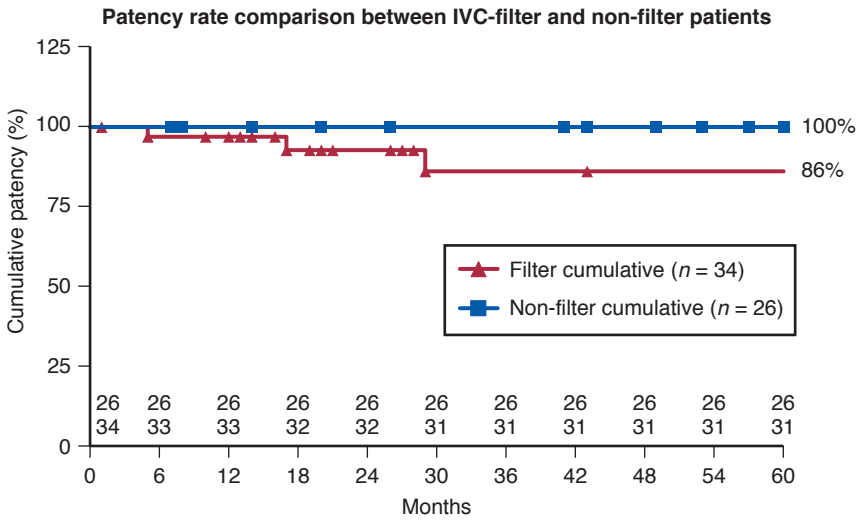

Figure 161.14 Cumulative patency of stent recanalization of inferior vena cava chronic total occlusions (IVC CTO) with (n = 36) and without (n = 24) thrombosed filter. There is no difference in patency between the two subsets. Three limbs in which iliac vein stents occluded on one side with IVC patency maintained by the remaining iliac vein stent are counted as patent. (From Murphy EH, Johns B, Varney E, Raju S. Endovascular management of chronic total occlusions of the inferior vena cava and iliac veins. *J Vasc Surg Venous Lymphat Disord*. 2017;5:47-59.)

CONCLUSIONS 2144

In the United States each year about 15,000 patients develop symptoms of venous congestion of the head and neck due to occlusion of the superior vena cava (SVC) or innominate veins.[1] SVC syndrome is caused by malignant tumors of the lung and mediastinum in 60% of the cases.[2] The most frequent nonmalignant causes include placement of intravenous catheters, pacemaker wires, or mediastinal fibrosis.

Treatment for SVC syndrome involves creating outflow for the congested veins in the head and neck. Both endovascular and open surgical techniques are possible. Endovascular treatment for both acute and chronic SVC occlusion has become the first line of treatment for most patients because it is less invasive, and patients recover more quickly than following open surgery. Treatment in patients with advanced malignancy is frequently palliative, but for those with benign disease it is usually curative. Few areas of venous disease provide a more satisfying experience for both the patient and the vascular specialist. Relief from severe, frequently incapacitating symptoms of venous congestion of the head and neck is almost instantaneous, and benefit is generally long lasting. In this chapter, we review the etiology, clinical presentation, and diagnostic evaluation of SVC syndrome, and present techniques and results for its treatment with endovascular and open surgical methods.

ETIOLOGY

The first case of SVC obstruction described by William Hunter in 1757 was due to an aortic aneurysm. Aortic aneurysms

Abstract

Few areas of venous disease provide a more satisfying experience for both the patient and the vascular specialist than intervention for superior vena cava (SVC) syndrome. Relief from severe, frequently incapacitating symptoms of venous congestion of the head and neck is almost instantaneous, and benefit after reconstruction is generally long lasting. In this chapter, we review the etiology, clinical presentation, diagnosis, technique of endovascular/ open surgical treatment and outcomes of management of patients with SVC syndrome.

Keywords

Superior vena cava syndrome
Benign SVC thrombosis
Small-cell lung cancer

remained the second most common cause of SVC syndrome after primary malignant thoracic tumors until the mid-1900s. Infectious causes such as tuberculous and syphilitic mediastinitis also decreased markedly early in the 20th century. Lung cancer with mediastinal lymphadenopathy and primary mediastinal malignancy have become the most frequent causes of malignant SVC syndrome in the past three decades, constituting approximately 60% of cases.[2–4] Of these cases, nonsmall cell lung cancer is the cause in 50%, followed by small cell lung cancer (22%), lymphoma (12%), metastatic cancer (9%), germ cell cancer (3%), and thymoma (2%).[1] Other mediastinal malignant tumors leading to SVC syndrome include medullary or follicular carcinoma of the thyroid, teratoma, angiosarcoma, and synovial cell carcinoma.[1–5]

Benign disease is the cause of SVC syndrome in 40% of cases. Mediastinal fibrosis and granulomatous fungal disease, such as histoplasmosis, were formerly the most frequent benign causes. However, indwelling central venous catheters and cardiac pacemakers are now the most common benign cause.[6–14] Over 5 million central venous catheters and 170,000 pacemakers are now implanted annually in the United States and are associated with upper extremity or central deep venous thrombosis (DVT) in 7% to 33% of patients. SVC syndrome reportedly occurs in 1% to 3% of patients with central venous catheters and 0.2% to 3.3% of patients with implanted pacemakers.[2] Previous radiotherapy to the mediastinum, retrosternal goiter, and aortic dissection can also cause SVC syndrome. The risk of venous thrombosis is increased in patients with thrombophilia such as factor V Leiden mutation and deficiencies in circulating natural anticoagulants, such as antithrombin III, protein S, and protein C.

CLINICAL PRESENTATION

Signs and symptoms of venous congestion of the head, neck, and upper extremities are determined by the duration and extent of venous occlusive disease and the amount of collateral venous circulation that develops. Patients with SVC syndrome present with a feeling of fullness in the head and neck that is exacerbated when the patient bends over or lies flat in bed. The severity of disease can be graded by the number of pillows needed by the patient to sleep comfortably. Other symptoms include dyspnea on exertion, orthopnea, headache, dizziness, syncope, visual changes, confusion, and cough (Table 162.1).[1,15,16] Dilated neck veins and swelling of the face, neck, and eyelids are the physical signs most commonly seen (Fig. 162.1). Prominent chest wall collateral veins and ecchymosis and cyanosis of the face can occur. Although symptoms are usually localized to the head and neck, mild to moderate upper extremity swelling may also develop. In cases of malignant SVC syndrome, hemoptysis, hoarseness, dysphagia, weight loss, lethargy, and palpable cervical tumor or lymph nodes may be present. Patients with lymphoma may also present with fever and night sweats. In patients with end-stage renal disease (ESRD), asymptomatic SVC occlusion may be unmasked upon creation of an arteriovenous fistula (AVF), with rapid development of arm swelling and neck engorgement.

TABLE 162.1 Signs and Symptoms of Superior Vena Cava Syndrome of Benign Etiology in 70 Patients

	Number of Patients	%
Symptoms		
Feeling of fullness in head or neck	61	87
Dyspnea on exertion or orthopnea	39	56
Headache	27	39
Dizziness or syncope	25	36
Visual problems	11	25
Cough	10	22
Nocturnal oxygen requirement	3	16
Protein losing enteropathy	1	2
Head and neck swelling	65	93
Large chest wall venous collaterals	40	57
Facial cyanosis	24	34
Arm swelling	23	33
Pleural effusion	2	3

DIAGNOSTIC EVALUATION

The diagnosis of SVC obstruction is usually suggested by a detailed history and physical examination. The diagnosis may be confirmed by a variety of tools, including plain radiographs, ultrasonography, computed tomography (CT), venography, and magnetic resonance imaging (MRI). The appropriate diagnostic study for an individual patient includes not only the demonstration of the underlying cause, but also the site and extent of obstruction as well as the routes of collateral venous circulation.

Radiography

Plain film radiographs of the chest are readily available and often abnormal in patients with SVC obstruction. Most common findings include mediastinal widening, right hilar mass, pleural effusion, bilateral diffuse infiltrates, and upper lobe collapse. However, a normal radiograph of the chest does not preclude the diagnosis of SVC obstruction.[1,3,17] Occasionally, dilated collateral veins may be visible, especially enlargement of the azygos vein or superior intercostal vein (aortic nipple) draining the hemiazygos system. In more than 90% of patients a diagnosis of SVC syndrome can be made on the basis of clinical presentation and plain chest radiograph.[16]

Ultrasonography

Duplex ultrasound (DUS) evaluation is an effective, noninvasive screening technique in the patient with suspected SVC obstruction. Although direct visualization of the SVC is not possible

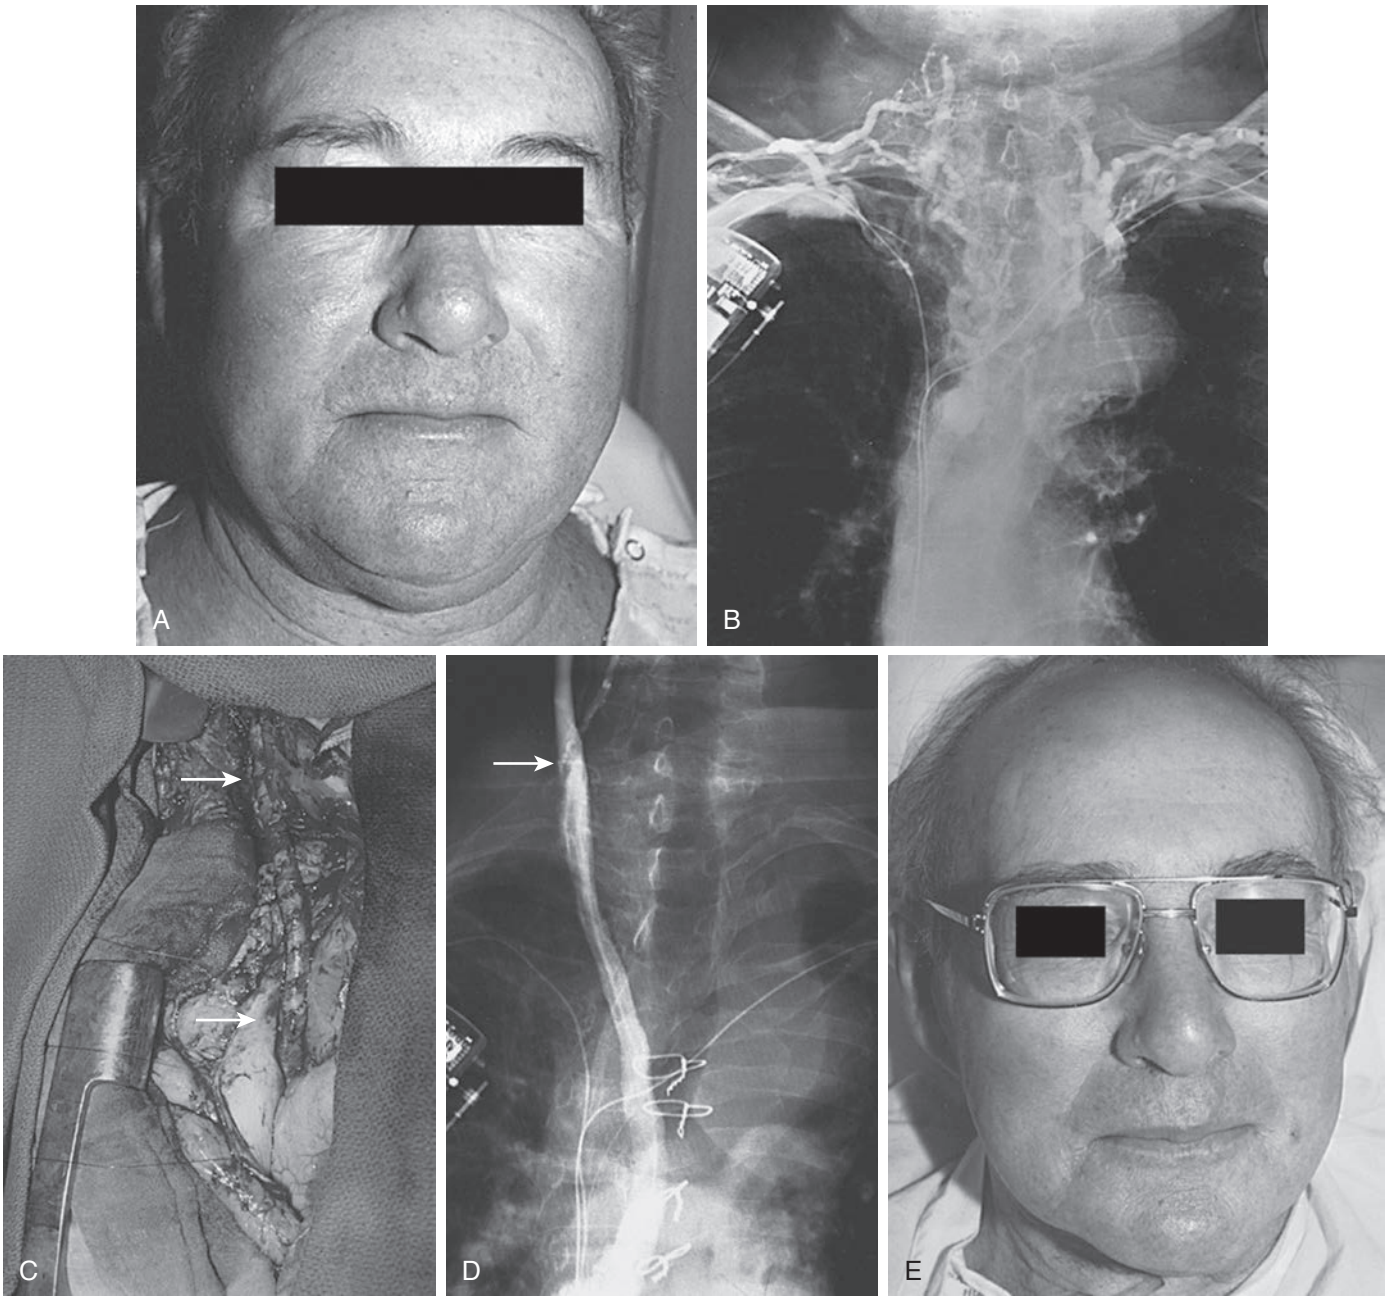

Figure 162.1 (A) Severe symptomatic superior vena cava (SVC) syndrome in a 69-year-old man. (B) Bilateral upper extremity venogram confirms thrombosis of the SVC and both innominate veins following placements of pacemaker lines bilaterally. (E) Photograph of the patient 5 days after spiral vein graft placement. The clinical result is excellent 8 years after the operation. (From Gloviczki P, Bower TC, McKusick M, Pairolero PC. Superior vena cava syndrome: endovascular and direct surgical treatment. In: Gloviczki P, Yao YST, eds. *Handbook of Venous Disorders*, London: Chapman & Hall; 1996:580–599.)

with transthoracic DUS, valuable information can be obtained. The subclavian and internal jugular veins are accessible to sonographic evaluation and can provide indirect evidence of SVC patency or obstruction. In the presence of SVC obstruction the normal respiratory flow variation caused by changes in intrathoracic pressure seen in patent subclavian veins is lost. This can be demonstrated by reduced or unchanged diameter and blood flow through the subclavian veins in response to respiratory maneuvers such as a sudden sniff or a Valsalva maneuver. Collateral vessels can be detected within the chest wall or in the mediastinum.

Radionuclide Imaging

Radionuclide venography has been used in the diagnosis of SVC syndrome. A technetium 99m pertechnetate scan (^{99m}Tc),

performed with bilateral simultaneous injection of the radionuclide tracer into the arm veins, can not only demonstrate the presence of SVC obstruction and associated collateral pathways but also provide functional aspects of the SVC obstruction using time–density curves. An advantage is the potential usefulness as a follow-up examination in determining therapeutic response.[18] The disadvantage of radionuclide venography is the lower-resolution anatomic detail and the inability to determine the cause of the SVC obstruction.

Computed Tomographic Angiography

Computed tomographic angiography (CTA) accurately depicts the location and extent of obstruction and can usually distinguish benign from malignant mediastinal disease.[19–22] Any mass or tumor is easily identified, and the central lines or pacemaker wires are well seen. CTA will also identify the collateral pathways, including the (1) azygos-hemiazygos pathway, (2) internal mammary pathway, (3) lateral thoracic-thoracoepigastric pathway, and (4) vertebral pathway and small mediastinal veins. Less commonly, unusual shunts, including hepatic parenchyma (an intense focal enhancement in the medial segment of the left lobe of the liver) and pulmonary pathways are identified on CTA.[23,24]

Contrast Venography

Venography has been considered the "gold standard" for accurate depiction of central venous obstruction and is used as an anatomic roadmap before reconstructive surgery. Venography also depicts the presence and direction of venous collateral flow. It is performed by simultaneous injection of contrast material in bilateral superficial arm veins. Stanford and Doty[25] described four venographic patterns of SVC syndrome, each having a different venous collateral network depending on the site and extent of SVC obstruction (Fig. 162.2). Type I is partial; type II is complete or near-complete SVC obstruction with antegrade flow in the azygos vein; type III is 90% to 100% SVC obstruction with reversed azygos blood flow; and type IV is extensive mediastinal central venous occlusion with venous return occurring through the inferior vena cava (see Fig. 162.2).

It is important to remember that during upper extremity venography only veins and collateral pathways between the injection site and right atrium are visualized; the internal jugular veins frequently used as inflow for a surgical bypass are not visualized.

Magnetic Resonance Venography

The advantages of magnetic resonance venography (MRV) include the ability to demonstrate anatomic structures in multiple planes and to delineate the central venous chest veins and collateral vessels. MRV is a relatively noninvasive modality and does not require the administration of iodinated contrast material. The disadvantage is its contraindication in patients with pacemakers and aneurysm clips. Recent problems using gadolinium in patients with renal insufficiency have also significantly decreased the utility of MRV.

INITIAL TREATMENTS

Conservative measures are used first in every patient to relieve symptoms of venous congestion and to decrease progression of venous thrombosis. These measures include elevation of the head during the night on pillows, modifications of daily activities by avoiding bending over, and avoidance of wearing constricting garments or a tight collar. Patients frequently need diuretic agents, at least temporarily, to decrease excessive edema of the neck and head.

Patients with acute SVC syndrome caused by malignant disease are generally treated with intravenous unfractionated or low-molecular-weight heparin, followed by long-term anticoagulation, to prevent recurrence and protect the collateral venous circulation. Thrombolytic treatment is considered in most patients with benign acute SVC syndrome, whereas those with chronic or malignant disease are candidates for treatment by endovascular stents, with or without thrombolytic treatment.

Symptoms of SVC syndrome caused by mediastinal malignancy frequently improve after irradiation, chemotherapy, or combination chemoradiation based on tumor histology.[1] Chen et al. treated 42 patients with malignant SVC syndrome using external beam radiotherapy and/or chemotherapy.[4] Symptoms of SVC syndrome resolved in 80% of the patients who underwent radiotherapy, with a mean interval of 4 weeks.[26] Similar benefits of radiation or chemotherapy have been noted by others as well.[27,28] Since external compression by the tumor is the usual mechanism of caval occlusion in these patients, endovascular treatment using stents, as discussed later, is the best technique to alleviate symptoms. A systematic Cochrane review by Rowell et al. evaluated 2 randomized and 44 nonrandomized studies addressing the treatment of SVC syndrome in patients with bronchial malignancy. Chemotherapy and/or radiotherapy relieved symptoms of SVC occlusion in 77% and 60% patients with small cell and nonsmall cell lung cancer, respectively. Endovascular treatment with stenting, however, relieved symptoms in 95% patients and much more rapidly.[28]

INDICATIONS FOR INTERVENTIONAL TREATMENT

The severe, incapacitating symptoms of SVC syndrome are frequently not alleviated by conservative measures. Up to one-fourth of malignant cases are resistant to radiochemotherapy, and even in cases where improvement occurs, symptomatic relief can require up to 3 weeks.[28] Further treatment options include endovenous or surgical intervention, depending upon the etiology and anatomy of the SVC lesion.

Endovenous treatment is considered the first choice for patients with malignant SVC obstruction because of the limited life expectancy. Surgical reconstruction should be contemplated only when the tumor is resectable, and life expectancy is greater than 1 year. Candidates for surgical reconstruction include those with lymphoma, thymoma, or metastatic medullary carcinoma of the thyroid gland.[29–34] In cases where endovascular treatment is not possible and major surgery is not indicated, extra-anatomic

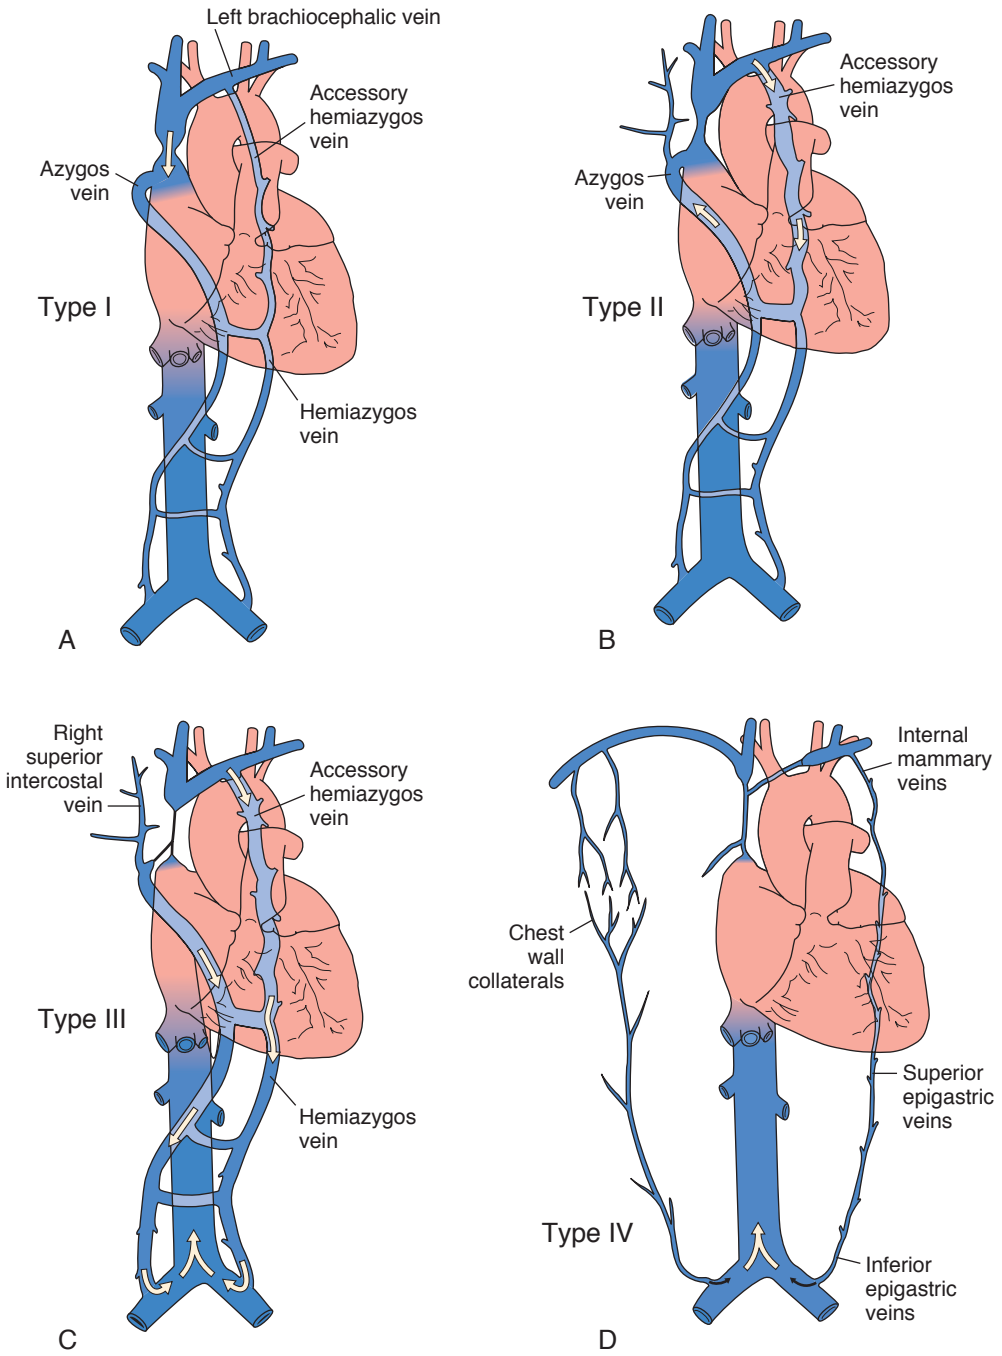

Figure 162.2 Venographic classification of superior vena cava (SVC) syndrome according to Stanford and Doty. (A) *Type I,* High-grade SVC stenosis with normal direction of blood flow, but still normal direction of blood flow through the SVC and azygos veins. Increased collateral circulation through hemiazygos and accessory hemiazygos veins. (B) *Type II,* Greater than 90% stenosis or occlusion of the SVC, but patent azygos vein with normal direction of blood flow. (C) *Type III,* Occlusion of the SVC with retrograde flow in both the azygos and hemiazygos veins. (D) *Type IV,* Extensive occlusion of the SVC and innominate and azygos veins with chest wall and epigastric venous collaterals. (From Alimi YS, Gloviczki P, Vrtiska TJ, et al. 1998; Reconstruction of the superior vena cava: the benefits of postoperative surveillance and secondary endovascular interventions. *J Vasc Surg.* 27:298–99.)

subcutaneous bypass between the jugular vein and the femoral vein using a composite saphenous vein graft is an alternative.[35,36]

In the past, patients with benign disease were treated with surgical replacement/bypass of the occluded SVC because of their longer life expectancy and the need for a durable reconstruction. However, as expertise and techniques have improved, most patients with benign SVC syndrome are considered for endovenous treatment first.[15,37–44] Surgical reconstruction is reserved for patients with extensive chronic venous thrombosis not anatomically suitable for endovascular treatment, and those with less extensive disease who have not benefited from endovascular attempts. Our group has performed reconstruction of

the SVC for obstruction caused by granulomatous and idiopathic mediastinal fibrosis, central venous catheters, pacemaker electrodes, or ventriculoatrial shunt and in patients with antithrombin deficiency or idiopathic venous thrombosis.[7,8,45,46] The indications for reconstruction in patients with benign disease were similar in the reports by Doty et al.[6] and Moore and Hollier.[47]

ENDOVENOUS TREATMENT

The first percutaneous angioplasty for an SVC lesion in an adult was performed in 1986 by Sherry. The lesion was caused by a pacemaker wire.[37] Since then there has been tremendous progress in the endovenous treatment of SVC syndrome, with increasing technical and clinical success. Endovenous treatment provides patients with rapid symptomatic relief; however, long-term results of stents placed in young patients for benign lesions are still not well known, and rethrombosis or intimal hyperplasia can be significant. In spite of this, many clinicians now consider endovenous procedures first line treatment in benign as well as malignant cases.[15,28]

Endovenous treatment includes percutaneous transluminal balloon angioplasty (PTA), stenting, and thrombolysis performed alone or in combination. Following early interventions with angioplasty alone, it became evident that this often resulted in early restenosis due to the elastic/fibrotic nature of many SVC lesions, with or without external compression from mediastinal masses. The earliest stents deployed were Gianturco Z stents, self-expanding stents with hooks for fixation to prevent migration. They are easy to place, rigid, and do not shorten with deployment. The large stent interstices, however, are worrisome for allowing tumor ingrowth. Palmaz (Cordis Corporation, Miami, Florida) balloon expandable stents are ideally suited for short, focal fibrotic/compressive lesions because of their precise deployment and good radial force. Disadvantages include poor flexibility and availability only in short lengths (Fig. 162.3). In recent years, other self-expanding stents such as Wallstents (Boston Scientific Corp., Natick, Massachusetts), Smart stents (Cordis Endovascular, Warren, New Jersey), Protégé stents (ev3, Plymouth, Minnesota), E*Luminexx (Bard GmbH/Angiomed, Karlsruhe, Germany), Sinus-XL (OptiMed Medizinische Instrumente GmbH, Ettlingen, Germany), and Zilver Vena (Cook Medical Inc., Bloomington, Indianapolis) have been used more frequently for longer SVC stenoses because of flexibility and availability in multiple sizes. Occasional reports of covered stents are also available. Covered stents are effective to prevent ongoing hemorrhage if a patent vein is perforated during the procedure, and potentially to control tumor ingrowth. Some evidence suggests they require fewer reinterventions compared to bare metal stents,[48,49] and we have used them in selected cases for this reason (unpublished data). Thrombolysis may be performed alone for acute SVC thrombosis related to indwelling catheters or prior to angioplasty/stenting to lyse the thrombus and reveal underlying stenotic lesions for definitive treatment.

The technique of endovenous repair involves ultrasound-guided percutaneous venous access of the common femoral vein and placement of 6 to 10 Fr sheaths, followed by crossing

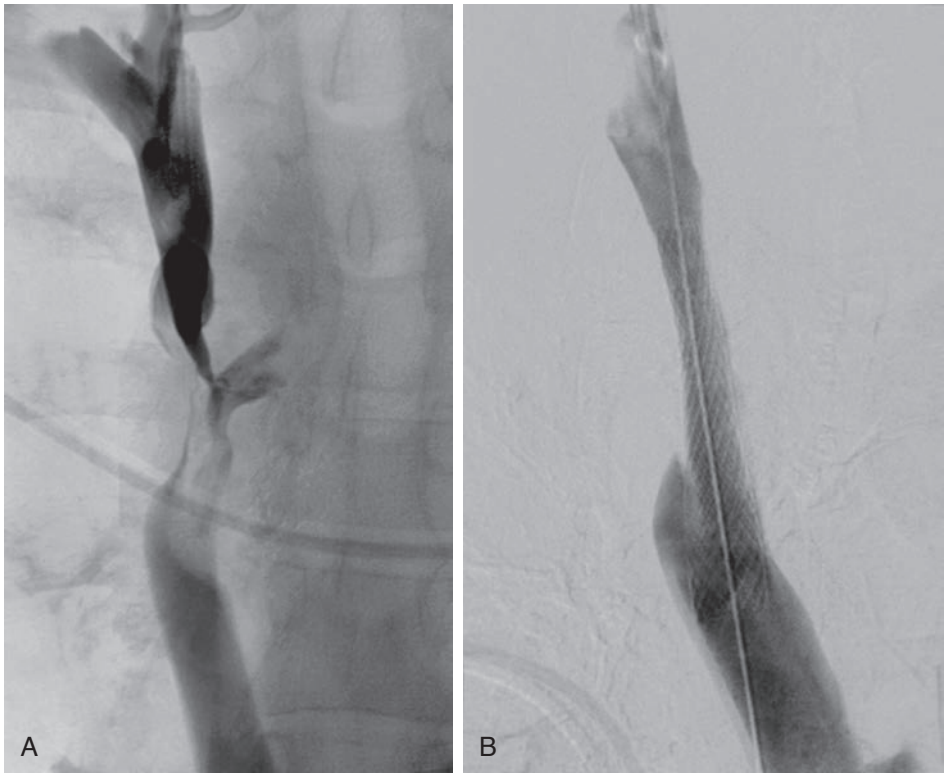

Figure 162.3 (A) Venogram showing type II superior vena cava obstruction due to mediastinal fibrosis in a 31-year-old man. Successful placement of a Palmaz stent resulted in immediate resolution of symptoms. (B) The patient has since undergone balloon dilation for in-stent stenosis 11 months later and remains asymptomatic.

the stenotic/occlusive lesion with hydrophilic guidewires and catheters. The right internal jugular or an arm vein can be an alternate or additional venous access site in patients with short focal lesions or if the lesion cannot be crossed from the femoral approach. Access of a hemodialysis AVF, if present, is also an option. Long sheaths extending to the site of occlusion can be helpful in providing the necessary support to cross the lesion. The PowerWire Radiofrequency Guidewire (Baylis Medical Company Inc., Montreal, Canada) has been reported to be useful in crossing thrombosed vessels.[50] Once wire access across the lesion is obtained, the hydrophilic wire can be exchanged for a stiff Amplatz wire (Boston Scientific) or a Lunderquist wire (Cook Medical Inc.), which is then used for PTA and/or stenting.

Primary PTA using 10 to 16 mm angioplasty balloons is performed followed by stenting. Venous stenoses can be very resistant, often requiring angioplasty with high-pressure balloons. The choice of stent is tailored to the etiology, degree, length, and tortuosity of the SVC stenosis, and more than one stent may be needed. Poststenting balloon dilation is performed when a self-expanding stent or a stent-graft is deployed (Fig. 162.4). When the confluence of the right and left brachiocephalic veins is involved in the primary lesion, or becomes so after caudal extension of stents within the SVC due to repeated stenoses, double barrel or parallel stents can be placed (see Fig. 162.4). Perforation can occur during the stenting process and if minor, manifesting as a small perivenous blush without hemodynamic changes, can be managed successfully with prolonged balloon inflation. Placement of a covered stent is required to control larger, more significant perforations, especially if associated with hemodynamic instability.[51] Rarely, SVC rupture can result in pericardial tamponade. Rapid diagnosis and immediate ultrasound guided pericardial drainage is necessary.[51]

Systemic anticoagulation with intravenous heparin (5000 U/kg) is given prior to any catheter-based intervention. Thrombolysis may be performed alone for acute nonmalignant SVC thrombosis related to indwelling catheters or prior to angioplasty/stenting to remove the thrombus and unmask the underlying stenotic lesion for definitive treatment. The original agents used for thrombolysis (streptokinase and urokinase[52,53]) have been replaced with recombinant tissue plasminogen activator (t-PA), which is utilized by us almost exclusively.[54]

If thrombolysis is determined to be appropriate prior to PTA or stenting, a suitable length catheter with side holes is placed across the lesion for catheter-directed lytic therapy. Successful catheter-directed thrombolysis with or without pharmacomechanical thrombectomy has been reported in catheter related thromboses and in malignant SVC occlusions. However, chronic occlusion with established collaterals in malignant SVC obstruction does not usually respond to lysis.[55]

Oral anticoagulation and/or antiplatelet therapy are routinely prescribed after SVC stenting for a minimum of 6 months. The need for postprocedure anticoagulation is individualized based on the cause of SVC syndrome. The majority of patients, especially those with malignancy and catheter related thrombosis, receive oral anticoagulation for at least several months until the stent is lined with pseudointima and the risk of rethrombosis decreases. Patients with mediastinal fibrosis are often treated with antiplatelet therapy alone. Both rethrombosis following cessation of anticoagulation as well as excellent results without anticoagulation have been reported.[56,57]

Figure 162.4 (A) Bilateral self-expanding kissing stents placement. (B) Poststenting balloon dilation.

SURGICAL TREATMENT

Graft Materials

Grafting of large veins has traditionally been difficult, because large-diameter autologous vein is not available to use as conduit.

Great Saphenous Vein Graft

The great saphenous vein is usually not suitable for direct reconstruction because of poor size match. However, extra-anatomic reconstruction performed by connecting the external or internal jugular vein to the ipsilateral common femoral vein, using both great saphenous veins sutured together in an end-to-end fashion and tunneled subcutaneously, has been reported by several authors with good results.[35] To prevent external compression, Panneton et al. placed the composite saphenous vein graft from the right internal jugular to the femoral vein inside an externally supported expanded polytetrafluoroethylene (ePTFE) graft.[58]

Femoral Vein Graft

The femoral vein, or the femoropopliteal vein, is a good conduit to reconstruct the SVC. It has been used with success because of its excellent suitability in terms of size and length (Fig. 162.5).[8,15] However, if the patient has underlying thrombotic abnormalities, removal of a deep leg vein may result in lower

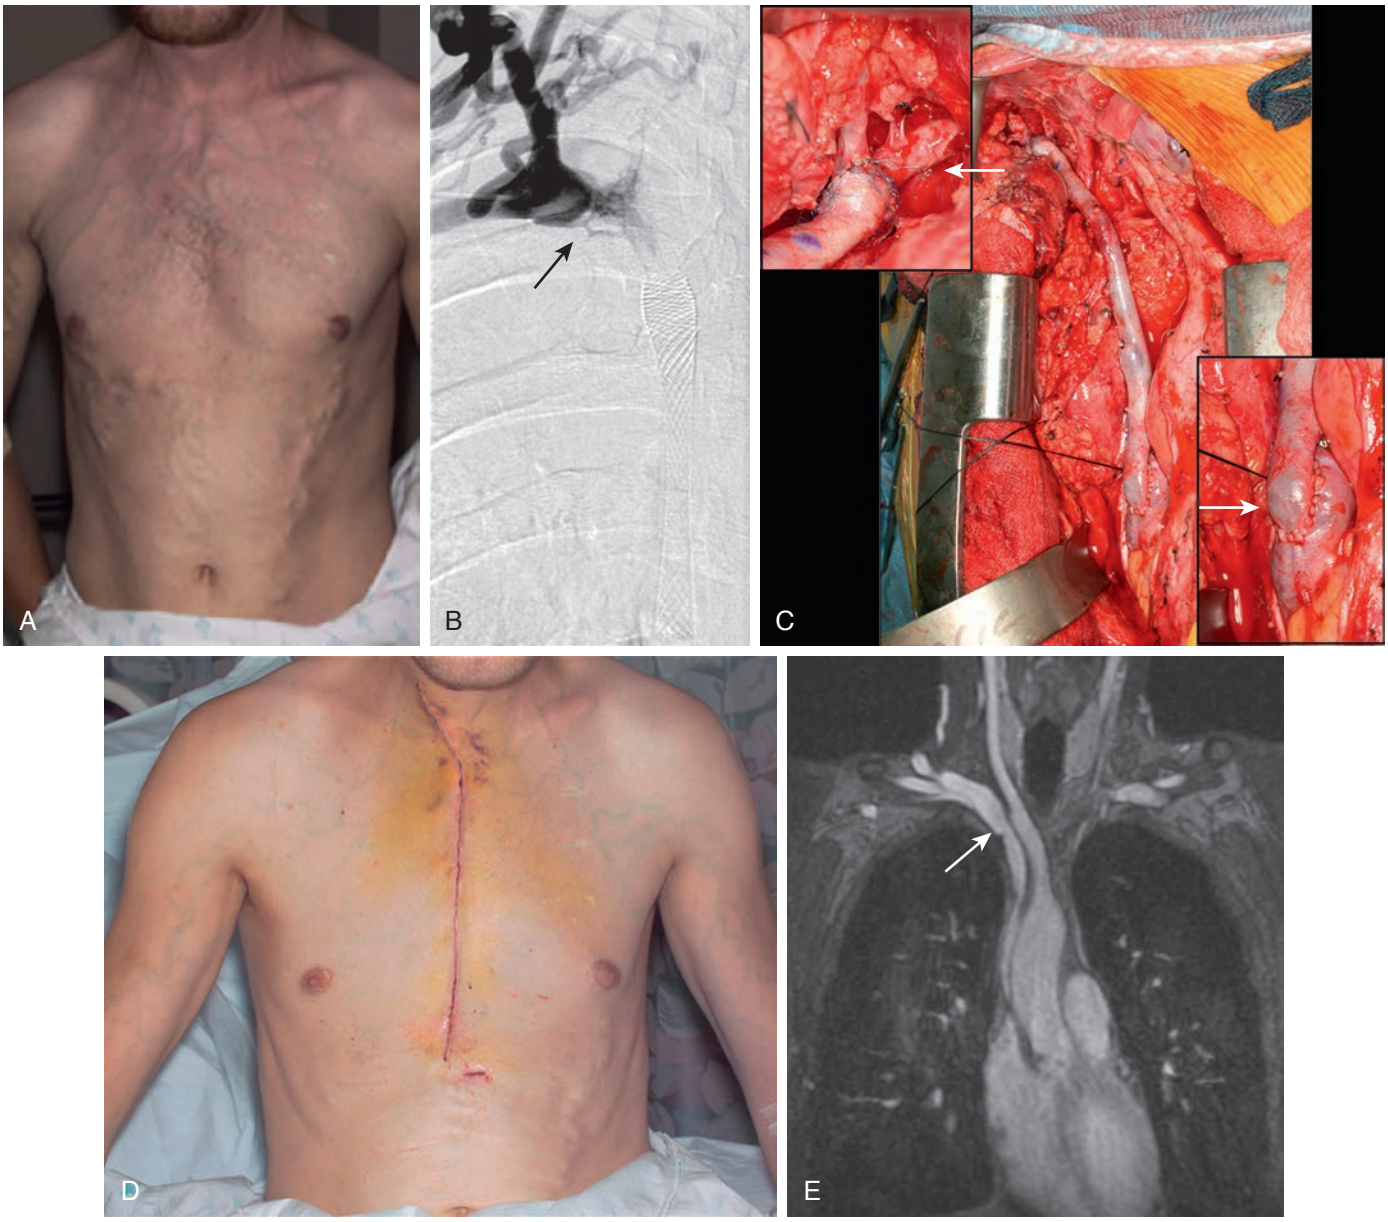

Figure 162.5 (A) Symptomatic recurrent superior vena cava (SVC) obstruction following occlusion of Wallstent prominent abdominal and chest wall collaterals. (B) Venogram demonstrating occlusion till the peripheral vein, right IJV, and subclavian veins patent with large draining collaterals. (E) Magnetic resonance Venogram 15 months after surgery confirms the graft *(white arrow)* to be widely patent.

extremity edema and pain. Compartment syndrome and chronic venous insufficiency following harvesting of longer segments of the femoropopliteal veins have been reported.[59,60] For this reason, in young patients who undergo SVC reconstruction for benign disease, the authors prefer using the spiral saphenous vein graft (SSVG).

Spiral Saphenous Vein Graft

The SSVG is autologous tissue with low thrombogenicity. Although its length is limited by the available saphenous vein segment, its diameter can be easily matched to that of the internal jugular or innominate vein (Fig. 162.6). This graft was first described in animal experiments by Chiu and colleagues,[61] and later in patients by Doty.[6,62] The technique used by the authors preparing the SSVG is illustrated in Fig. 162.5.[61]

The saphenous vein is harvested, distended with papaverine-saline solution, and opened longitudinally. The valves are excised and the saphenous vein is wrapped around a 32 or 36 French polyethylene chest tube. The edges of the vein are sutured together with running 6-0 or 7-0 monofilament nonabsorbable sutures to form the SSVG conduit, interrupting the suture line at every three-quarter turn (Fig. 162.7). Alternately, metal clips may be used with the advantage of decreased time and less chance of "purse-stringing" the suture line (see Fig. 162.7). The length of saphenous vein to be harvested to create a graft of sufficient length is determined according to the equation proposed by Chiu and coworkers ($l = RL/r$; r and l = radius and length of saphenous vein, R and L = radius and length of SSVG).[61] Harvesting vein from the groin to the knee usually results in an SSVG approximately 10 cm long.

Expanded Polytetrafluoroethylene Graft

Of the available prosthetic grafts, externally supported ePTFE is used for large vein reconstruction almost exclusively (Fig. 162.8).[7,61,63] Short, large-diameter (10 to 14 mm) grafts have excellent long-term patency, because flow through the innominate vein usually exceeds 1000 mL/min. If the peripheral anastomosis is performed with the subclavian vein, venous inflow is significantly less, and the addition of an AVF in the arm is usually required to ensure graft patency. For an internal jugular-atrial appendage bypass, a large-diameter (12 mm) ePTFE graft is a suitable alternative if the spiral saphenous vein is not possible. An externally supported prosthetic graft is a good choice in patients with a tight mediastinum and for all patients with malignancy, because its stiffness prevents recurrent tumor from compressing the graft.

Other Grafts

Fresh iliocaval allograft homografts, cryopreserved femoral vein, aortic arch grafts, and grafts prepared from autogenous or bovine pericardium have also been used.[64,65]

Surgical Technique

The operation is performed through a median sternotomy. If the internal jugular vein is used for inflow, the midline incision is extended obliquely into the neck along the anterior border

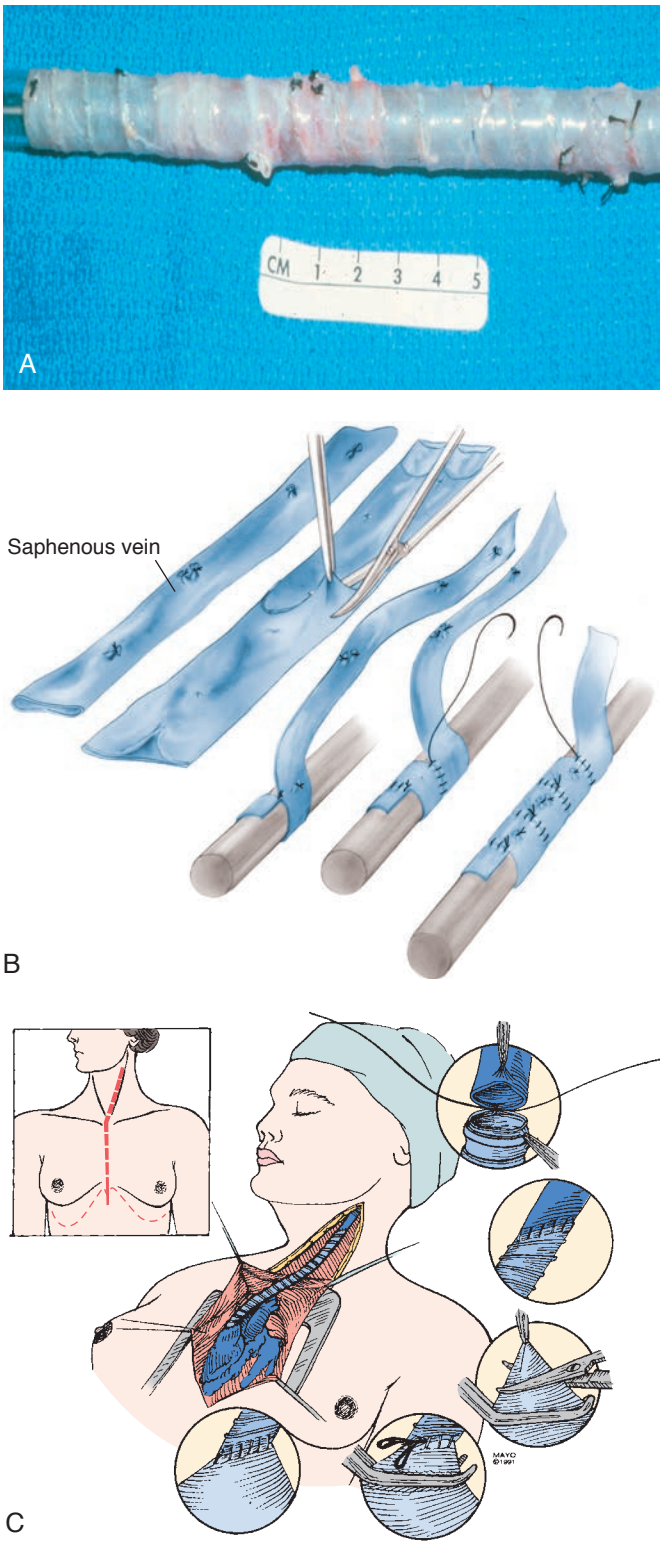

Figure 162.6 (A) Technique for a spiral saphenous vein graft. The saphenous vein is opened longitudinally, valves are excised, the vein is wrapped around an argyle chest tube, and the vein edges are approximated with sutures. (B) A 15-cm-long spiral saphenous vein graft ready for implantation. (C) Technique of left internal jugular–right atrial spiral vein graft implantation. (From Gloviczki PG, Pairolero PC. Venous reconstruction for obstruction and valvular incompetence. In: Goldstone J, ed. *Perspectives in Vascular Surgery*, St. Louis: Quality Medical Publishing; 1988:75–93.)

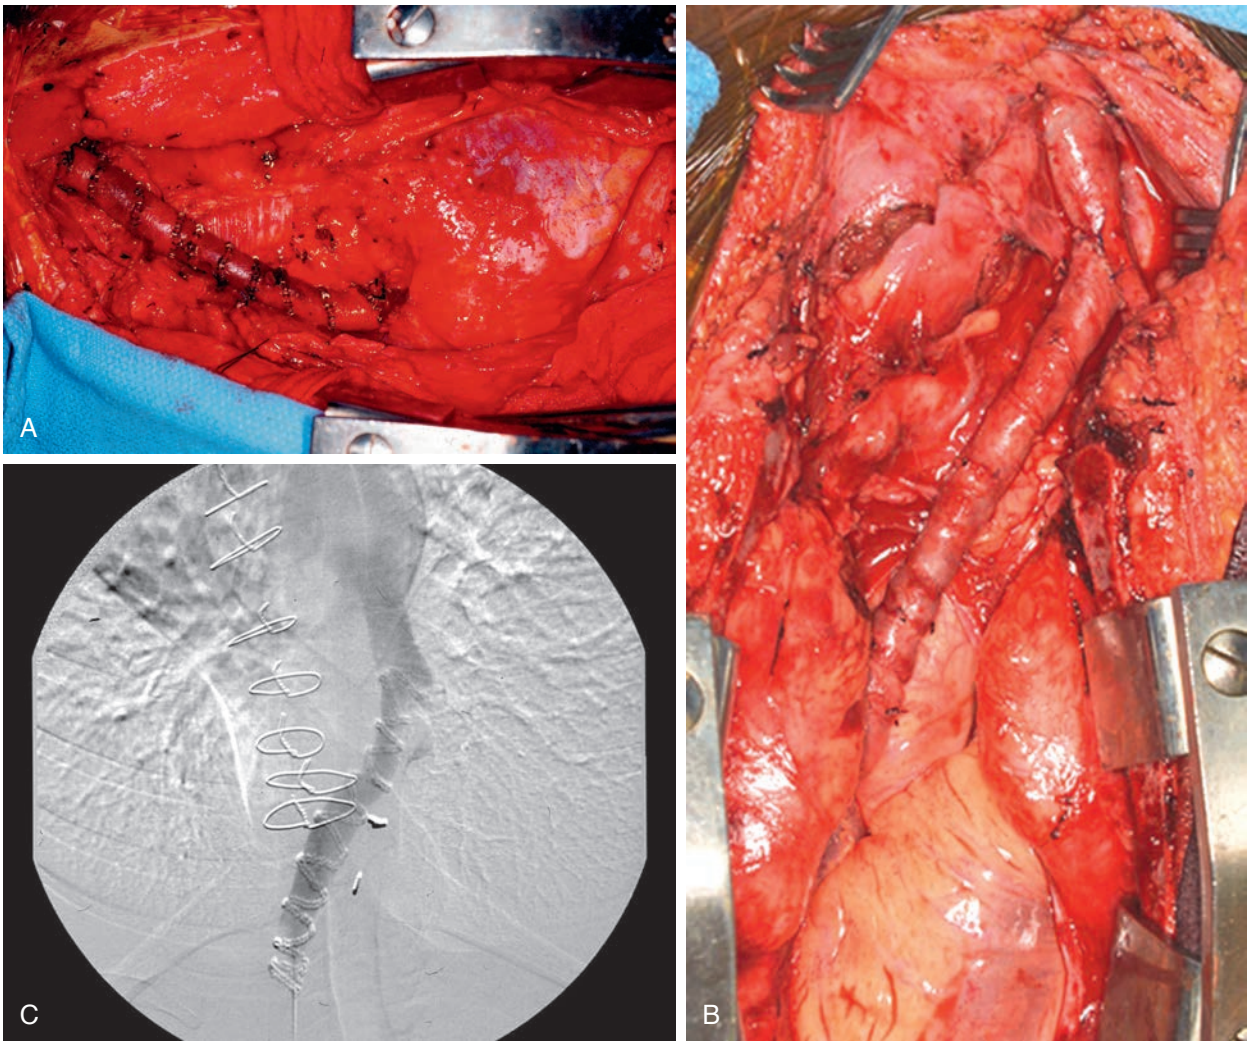

Figure 162.7 (A) Nonpenetrating vascular clips used for preparation of a spiral vein graft. (B) Intraoperative image of spiral vein graft and (C) postoperative venogram demonstrating the patent left internal jugular–right atrial appendage bypass graft. The graft is patent and the patient is asymptomatic 3 years later.

of the sternocleidomastoid muscle on the appropriate side. The mediastinum is exposed, and biopsy of the mediastinal mass or resection of the tumor is performed before caval reconstruction. Once this is completed, the pericardial sac is opened to expose the right atrial appendage, which is used most frequently for the central anastomosis. A side-biting Satinsky clamp is placed on the right atrial appendage, which is opened longitudinally. Some trabecular muscle is excised to improve inflow, and an end-to-side anastomosis with the graft is performed using running 5-0 monofilament suture (see Fig. 162.4C). If not involved in the fibrosing process, a patent SVC central to the occlusion can also be used for this purpose. The peripheral anastomosis of the graft is performed with the internal jugular or innominate vein in an end-to-side or, preferably, an end-to-end fashion.

Although we have performed bifurcated SSVGs (Fig. 162.9) or prosthetic grafts to both internal jugular veins in a few patients, a single straight graft from the internal jugular or innominate vein is our current operative choice for SVC reconstruction. Because collateral circulation in the head and neck is almost always adequate, unilateral reconstruction is sufficient to relieve symptoms in most patients. When only part of the circumference of the SVC is invaded by the tumor, resection and caval patch angioplasty using prosthetic patch, bovine pericardium, or autogenous material, such as saphenous vein or pericardium, is also an option.

Postoperative anticoagulation is started 24 hours later with heparin, and the patient is discharged on an oral anticoagulation regimen. Patients with SSVGs or femoral vein grafts who have no underlying coagulation abnormality are maintained on anticoagulation for 3 months only. Those with underlying coagulation disorders and most patients with ePTFE grafts continue lifelong anticoagulation therapy.

RESULTS

Results of Endovenous Treatment in Patients With Malignancy

Initial attempts at treating SVC syndrome by endovascular means employed PTA alone. The earliest reports of SVC stenting

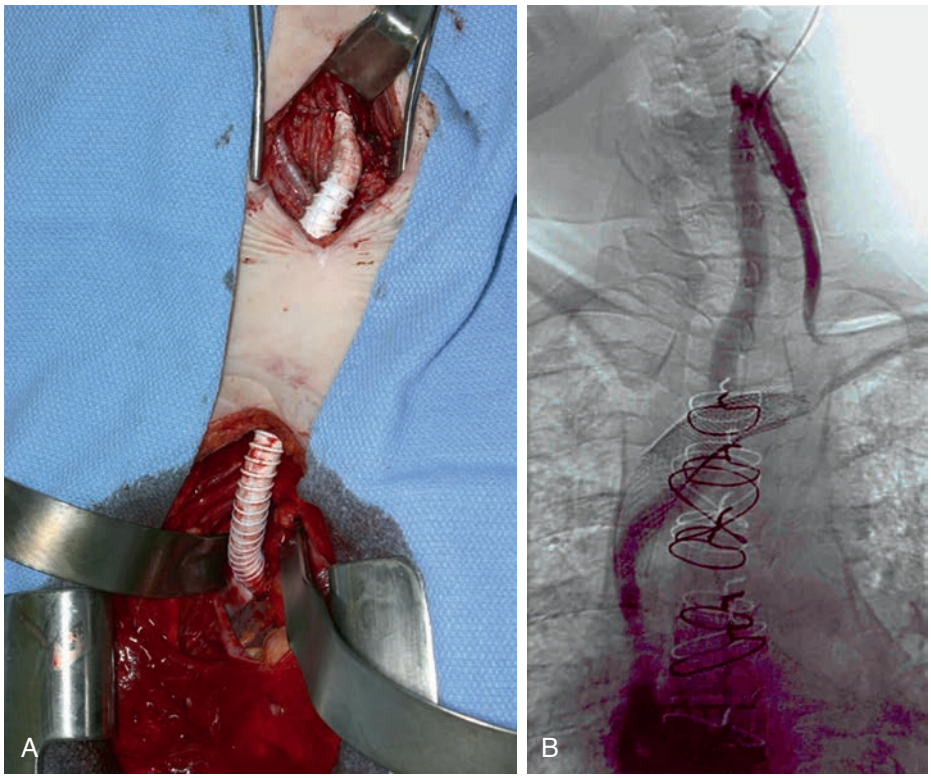

Figure 162.8 (A) Left internal jugular vein–atrial appendage externally supported expanded polytetrafluoroethylene graft. (B) Widely patent graft at 13 months after the operation.

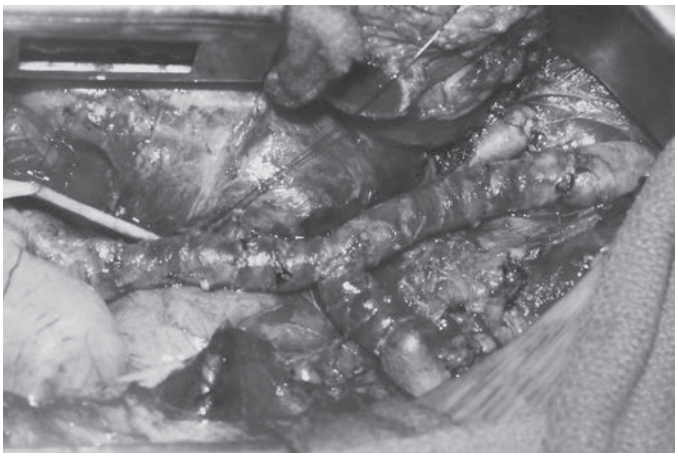

Figure 162.9 Bifurcated spiral saphenous vein graft in a 43-year-old woman. (From Alimi YS, Gloviczki P, Vrtiska TJ, et al. Reconstruction of the superior vena cava: the benefits of postoperative surveillance and secondary endovascular interventions. *J Vasc Surg.* 1998;27:298–299.)

in 1986/7 were in patients with malignant SVC occlusion; prompt relief of symptoms occurred and was maintained until death at 3 weeks to 6 months.[39,66] Relief of symptoms included "immediate" relief of headache and resolution of arm and face edema within 24 to 72 hours. These procedures were performed with Gianturco Z stents, which were subsequently modified by Rosch et al.[66] to create a multibody design that minimized stent migration. In the early 1990s occasional cases of stent deployment for pacemaker wire-induced thrombosis were reported, but repeated interventions were required to maintain patency in the short term.[39,57,66]

Nicholson et al.[67] reported the largest study of endovenous interventions to that time in 75 patients with malignant SVC syndrome. Symptomatic relief was achieved in all patients within 48 hours, and 90% remained symptom free until death. The authors compared SVC stenting with palliative radiation, and concluded that stenting had significantly greater efficacy. In a later study by Garcia Monaco et al.,[68] dramatic symptomatic improvement was seen in 91% of 40 patients with malignant SVC syndrome following stenting, and was maintained in 83% during the course of the disease. Greillier et al.[69] reported complete resolution of symptoms more frequently in stented than in unstented patients with lung cancer (75% vs. 25% respectively), as well as a lower relapse rate and longer time to relapse. Maleux et al. reported stenting in 78 patients with malignant SVC syndrome (Large bore Nitinol SE Zilver, Cook Medical), demonstrating 100% technical success rate and 89% primary patency at 12 months.[70] The recent development of large-caliber stents developed specifically for the SVC has also appeared to improve results.[71,72] Based on these data, endovenous treatment has become the first-line treatment for malignant SVC syndrome.[73–76]

Results of Endovenous Treatment in Patients With Benign Superior Vena Cava Syndrome

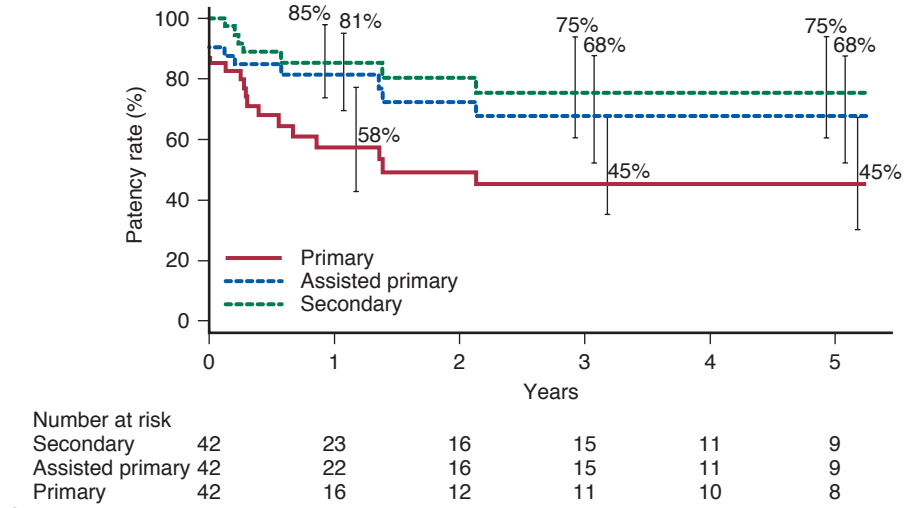
Studies reporting on the treatment of benign SVC syndrome are scarce. We have reported our results of successful endovenous

treatment of SVC syndrome of benign etiology in 28 of 32 patients, 19 with catheter related thrombosis and 9 with mediastinal fibrosis.[15] Six patients underwent PTA and 22 underwent stenting; 5 procedures (2 PTA, 3 stents) were preceded by thrombolysis. Primary patency at 1 and 3 years was 70% and 44%, assisted primary and secondary patency rates at 3 years were 96% and 96%, respectively (see Fig. 162.9). These were not significantly different from the patency of surgical reconstructions at our institution. However, more reinterventions over longer periods of time occurred in the patients treated with endovascular procedures compared to those who underwent open surgery (Fig. 162.10).[15] Other studies reported excellent technical success with secondary interventions required in approximately 10% of cases over 1 to 2 years.[38,77]

Additional studies provided evidence of the efficacy of thrombolysis followed by PTA and stenting in patients with benign SVC syndrome. Kee et al. reported on 27 patients treated with this technique. In the majority, successful lysis revealed underlying significant stenoses which were treated by stenting.[78] Although thrombolysis was generally safe, a Cochrane review concluded that when added to stenting, it resulted in increased morbidity compared to stenting alone.[28]

Complications, Restenosis, and Outcomes

Most studies have emphasized the need for customizing treatment with a combination of thrombolysis, angioplasty, and stenting to achieve an initial technical success rate of 90% to 100% and secondary patency rates up to 85% at 1 year in small numbers of patients.[43,55,78,79] Barshes et al. reported 100% technical success and 96% symptomatic relief following stenting in patients with both benign and malignant SVC



A

Figure 162.10 (A) Cumulative primary, assisted primary, and secondary patency rates at 1, 3, and 5 years of open surgical reconstruction ($n = 42$). *Solid bars* represent SEM < 10%. (B) Cumulative primary, assisted primary, and secondary patency rates at 1 and 3 years of endovascular repair ($n = 28$). *Solid bars* represent SEM < 10%. (From Rizvi AZ, et al. Benign superior vena cava syndrome: stenting is now the first line of treatment. *J Vasc Surg.* 2008;47(2):372–380.)

syndrome, with primary patency rates of 76% and 64% at 1 year, respectively.[80] However, to this date, prospective, randomized data comparing stent types or treatment algorithms does not exist. Oudkerk et al. compared outcomes between Giantarco and Wallstents, and reported the latter to be more prone to occlusion, possibly because of a closer weave and greater surface area of metal.[81]

Occlusion of stents because of protrusion of tumor between stent struts in patients with malignancy, as well as intimal hyperplasia, fibrosis, and extrinsic compression from mediastinitis, are real concerns following endovenous treatment. Restenosis usually results in recurrence of symptoms and necessitates repeat interventions, especially in patients with benign SVC syndrome (Fig. 162.11). Endovenous treatment

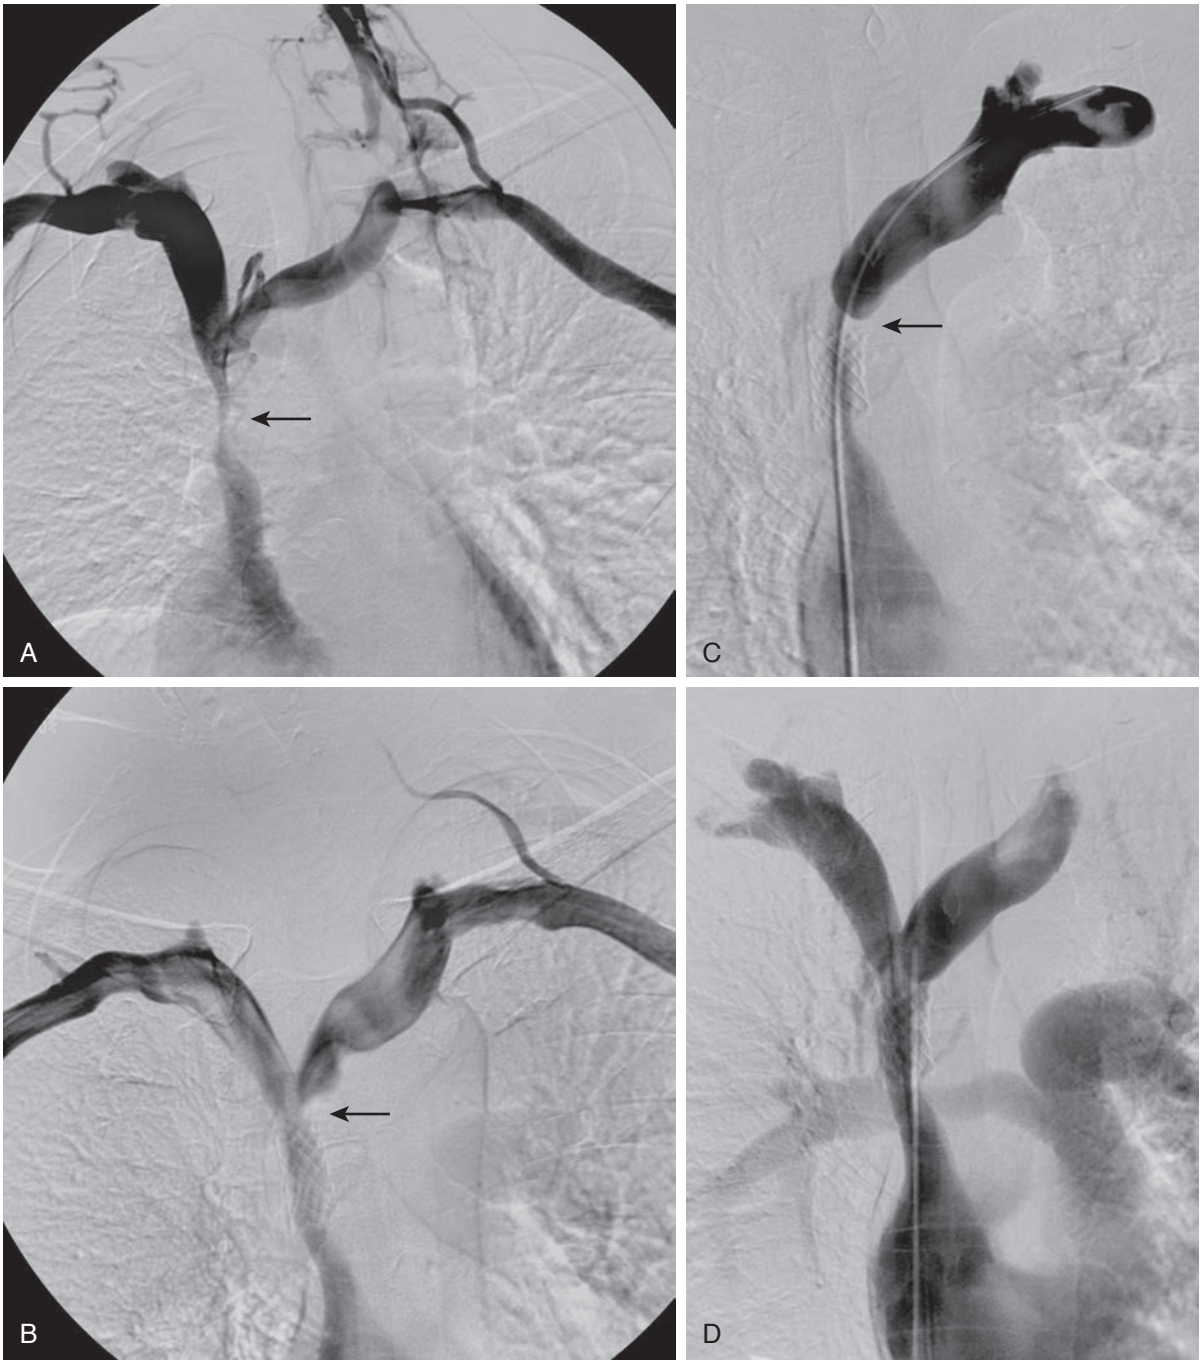

Figure 162.11 (A) Venogram showing Type II superior vena cava obstruction *(arrow)* due to mediastinal fibrosis in a 38-year-old man. Successful placement of a Palmaz stent resulted in immediate resolution of symptoms. (B) Venogram 14 months after stent placement shows high-grade stenosis of the left innominate vein proximal to the stent *(arrow)*. This was successfully treated with balloon angioplasty. (C) Venogram 8 months later shows recurrence of stenosis *(arrow)*. (D) Venogram following balloon angioplasty of stenosis left innominate vein and stent shows widely patent stent. Patient has undergone two further balloon angioplasties over the next 10 months to maintain patency.

is also associated with access site complications, bleeding related to thrombolysis/anticoagulation, stent migration, and cardiac tamponade from intrapericardial hemorrhage. The latter occurs infrequently, but has been reported after both PTA and stenting and necessitates urgent ultrasound-guided pericardiocentesis. We encountered this complication during repeat PTA in two patients.

Concerns regarding restenosis and symptomatic recurrence have led to the use of covered stents, based upon data suggesting that their use is associated with lower recurrence rates. In one study, Gwon et al. reported better cumulative patency with covered than uncovered stents (94% vs. 48%; $P = .038$).[48] Over the last decade we have used covered stents selectively in the SVC, and placed them in 13/44 patients with benign SVC syndrome (unpublished data). Although not statistically significant, we observed a decreased rate of reintervention at 1 year in the group with covered stents (15%) versus those with uncovered stents (39%). These data are preliminary, but our experience mirrors the findings reported by Gwon et al.[48,82,83]

Despite the attraction of the minimally invasive nature of SVC stenting, the need for frequent, repeated reintervention remains a limiting factor in long-term success. Given the longevity of patients with benign SVC syndrome it is not surprising that a fair number eventually opt for surgical treatment.

Results of Surgical Treatment

Open surgical treatment for SVC syndrome has excellent long-term results, but is now considered only after failure or inability to perform endovascular treatment. Outcomes depend on etiology, conduit, and the length of venous reconstruction. Of the autologous graft materials, experience with SSVG and femoral vein grafts has been the largest. Doty and colleagues reported on long-term results with 16 SSVGs used for benign SVC syndrome, demonstrating 88% patency and excellent clinical results at a mean follow-up of 10.9 years. The author's experience includes 22 SVC reconstructions with SSVG, with 86% secondary patency at 5 years and good to excellent clinical results.[6,62,84–86]

Increasing success with femoral vein as an arterial conduit has resurrected this autologous graft for large vein reconstructions as well.[87] All six femoral vein grafts performed by our group have remained patent.[15] However, two of the six patients developed mild but persistent swelling and venous claudication in the lower extremity from which the graft was harvested.

In several series, ePTFE grafts implanted into the mediastinum have resulted in excellent patency. Dartevelle and associates observed continued patency in 20 of 22 ePTFE grafts at a mean follow-up of 23 months.[32] Moore and Hollier observed no graft occlusion at a mean follow-up of 30 months in 10 patients who underwent large central vein reconstruction.[47] In 8 of these 10 patients, an additional AVF in the arm was used to increase flow. Similar results have been reported in other studies.[33,88,89]

In our experience, some thrombus formation occurs even in patent ePTFE grafts, with occlusion occurring much more frequently in patients with longer ePTFE grafts in whom the distal anastomosis is performed with the internal jugular or the subclavian veins. Long-term patency is better in patients with innominate or SVC interposition grafts, and we now use ePTFE as a conduit only when the extent of the graft is limited to within the anterior mediastinum (Fig. 162.12).

Graft Surveillance

Postoperative graft surveillance is important for maintenance of patency. DUS provides only indirect evidence of patency of an intrathoracic graft. Therefore CT or MRV is recommended before discharge and at 3 to 6 months and 1 year after surgery. In our experience, most graft stenoses presented within 1 to 2 years after implantation, and half of these had mild stenoses on the first postoperative surveillance venogram (Fig. 162.13).

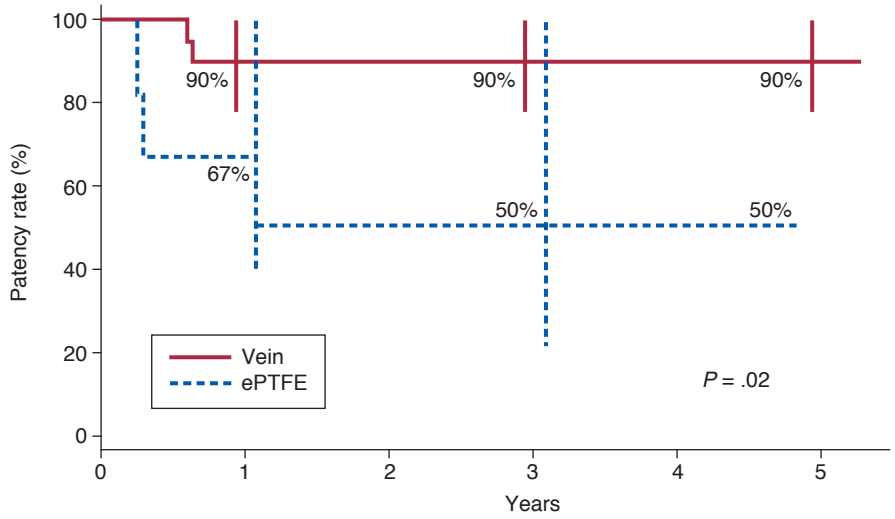

Figure 162.12 Cumulative secondary patency rates of 23 vein grafts and 6 expanded polytetrafluoroethylene bypass grafts used for reconstruction of the superior vena cava. (From Kalra M, et al. Open surgical and endovascular treatment of superior vena cava syndrome caused by nonmalignant disease. *J Vasc Surg*. 2003;38:215–223.)

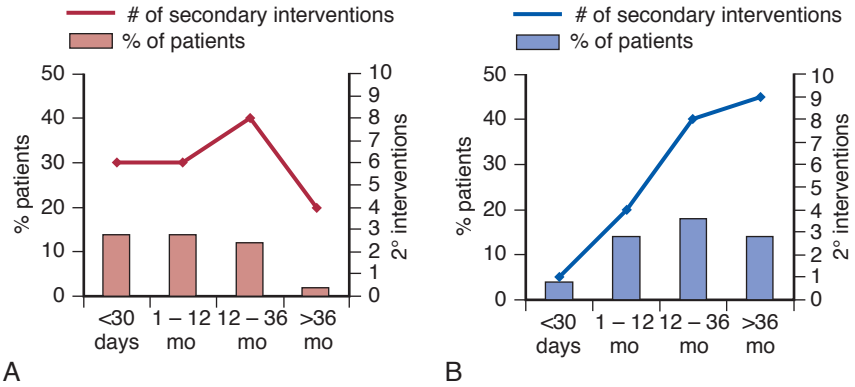

Figure 162.13 (A) Treatment of benign superior vena cava syndrome. Secondary interventions required to maintain patency in (A), the open surgical group ($n = 42$), and (B). The endovascular group ($n = 28$). The *bars* represent the percentage of patients in each group and the *line graphs* represent total number of interventions. (From Rizvi AZ, et al. Benign superior vena cava syndrome: stenting is now the first line of treatment. *J Vasc Surg*. 2008; 47(2):372–380.)

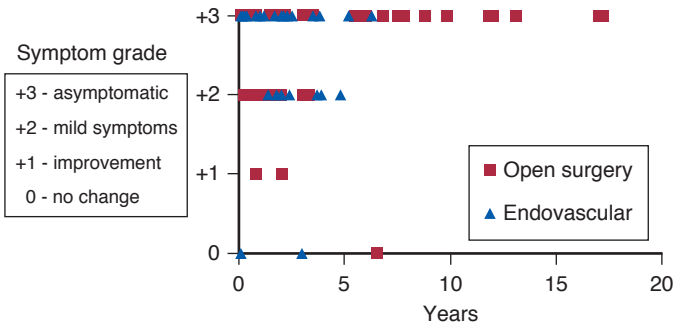

Figure 162.14 Grading of symptom relief at last clinical follow-up in patients undergoing open surgical reconstruction ($n = 42$) or endovascular repair ($n = 28$). (From Rizvi AZ, et al. Benign superior vena cava syndrome: stenting is now the first line of treatment. *J Vasc Surg*. 2008;47(2):372–380.)

Regardless of the treatment modality, the discovery of all stenoses was accompanied by recurrence of symptoms except in one instance. Similar outcomes have been reported by Doty and associates.[85] Based on these data, graft patency can be inferred based upon freedom from symptoms, and imaging after the first year need only be performed in symptomatic patients or in asymptomatic patients with known stenoses. Both endovascular therapy and open surgery have been used to treat graft stenoses, although endovascular treatment is more common (Fig. 162.14).[46]

CONCLUSIONS

The incidence of SVC syndrome is increasing with the growing use of indwelling catheters and pacemakers. The techniques of endovascular treatment have been refined, and experience with their use has increased. Endovascular treatment is now an appropriate primary intervention in patients with SVC syndrome of both malignant and benign etiology. It is less invasive with lower morbidity than open surgical reconstruction, with equal midterm efficacy, albeit at the cost of multiple secondary interventions. Covered stents may prove to have improved patency compared to bare metal stents, although definitive data do not exist at this time. Endovascular therapy does not adversely affect the feasibility or patency of subsequent open surgical procedures. However, surgical treatment of SVC syndrome with spiral vein grafts or prosthetic grafts is effective, provides long-term relief, and remains an excellent option in patients who are not suitable for or fail endovascular treatment.

SUMMARY 2150

Congenital absence of the inferior vena cava (AIVC) is a rare entity and is often first detected in the setting of an idiopathic deep venous thrombosis (DVT) of the lower extremity. The overall incidence of AIVC in the general population has been estimated to be 0.3% to 0.5%, but it may be present in up to 5% of cases of patients under the age of 30 with idiopathic DVT. This incidence was first noted by Ruggeri et al. in 2001.[1] These authors noted that in their own review of published reports from 1966 to 1999, there were fewer than 10 cases of DVT in patients with AIVC. They also noted that this could have represented an underestimation, because the most common diagnostic imaging technique, the duplex scan, does not routinely include the abdominal veins. Indeed, more dedicated abdominal duplex scanning or computed tomography (CT) is required to make the diagnosis.

It is likely that most cases of congenital absence of the IVC remain undiagnosed and are of little clinical consequence. However, it is the smaller subset of those presenting with a DVT that represents more complex management issues regarding both treatment of the acute DVT and subsequent identification and treatment of associated thrombophilia.

ASSOCIATION WITH DEEP VENOUS THROMBOSIS

Several authors have noted an association of AIVC with deep venous thrombosis.[1-4,5] It has recently been reported in adolescent males; the authors note that this entity is an important risk factor for the development of spontaneous DVT in young males.[2,6] The possible explanation for this is that the congenital absence of the IVC creates a low-flow state, making the lower extremity more susceptible to DVT. This may be further exacerbated in the presence of thrombophilia, such as factor V Leiden mutation or homocysteinemia.[4] Halparin et al. evaluated a pediatric and adolescent population and noted that congenital AIVC does not seem to present with symptoms of DVT until at least the second decade of life. The authors suggest that for the anomaly to manifest as DVT, a second "hit" is required.[6] Venous collaterals appear to be able to compensate for the lack of a normal IVC but fail when the demands for venous drainage exceed the capacity of the collateral veins, with DVT then occurring via a mechanism of stasis. Factors specific to the

Abstract

Congenital absence of the inferior vena cava (AIVC) represents a rare but underappreciated central venous condition. The impediment to central venous flow caused by AIVC results in venous stasis. Consequently, there is a strong association with deep vein thrombosis (DVT), particularly in younger individuals.

The vast majority of patients with AIVC will be identified incidentally, and therefore a high index of suspicion needs to be maintained. Given that AIVC is a congenital condition, there is also an association with other congenital anomalies such as cardiopulmonary defects that may arise during the 6th week of gestation. Moreover, hypercoagulability workups are performed frequently in this patient population due to the atypical presentation of DVT.

Venous duplex and axial imaging, including computed tomography venography and magnetic resonance venography remain the mainstay of diagnosis. The axial imaging studies allow for the accurate delineation of the anomalous anatomy. Ultimately, conventional venography may be required, especially if invasive treatment is being considered.

In general, asymptomatic patients may be managed conservatively and with regular surveillance. Symptomatic patients and patients who present with DVT may warrant medical management and / or intervention. Intervention may consist of endovascular procedures, open surgery or a combination thereof. The decision and modality for treatment are highly individualized; however, the principles are extrapolated from the treatment for other central venous and post-thrombotic processes. Often symptoms resolve with restoration of axial flow or restoration of baseline collateralized circulation. Ultimately, long-term management and follow-up are necessary to successfully manage this challenging group of patients.

adolescent and young adult population may include an increased demand for venous drainage, as from strenuous physical activity, a growth spurt, or the presence of inherited or acquired thrombotic risk factors. Acquired factors include immobilization, trauma, surgery, malignancy, vascular catheterization, smoking, or the use of oral contraceptives.[6]

EMBRYOGENESIS

AIVC may be associated with other congenital abnormalities, including atrial septal defects, polysplenia, or dysgenesis of the lungs.[7,8] The complex embryogenesis of the IVC begins at week 6, as it develops from three pairs of primitive veins, the supracardinal, subcardinal, and postcardinal veins. These veins form collaterals and connections during development but then regress, leading to a single continuous channel, the IVC.[9]

The IVC can be divided into four segments, the hepatic, prerenal, postrenal, and renal collar. These segments arise from the primitive veins. The supracardinal vein gives rise to the postrenal IVC as well as the hemiazygos and azygos veins. The subcardinal vein gives rise to the prerenal portion, and the renal collar is formed from the subcardinal and supracardinal segments. Hepatic sinusoids form the hepatic segment.[9] It has been proposed that AIVC may be caused by dysgenesis of this complex process or by an interruption of the process by an intrauterine insult.[10,11] The most common types of IVC anomalies are isolated left IVC, double IVC, atresia or agenesis of a segment or the total IVC, and azygos or hemiazygos continuation of the IVC (Figs. 163.1, 163.2, and 163.3).[2] Regression of the right supracardinal vein with persistence of the left supracardinal vein results in a left IVC. If both the left and right supracardinal veins persist, there will be a double IVC. Atresia of a segment of the IVC or total IVC atresia is caused by failure of anastomosis of one (segmental AIVC) or multiple (total AIVC) segments of the IVC.[2,12]

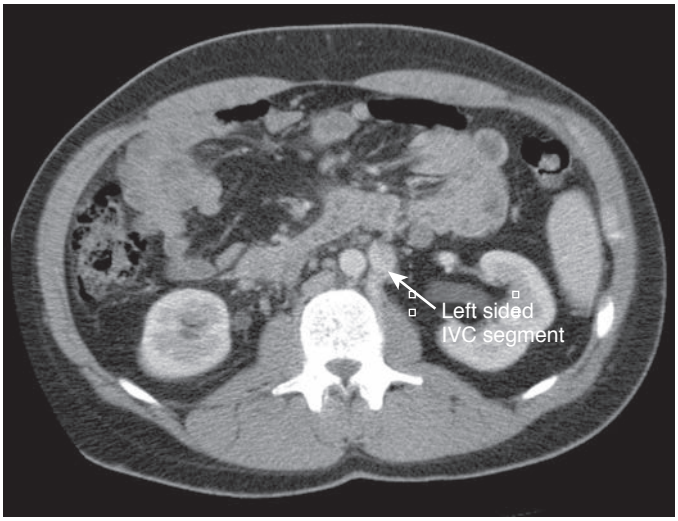

Figure 163.1 Computed tomography scan demonstrating left-sided infrarenal inferior vena cava (IVC) with an absent suprarenal IVC.

PRESENTATION

AIVC may be noted incidentally, or it may present with complications such as DVT with mild or severe symptoms of leg swelling and venous congestion. When AIVC is found, a thrombophilia workup is recommended.

Clinical Diagnosis

Diagnosis of the congenital absence or occlusion of the IVC relies on a high index of suspicion. For example, young patients (<40 years) are considered to be at lower risk for DVT compared

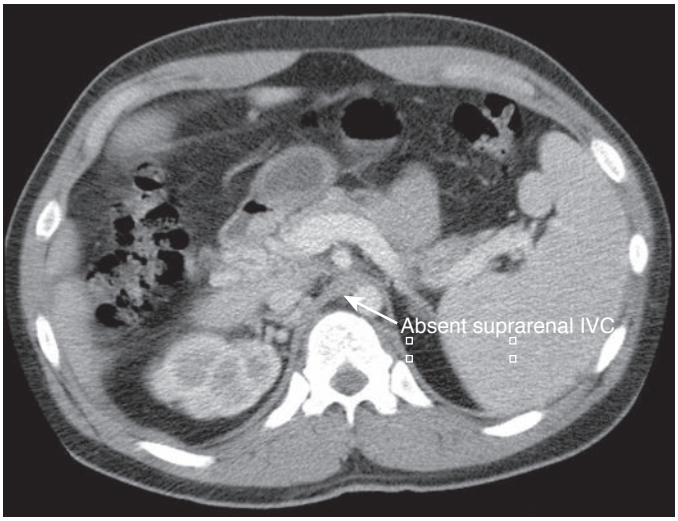

Figure 163.2 Computed tomography scan demonstrating an absent suprarenal inferior vena cava (IVC).

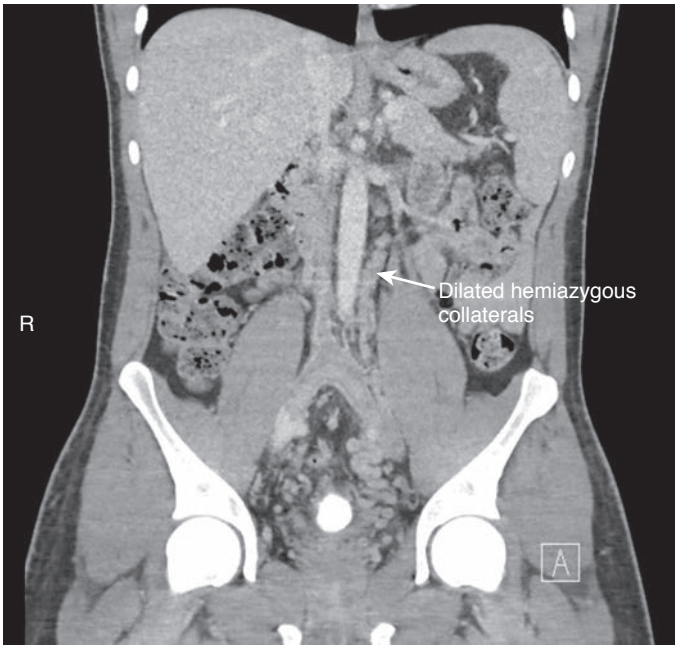

Figure 163.3 Coronal image of computed tomography scan showing hemiazygos continuation of an absent inferior vena cava.

with older ones. Therefore in a young person with an idiopathic DVT, evaluation for hypercoagulability might be accompanied by imaging looking for congenital abnormalities of the deep venous system, including absence of the IVC. This may hold true in even more particular circumstances, such as young patients presenting with severe bilateral lower extremity chronic venous insufficiency or extensive bilateral iliofemoral thrombosis. As noted previously, up to 5% of individuals between 20 and 40 years of age who develop a DVT may have an underlying congenital abnormality of the IVC.[1] Moreover, the clinical presentation may also sway the decision-making process. For example, in patients with significant evidence of collateralization (i.e., abdominal wall varicosities) in the setting of the aforementioned presentation, congenital absence of the IVC is more likely, and these findings would influence the choice of subsequent diagnostic modalities.

Imaging Modalities

Duplex Scan of the Lower Extremities and Pelvis

In the majority of cases the initial study of choice is lower extremity venous duplex. With regard to the deep venous system, duplex may identify direct or indirect signs related to central venous obstruction. In the setting of chronic venous hypertension, where the more peripheral deep veins exhibit damaged valves, significant reflux may be present to a variable extent in the iliac, femoral, popliteal, or tibial veins.[13] Even in the setting of competent deep veins, there may be signs suggestive of a central obstruction, such as diminished or absent respiratory phasicity.[13] There may also be evidence of chronic DVT in the iliofemoral and popliteal veins, suggestive of a prior history of DVT. In this setting, findings would include a contracted, thick-walled, hyperechoic lumen, possibly with associated recanalization.[14] In addition, due to the significant burden placed on the lower extremity's venous system in the setting of AIVC, reflux may be present in the truncal superficial veins or perforator veins. Significant superficial collateral networks emanating from the abdominal wall or the pelvis may also be identified by duplex ultrasound, suggesting congenital absence of the IVC. Last, direct insonation of the iliocaval venous segments may be performed and may show absence of flow in these segments or complete absence of the segments themselves. The disadvantage of duplex is that it is highly operator-dependent as well as being dependent on patient-specific factors such as size, bowel gas, and patient cooperation.[14] Once clinical suspicion for severe iliocaval disease is present and duplex ultrasound corroborates the clinical findings, confirmatory imaging is typically required. This would be performed most commonly with noninvasive axial imaging, such as CT venography (CTV) or magnetic resonance venography (MRV). Invasive methodologies, such as ascending venography or intravascular ultrasound, may also be performed as adjunctive studies.

Axial Imaging (Computed Tomography Venography and Magnetic Resonance Venography)

CTV or MRV may be utilized to diagnose and determine the exact anatomic variant characterizing congenital absence of the IVC. Both modalities have advantages and disadvantages. Each will identify acute DVT in the central veins. A possible advantage of MRI may be the ability, with certain sequences, to estimate, the chronicity of the DVT.[15]

For CTV, the significant potential complication is contrast-induced nephropathy. Therefore this modality should be used judiciously in patients presenting with chronic kidney disease. This may be especially true in patients with renal aplasia, which has a known association with congenital absence of the IVC.[5] Moreover, CT scans pose the added long-term risk of radiation, which may be of greater consideration in evaluating younger patients.[16] Patients with significant reactions or allergies to iodinated contrast may be precluded from utilizing this modality. With regard to image quality, the timing and acquisition of CTV are variable, and this variability may be exaggerated in patients with congenital absence of the IVC, given the alteration in flow dynamics leading to poor imaging of the pathology.

However, there are advantages to using CTV as opposed to MRV. It allows for the rapid acquisition of images and is readily available in most centers. In addition, if a patient has known metal implants, there is substantially less artifact with the use of CTV as compared with MRV, and the intraluminal contents of stented vasculature can be evaluated more readily. Moreover, luminal diameter may be measured more accurately, since the full extent of the vessel wall is more readily appreciated on CTV than on MRV (Figs. 163.4 and 163.5).[17]

MRV has the advantage of lack of radiation. With regard to evaluation of the vasculature, the gadolinium may dwell longer than the iodinated contrast utilized for the CTV; therefore, the vasculature may be evaluated more completely over prolonged

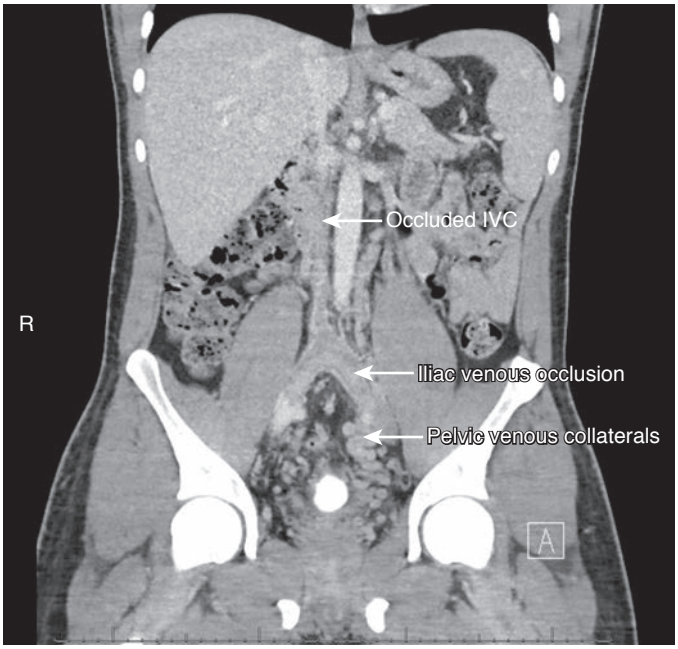

Figure 163.4 Coronal computed tomography image of thrombosed distal inferior vena cava (IVC) and iliac veins with pelvic collaterals in the setting of an absent IVC.

time intervals (Figs. 163.6, 163.7, and 163.8).[18] This allows for a more complete assessment of the vasculature and the ability to obtain time-resolution images. These may provide critical information with regard to collateral circulation and patterns of flow. In the elective setting, MRV may be the preferred modality by a small margin, given the improved filling of the vasculature and the possibility for improved time resolution.[19] Disadvantages to obtaining an MRV include strict contraindications in patients with certain metal implants, such as pacemakers. Moreover, patients with advanced (stages IV-V) chronic kidney disease are at risk for nephrogenic systemic fibrosis (NSF) following the administration of gadolinium.[20] There are time-of-flight sequences that do not utilize intravenous contrast agents; however, the resolution of these images is often suboptimal for full delineation of the vasculature. Last, the degree of stenosis may be overestimated by MRV owing to the way in which the image is acquired, with the associated flow voids.[21]

Venography

Venography is typically considered the gold standard for direct visualization of the venous vasculature. It serves most commonly as an adjunctive study to the aforementioned noninvasive imaging modalities. The procedure itself allows for direct visualization of flow through central and peripheral veins, and it can provide

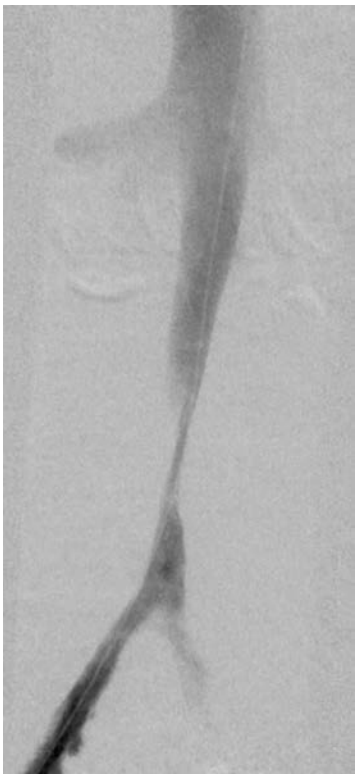

Figure 163.9 Venogram of segmental atresia of the infrarenal inferior vena cava.

for real-time visualization of the flow through axial as well as collateral pathways. As is true with other invasive imaging studies, multiple projections may be required, and selective catheterization may help to further delineate anatomy and flow. Acute and chronic processes may be visualized as well. Last, should an intervention be considered, venography will by its nature be a component of the procedure, and this is the role that it plays most commonly (Fig. 163.9).

MANAGEMENT

Owing to the absence of the IVC and the commensurate lack of axial flow, there is limited possibility for the development of pulmonary emboli in the setting of a peripheral DVT.[19] Therefore the indications for treatment are based on the presenting signs and symptoms as opposed to the prevention of a pulmonary embolus. As stated previously, the patient may be asymptomatic at presentation, or there may be signs and symptoms of an acute process, such as an acute DVT, or a chronic process, such as the stigmata of chronic venous insufficiency. In all settings the severity may vary significantly, and this also affects decision making as it relates to treatment. Truly emergent presentations are rare because patients have already developed a significant collateral network that compensates following the development of an acute process. Consequently the mainstay of treatment is anticoagulation with the concomitant use of graduated compression stockings to mitigate the sequelae of postthrombotic syndrome.[22]

Acute Deep Venous Thrombosis With Mild Symptoms

Conventional treatment for an acute DVT with mild symptoms consists of anticoagulation with the use of graduated compression stockings.[22] In the case of AIVC, the goal of anticoagulation is to prevent further propagation of thrombus, particularly into patent collateral networks that are contributing to venous return. The type of anticoagulation may be left to the discretion of the practitioner. Because of the presence of a significant fixed anatomic defect, the general recommendation is to treat with lifelong anticoagulation.[3] Warfarin and low-molecular-weight heparin may be utilized. The novel oral anticoagulants (NOACs) such as apixaban, rivaroxaban, and dabigatran are attractive alternatives due to their convenience, particularly in young patients who require long-term therapy. Treatment with systemic (as opposed to catheter-directed) thrombolytics may be considered but has demonstrated limited success in this setting, and there is a significant risk for complications that is not commensurate with the efficacy of the treatment in the setting of mild symptoms.[23] With regard to graduated compression, emerging evidence suggests that it may not prevent the development of a postthrombotic syndrome; however, it is still considered an appropriate treatment in patients in whom the postthrombotic syndrome has already been diagnosed.[24]

Even in the setting of mild symptomatology, there should be a discussion with the patient regarding invasive management for the treatment of iliofemoral acute DVT to prevent postthrombotic syndrome.[25] The relevant invasive treatments include catheter-directed thrombolysis and pharmacomechanical thrombectomy with or without adjunctive catheter-directed thrombolysis (see Chapters 148 and 161). Open venous thrombectomy would not be a consideration in the setting of mild symptoms and congenital absence of the IVC.

When they are considered, interventional treatments should typically be offered in the acute presentation period (less than 2-4 weeks). The efficacy of thrombolytic-based treatments diminishes over time. They should be utilized to treat the iliofemoral veins; there are few data demonstrating benefit in the treatment of patients with isolated femoropopliteal or more peripheral DVTs.[25] Important tools in ensuring restoration of luminal patency of the treated veins include performing venography in multiple oblique projections as well as intravascular ultrasound to assess for the full resolution of thrombus. Restoration of adequate inflow is predicated on restoration of flow from a patent femoral or profunda femoris vein into a patent iliac venous system.

The restoration of outflow is the clear obstacle in the setting of the congenital absence of an IVC. Often, the more proximal outflow collateral network that has developed over time, perhaps communicating with the azygos system, is robust enough to maintain patency with the assistance of long-term anticoagulation.[3]

The use of pharmacomechanical thrombectomy may expedite treatment and limit the dosage of the chosen lytic agent (see Chapters 148 and 161). Level 1 evidence supporting the invasive management of acute iliofemoral DVT is sparse. However, the

preponderance of case series and prospective registries suggest long-term anatomic and clinical benefits to the invasive treatment of iliofemoral DVT.[25] The primary outcomes that are commonly evaluated include anatomic patency of the iliofemoral veins as well as freedom from the development of postthrombotic syndrome. The only randomized trial at present that has evaluated the long-term outcomes for the treatment of iliofemoral venous thrombosis is the Catheter-Directed Venous Thrombolysis in Acute Iliofemoral Vein Thrombosis (CaVenT) study.[26] This study compared the treatments of anticoagulation alone to the use of catheter-directed lytic therapy. At the 5-year time point there was an improvement in iliocaval patency from 47% to 66% ($P = .012$) in patients treated with lytic therapy and an improvement in the freedom from development of postthrombotic syndrome from 41% to 55% ($P = .047$). The remaining data are heterogeneous, but a Cochrane database review showed that catheter-directed thrombolysis improves iliofemoral venous patency and reduces the incidence of postthrombotic syndrome by approximately one-third.[25]

The most significant risk of interventional therapies using thrombolytic agents is the risk of bleeding, which ranges from 5% to 10%. However, most reported cases reference only minor bleeding at the access site.[22] Considering the lack of evidence to guide the invasive management of iliofemoral venous DVT, particularly in the setting of mild symptoms such as are often present in AIVC, a full assessment of the risks, benefits, and alternatives must be undertaken and the treatment should be individualized to the patient. Moreover, all treatments are predicated on periprocedural conservative management with anticoagulation and compression.

Acute Deep Venous Thrombosis With Severe Symptoms (Leg Swelling, Venous Congestion)

In patients who present with more severe symptoms, the risk-benefit ratio for invasive management is altered, and progressively more so as the pathology approaches limb-threatening stages. Fortunately this situation is rare in the setting of congenital absence of the IVC, given that the compensatory collateral pathways have matured over time. Nonetheless, debilitating acute limb swelling and the presentations of phlegmasia cerulea dolens, phlegmasia alba dolens, or even venous gangrene are possible. In these settings, the focus of treatment is rapid restoration of deep venous circulation for limb-salvage purposes.

The aforementioned techniques and principles remain unchanged except that pharmacomechanical thrombectomy would be favored compared with isolated catheter-directed therapy given that it restores luminal patency more rapidly (see Chapters 148 and 161). Open venous thrombectomy may also be considered (see Chapters 148 and 160).[27]

Severe Symptoms Refractory to Thrombolysis and Compression or Severe Chronic Sequelae (Venous Ulceration)

In the setting of refractory symptoms of chronic venous insufficiency, the initial consideration should be to ensure that the iliofemoral veins are patent using techniques described previously (venography and intravascular ultrasound). If there is evidence of chronic disease peripheral to the congenitally absent IVC, there may be a role for venography with or without angioplasty. Although stenting is employed widely in the treatment of thrombotic and nonthrombotic iliofemoral venous lesions, the success of stenting is predicated on a widely patent conduit with adequate inflow and outflow. In the setting of an absent IVC, the risk of thrombosis may be prohibitive with regard to iliofemoral venous stenting.

As a last resort in a patient with debilitating chronic venous insufficiency and after confirming that the peripheral veins are patent, an open venous reconstruction may be warranted.[28] The majority of the literature as it relates to open reconstruction of the IVC is in the setting of oncologic resections (see Chapter 167).[29] The principles of adequate inflow, outflow, and conduit still require strict adherence. Preoperative axial imaging is especially helpful for operative planning; it can identify the extent of the defect and the presence of abdominal wall collaterals, which, if injured or ligated during surgery, can lead to excessive bleeding.

Autologous tissue is preferred for conduit because lifelong anticoagulation may not be needed, as it would be for synthetic grafts. Aortic and IVC homografts have both been utilized.[30] In depopulated homografts there does not appear to be a concern for rejection; however, some authors report placing patients on immunosuppression for up to 1 year postprocedure.[31] Another theoretical complication is aneurysmal degeneration; however, this has not been observed in patients undergoing reconstruction of the IVC. The configuration of the proximal and distal anastomoses (end to end or end to side) is determined by the anatomy. An arteriovenous fistula may be created to ensure adequate inflow. However, in one series of three patients undergoing arteriovenous fistula construction concomitant with IVC reconstruction, high-output cardiac failure occurred in two of the three patients. The fistulas were all ligated accordingly.[32] Although the data for open IVC reconstructions are limited, anecdotal reports suggest the potential for long-term patency.[29,30] Overall, the clinical success of any open reconstruction is predicated on continued and diligent conservative management with anticoagulation and compression.

SUMMARY

It is likely that most cases of congenital absence or occlusion of the IVC remain undiagnosed and if asymptomatic are considered of little clinical importance. However, this diagnosis should be considered in patients under the age of 30 with idiopathic DVT. In association with extensive iliofemoral DVT and/or thrombophilia, management of this condition can be challenging. Based on the severity of presenting symptoms, thrombolysis should be considered in these patients, with an endpoint of restoring baseline venous flow to previously established venous collaterals. Long-term anticoagulation is often indicated, particularly if thrombophilia is identified. Table 163.1 summarizes the presentation and treatments of all recent publications.

INTRODUCTION

Portal hypertension (PHT) occurs when there is an abnormal increase in pressure in the veins that carry blood from the visceral organs to the liver. This can be explained by Ohm's law, where the change in pressure is equal to the flow times the resistance ($P = Q \times R$). Therefore the pressure can be increased by increasing the flow or increasing the resistance. Normal portal pressure is between 5 and 10 mm Hg. Clinically significant portal hypertension (PHT) occurs at pressures of 10 mm Hg above systemic venous pressure. Both intrahepatic and portocollateral resistance can increase vascular resistance when compared to the low resistance of a normal liver.[1]

PATHOPHYSIOLOGY

PHT occurs as the result of an increase in portal flow, an obstruction to portal circulation resulting in increased intrahepatic resistance, or both. An increase in intrahepatic resistance is seen due to narrowing of the vascular lumena from distortion of sinusoidal structures and regenerative nodule formation in the cirrhotic liver. Hepatic stellate cells have also been shown to play a role in the development of increased intrahepatic resistance due to their enhanced contractility and the development of intrahepatic vasoconstriction. In normal conditions, they regulate sinusoidal blood flow by the balance between vasoconstrictors and vasodilators. In the cirrhotic liver there is a decrease in vasodilators and an increase in vasoconstrictors, as well as an increase in fibrosis, which promotes overall intrahepatic vasoconstriction and an increase in portal pressure.[2,3]

Portal blood flow is increased by vasodilation in the splanchnic vasculature. While the liver experiences vasoconstriction of the intrahepatic vessels, the splanchnic vessels are affected by endogenous vasodilators and a decrease in reactivity to vasoconstrictors. This is the main cause of the increase in portal blood flow seen in cirrhosis. Splanchnic vasodilation is

Abstract

Portal hypertension occurs when there is an abnormal increase in the pressure in the veins that carry blood from the visceral organs to the liver. It is responsible for causing many findings seen with liver disease, such as ascites, abdominal wall varicosities, spider angiomas, palmer erythema, gynecomastia, and muscle wasting. Encephalopathy, asterixis, and fatigue may also be present. Collaterals form to connect the high-pressure portal veins with the low-pressure systemic veins and thus develop into the diseased gastroesophageal varices that are susceptible to bleeding. This chapter serves to explain the pathogenesis behind the evolution of portal hypertension, as well describe common causes and up to date management.

compensated by an increase in heart rate and cardiac output early on, but eventually results in arterial hypotension. The arterial hypotension in turn activates high-pressure baroreceptors and the sympathetic nervous system. This causes the release of vasoconstrictors which affect the peripheral but not the splanchnic vessels, leading to a hyperdynamic circulation. Collaterals form to connect the high-pressure portal veins with the low pressure systemic veins and develop into gastroesophageal varices. Shunting of blood into the systemic system occurs, resulting in hepatic encephalopathy.[2]

CLASSIFICATION

PHT is classified according to anatomic location, as extrahepatic, intrahepatic, and posthepatic. Posthepatic causes include veno-occlusive disease and cardiac conditions. These categories are further subdivided according to their relationship to sinusoids within the liver (Table 164.1).

TABLE 164.1 Causes of Portal Hypertension

Presinusoidal
Portal Vein Thrombosis
Omphalitis
Pancreatitis
Trauma
Malignancy
Hypercoagulable states
Other
Polycythemia vera
Biliary atresia
Schistosomiasis
Sarcoidosis
Wilson disease
Congenital hepatic fibrosis
Sinusoidal
Cirrhosis
Toxic hepatitis
Postsinusoidal
Cirrhosis
Hemachromatosis
Veno-Occlusive Disease
Budd-Chiari syndrome
Hepatic vein webs
Malignant obstruction
Hypercoagulable states
Cardiac
Congestive heart failure
Constrictive pericarditis

Extrahepatic Presinusoidal Obstruction

Presinusoidal extrahepatic obstruction is most commonly caused by thrombosis of the portal vein. Portal vein thrombosis occurs in both children and adults. In children, the most common cause is infectious, such as appendicitis or omphalitis. In adults, there are multiple causes, including hypercoagulable states, inflammatory diseases, complications of medical interventions, malignancy, and most commonly cirrhosis. Portal vein thrombosis occurs with an incidence of 0.6% to 22% in adult patient with these conditions.[4]

Intrahepatic Presinusoidal Obstruction

Intrahepatic presinusoidal obstruction occurs from fibrosis and compression of portal venules, which subsequently restrict portal flow. This can be seen with hepatic fibrosis, sarcoidosis, chronic arsenic exposure, Wilson disease, hepatoportal sclerosis, primary biliary cirrhosis, schistosomiasis, and myeloproliferative disorders. Wilson disease is a hereditary disorder of copper metabolism, in which copper accumulates in hepatocytes due to an inability to excrete copper into the biliary system.

Schistosomiasis is the most common cause of PHT in third world countries. It occurs from ova deposition in portal vein walls, resulting in a granulomatous inflammatory reaction that causes fibrosis and restriction of portal blood flow. The mechanism of action in myeloproliferative disorders involves deposition of cellular material into the portal zones. In sarcoidosis the deposition of sarcoid granulomas within the portal vein leads to its obstruction and increase in portal blood flow.[5,6]

Intrahepatic Sinusoidal and Postsinusoidal Portal Hypertension

Sinusoidal hypertension results from alcoholic, viral, and toxic hepatitis. Postsinusoidal obstruction is caused by alcoholic liver disease, postnecrotic cirrhosis, and hemochromatosis. Together, sinusoidal and postsinusoidal hypertension resulting in cirrhosis are the most common causes of PHT in the Western world. The mechanism of action is mechanical obstruction of portal blood flow by regenerating hepatic nodules and cirrhotic bands in the liver. In addition to the effects on the hepatic sinusoids, these phenomena can also damage presinusoidal and postsinusoidal structures. The normal architecture becomes distorted.

Cirrhosis also results in increases in hepatic blood flow. The liver generates multiple arteriovenous shunts and collaterals, which lead to nearly 33% of blood flow bypassing functional hepatocytes. This causes an increase in cardiac output and diminished systemic resistance, therefore elevating hepatic wedge pressure and portal liver pressure. Moreover, since a third of portal blood is shunted away from functioning hepatocytes, the cirrhotic patient develops impaired hepatic function.[1-3]

Extrahepatic Postsinusoidal Obstruction

Extrahepatic postsinusoidal obstruction results from hepatic vein thrombosis and cardiac disease. Precipitating factors for

hepatic vein thrombosis include malignancies, trauma, pregnancy, and oral contraceptives. Hepatic vein occlusion also occurs in Budd-Chiari syndrome, which in turn is associated with myeloproliferative disorders and hypercoagulable states.[1-3]

Arteriovenous Fistulae

Arteriovenous fistulae cause PHT by increasing flow in the portal circulation. As the disease progresses to fibrosis and obstruction of the presinusoidal spaces, PHT is exacerbated. Arteriovenous fistulae can be caused by percutaneous transhepatic manipulation or penetrating trauma. They can also be associated with splenic fistulae from splenic artery aneurysms, sarcoidosis, Gauche disease, and myeloid metaplasia.[1-3]

CLINICAL PRESENTATION

Physical examination findings consistent with liver disease include ascites, spider angiomas, palmer erythema, gynecomastia, enlarged abdominal wall collateral veins (caput medusae), and muscle wasting. Encephalopathy, asterixis, and fatigue may also be present. In many cases, variceal bleeding constitutes the initial presentation.[7-9]

COMPLICATIONS OF PORTAL HYPERTENSION

Variceal Formation and Hemorrhage

The formation of portal-systemic collaterals is seen when portal pressures reach 10 to 12 mm Hg above systemic venous pressures. Due to elevated portal pressures and increased splanchnic blood flow diverted from the portal to the systemic system, the vascular resistance of the collateral beds increases. Although it is lower than the obstructed portal system, it is still higher than normal portal pressure. This phenomenon explains why the formation of portal-systemic collaterals does not normalize the elevated portal pressures.[10]

Varices are mainly the result of dilation and dysfunction of the preexisting embryonic connections between the portal and venous systems, but formation of new blood vessels via neoangiogenesis also occurs. These new vessels are abnormal, with marked hyperplasia and hypertrophy of their walls. The left gastric vein arising from the portal vein and the short gastric veins arising from the splenic vein are the vessels most often affected.[10]

Esophageal varices form when the left gastric vein becomes dilated, and both esophageal and gastric varices form as a result of dysfunction and dilation of the short gastric veins. These vessels divert portal blood flow into the azygos venous system via the venous plexus of the lamina propria and submucosa of the esophagus and stomach. Esophageal varices form from the distal to proximal esophagus and can be divided into four zones: the gastric, palisade, transitional, and truncal zones. The transitional zone is defined as the 2 cm above the gastroesophageal junction and extends superiorly for another 2 cm; it is the zone most susceptible to bleeding. Gastric varices can be divided into type I and type II, where type I are gastric varices that extend above the cardia as esophageal varices and type II are isolated to the stomach, most commonly on the fundus.[10]

Varices can also be seen on the abdominal wall from collateralization between the left portal vein and the systemic system via periumbilical veins in the falciform ligament. The physical exam finding associated with this is known as caput medusae.

Esophageal and gastric varices are present in roughly 50% of cirrhotic patients at the time of diagnosis, and the incidence increases to 90% of patients with long-term follow-up. Rupture with bleeding occurs from small varices (<5 mm) in 7% of patients over a 2-year period, and in 30% of patients with large varices over the same period.[9] The mortality rate after the first bleed reaches 35%, and 60% of patients re-bleed within the first year. Each additional bleed carries a mortality rate of 20%.[1,11]

The most widely accepted explanation as to why varices bleed is the explosion hypothesis. It suggests that when the hydrostatic pressure inside varices increases to above 10 mm Hg, variceal dilation, and a decrease in wall thickness occurs. Ruptures occur when the tension in the expanding wall can no longer be countered by wall tension (Law of LaPlace). The critical hepatic venous pressure gradient is 12 mm Hg. In the presence of varices, pressures above 12 mm Hg are associated with a significant risk of variceal bleeding; however, the magnitude above this value does not necessarily correlate with risk of hemorrhage. Medical therapy and interventions are aimed at keeping the hepatic venous pressure gradient below 12 mm Hg; pressures below this level are associated with minimal risk of bleeding.[10]

Ascites

Ascites occurs in up to 80% of patients with PHT. With the increase in portal pressure, Starling forces drive fluid out of vessels and into the interstitial space, causing ascites. Low oncotic pressure resulting from the hypoalbuminemia manifested by cirrhotic patients also occurs, exacerbating the problem. In addition, the lymphatic system typically becomes overwhelmed.[5]

The accumulation of ascites places patients at risk for spontaneous bacterial peritonitis (SBP). In the past, approximately 75% of these infections were attributed to gram-negative aerobic bacteria, suggesting the gastrointestinal tract as the source. However, more recent data show that up to one-third of cases are associated with gram-positive bacteria.[12,13] Approximately 30% of patients with ascites require hospital admission at some point for antimicrobial treatment of SBP. Its presence is associated with increased mortality in cirrhotics.[14]

Encephalopathy

Hepatic encephalopathy refers to any neuropsychiatric dysfunction caused by liver disease. The symptoms are broad, ranging from subclinical to coma or death. Due to malfunctioning hepatocytes and portosystemic shunting, increased levels of

ammonia and glutamine derived from ammonia occur in the arterial system. These cause dysfunction of astrocytes in the brain as well as mitochondrial dysfunction, ultimately resulting in alterations of cerebral function, cerebral edema, and potentially cerebral herniation. These changes are graded by the Wes Haven Criteria. Grades I and II include mild symptoms such as changes in cognition, altered sleep patterns, mood changes (anxiety or euphoria), mild disorientation, asterixis, and increasing apathy and drowsiness. Grades III and IV consist of somnolence or coma.[7,15]

Encephalopathy occurs in 30% to 40% of patients with decompensated liver failure and is associated with an increase in mortality.[7] It is thought that obstruction of blood flow in the liver together with the development of collaterals result in the shunting of neuroactive peptides into the systemic circulation. It is considered a reversible disorder; early recognition can prevent progression.[16]

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) occurs when renal function is decreased in the presence of cirrhosis and ascites. It is considered a "diagnosis of exclusion"; therefore, other causes of renal dysfunction must be ruled out to confirm its presence. Clinically it presents as oliguria, hyponatremia, and low urinary sodium output. It can occur rapidly (deterioration of renal function within 2 weeks) or as a more chronic disorder. Rapid deterioration is associated with a poor prognosis; only 10% of patients survive hospitalization.[17]

Hepatopulmonary/Portopulmonary Syndromes

These syndromes are defined as combinations of PHT, pulmonary hypertension, pulmonary vasodilation/shunting, and impaired oxygenation. They present with clubbing, dyspnea, and deoxygenation induced by the upright position. In general, mortality is the result of liver failure rather than pulmonary complications.[18]

DIAGNOSIS

Laboratory Evaluation

The initial evaluation of liver disease should include an arterial blood gas, lactate, complete blood count, International Normalized Ratio (INR), activated partial thromboplastin time (aPTT), fibrinogen, factor V level, aspartate aminotransferase (AST), alanine aminotransferase (ALT), bilirubin, alkaline phosphatase, lactate dehydrogenase (LDH), amylase, lipase, magnesium, phosphorous, creatine kinase, and comprehensive metabolic panel. Ammonia levels are commonly obtained, although they have not been shown to correlate well with neurologic abnormalities.[9] The results of these studies in conjunction with the history of onset and physical examination findings can help determine whether liver dysfunction is acute or chronic, and determine its severity.[19]

Specific testing for etiology should also be included in the diagnostic evaluation, including viral hepatitis immunology, human immunodeficiency virus (HIV), ceruloplasmin, serum copper, antinuclear antibody, and a toxicology screen.[19]

A decrease in serum testosterone has been seen in up 90% of men with cirrhosis, and low testosterone levels are associated with an increase in mortality. The conversion rates of testosterone to estradiol are significantly increased in men with cirrhosis, while the overall plasma production rates of estradiol and clearance rates of estradiol remain similar to men without cirrhosis. These findings may be responsible for the physical examination findings described previously and are associated with liver failure. However, data supporting the specific mechanisms of action are lacking.[20,21]

Upper Gastrointestinal Endoscopy

Endoscopy is critical in the evaluation of patients with PHT to diagnose and evaluate varices, and should be performed in all patients with varices, regardless of whether they have bled. After an episode of bleeding, it is recommended that repeat endoscopy be performed every 3 to 6 months. Endoscopy can also diagnose gastropathy, gastritis, ulceration, and mucosal lacerations.[8,11,22]

Liver Biopsy

Liver biopsy can determine the etiology of liver disease as well as its acuity. Although the necessity of biopsy is controversial, determining the cause of PHT through biopsy is useful in guiding treatment. Pathologic features of cirrhosis include rounding of edges seen on low power with remodeling of hepatic architecture causing nodularity, loss of terminal hepatic venules in parenchyma between portal tracts, spacing between portal tracts, portal veins and hepatic veins, increase in vascular channels within areas of scar and fibrous tissue, and evidence of hepatocyte regeneration. Plasma cells at the portal/septal interface can be seen in chronic hepatitis B infections. Mallory-Denk bodies are seen with alcoholic liver disease, but are also present in Wilson disease, drug-induced liver disease, and primary biliary cirrhosis.[23] Mallory-Denk bodies (MDB) are eosinophilic cytoplasmic inclusion bodies that hover near the hepatocyte nucleus. The clinical and prognostic significance of MDBs is not entirely clear, but their accumulation is reversible with removal of the causal agent, such as abstaining from alcohol. Therefore if seen on biopsy, consideration may be given to postponing elective procedures to allow the liver time to heal.[24,25] Chronic schistosomiasis results in a characteristic "pipestem" fibrosis and may demonstrate calcified eggs and periportal granulomas; the acute infection will demonstrate live eggs surrounded by eosinophils.[23]

Duplex Scanning

Duplex scanning is a simple and effective way to determine portal vein patency. It can also determine direction of flow through the portal vein. This information is imperative in

preoperative planning for TIPS, shunt procedures, and liver transplant. It is also a key surveillance tool after these procedures to confirm portal vein patency.[26,27]

Computed Tomography Angiography

Computed tomography angiography (CTA) can be performed in the setting of normal renal function to determine portal vein patency and provide clues to the chronicity of thrombus, if present. CTA can also identify other pathologic features of liver disease such as nodularity of liver parenchyma and the presence of malignancy.[27]

Percutaneous Angiography

Transhepatic percutaneous portal venography is necessary for evaluation of anatomy of the portal vein prior to surgical shunting procedures. It can be achieved by evaluating the venous phase following selective catheterization of the celiac and superior mesenteric arteries. The procedure is used to define the portal tributaries as well the portal hepatic wedge pressure, which quantifies the presence and severity of PHT. It can also be useful in determining the extent of cirrhosis. In advanced cirrhosis, the network of dense collaterals and dilation of the hepatic artery will become apparent on angiogram, as will reversal of flow in the portal vein.[28-30]

NONSURGICAL TREATMENT OF PORTAL HYPERTENSION AND ITS COMPLICATIONS

The goal of treatment of PHT is to prevent and/or control complications, in particular variceal bleeding, ascites, and encephalopathy.

Prevention and Treatment of Variceal Bleeding

Prevention and treatment of variceal bleeding is divided into primary prophylaxis (treatment to prevent bleeding before it occurs), treatment of acute variceal hemorrhage, and secondary prophylaxis (treatment after a bleeding episode to prevent a second one).

Primary Prophylaxis

Preferred options for primary prophylaxis include nonselective beta blockade, endoscopic variceal band ligation (EBVL), and endoscopic sclerotherapy.

Nonselective Beta Blockade

Propranolol has been used in the prevention of both primary and recurrent variceal bleeding. It is a nonselective beta-blocker; it is thought that by reducing cardiac output and thereby systemic pressure, it reduces portal venous pressure. Nonselective beta blockers are recommended in patients with small varices and high risk of bleeding and in all patients with large varices. The decision as to which nonselective beta-blocker is better is unclear, but there is some evidence that carvedilol may offer added benefits over propranolol. Beta blockade in the treatment of acute bleeding episodes has not been studied.[11,31]

Endoscopic Variceal Band Ligation

EBVL is indicated as primary prophylaxis in patients with medium and large esophageal varices and a high risk of bleeding. In those without high bleeding risk, the efficacy is similar to that of prophylaxis with nonselective beta blockade alone. EBVL has risks of esophageal perforation, pain, and bleeding; therefore, most physicians recommend beta blockade in patients at low risk for bleeding unless contraindicated.[11] Repeat endoscopy is recommended every 3 to 6 months.[32]

Endoscopic Sclerotherapy

Endoscopic sclerotherapy is recommended in patients with gastric varices as primary prophylaxis. In these patients, the efficacy is greater than prophylaxis with beta blockers. Adverse events are rare but include pulmonary and cerebral embolization.[11]

Cyanoacrylate sclerotherapy has been used for treatment of bleeding gastric ulcers in patients with decompensated cirrhosis who are not candidates for transjugular intrahepatic portosystemic shunt (TIPS) procedures. Cyanoacrylate causes polymerization and hardening upon contact with blood. In published studies, it has been shown to stop bleeding in 93% of these patients; early re-bleeding occurred in only 7%. No postprocedural complications were seen.[33]

Endoscopic sclerotherapy is as effective as endoscopic variceal ligation in the treatment of high risk patients with esophageal varices as prophylaxis and in the acute setting of variceal hemorrhage.[32,34] In one study, both techniques were effective as prophylaxis in 80% of high risk patients.[34] Another studied demonstrated that the use of either technique achieved complete control of active bleeding in 100%.[32]

Acute Variceal Hemorrhage

Acute variceal hemorrhage will stop spontaneously in 40% to 50% of patients. This is thought to be secondary to hypovolemia and subsequent splanchnic vasoconstriction.[35] Because of this, transfusions should be given sparingly to avoid rebleeding.

Treatments used to control active hemorrhage include vasoactive agents such as vasopressin, somatostatin, and octreotide, balloon tamponade, EVBL, and/or endoscopic sclerotherapy (described previously), balloon-occluded retrograde transvenous obliteration (BRTO), and TIPS.

Vasopressin

Vasopressin was formerly considered first line therapy for active bleeding from varices, and has been shown to control bleeding in 60% to 80% of cases. Moreover, it is the only medication shown to decrease mortality.[35] Its use leads to decreased portal flow and, in turn, decreased hepatic flow. However, its vasoconstrictive effects can lower cardiac output; it is therefore used in conjunction with other pharmacologic agents that increase cardiac output without reducing the positive effects of decreased portal flow.[36]

Somatostatin/Octreotide

Somatostatin and octreotide have the same effects as vasopressin in lowering splanchnic blood flow, but have fewer side effects. Somatostatin is a tetradecapeptide derived from the hypothalamus, and octreotide is a synthetic analog of somatostatin. Octreotide has a longer half-life than somatostatin (100 vs. 2 minutes). Both have been shown to control bleeding and decrease portal venous pressure. Somatostatin appears to produce less cardiac compromise when compared to vasopressin.[5]

Balloon Tamponade

Balloon tamponade is effective in controlling acute variceal hemorrhage. A tube with one or two inflatable balloons is inserted into the stomach; the balloon or balloons are then inflated to compress gastric and esophageal varices. The technique originated in the 1950s, and the balloons are named after their developers, Linton-Nachlas and Sengstaken-Blakemore. The Sengstaken-Blakemore tube is composed of two balloons, one to control esophageal varices and the second to control gastric varices, as well as a port to suction gastric contents. It has been shown to control initial hemorrhage in up to 95% of patients and results in permanent cessation of bleeding in 40% to 50%.[37,38] The Minnesota tube is a variation of the Sengstaken-Blakemore tube that includes an additional lumen to suction esophageal secretions.

The use of balloon tamponade is generally reserved for patients unresponsive to medical therapy and is thought to be a bridge to more permanent control such as endoscopic banding, sclerotherapy, or surgery.[38] Complications associated with its use include aspiration pneumonia, airway obstruction, tube migration, and esophageal ulceration and rupture.[39] To some extent these can be avoided by using indirect laryngoscopy with a glidescope to position the tube properly.[40]

Balloon-Occluded Antegrade and Retrograde Transvenous Obliteration

Endoscopic treatments can be used in conjunction with BRTO in the management of large, high flow gastric varices when bleeding cannot be controlled by these treatments alone or by TIPS. The goal of the therapy is to occlude portosystemic collaterals that exist between the stomach and the renal vein ("gastro-renal shunts") using a systemic transvenous access such as the common femoral vein. Esophageal varices should be treated prior to utilizing BRTO. Portal vein patency should be evaluated prior to BRTO, as the presence of an occluded portal vein may mean that the gastrorenal shunts constitute the primary outflow for mesenteric and splenic veins. In this situation, occlusion of the shunts may cause mesenteric venous hypertension.

The procedure is performed using an occlusion balloon inserted percutaneously from the common femoral vein into the outflow of the gastrorenal shunt, resulting in occlusion of the tract (Fig. 164.1). Venography can be performed to define the extent of the outflow tract and varices. A sclerosing agent such as sodium tetradecyl sulfate or polidocanol is then injected into the varices and outflow track via a microcatheter advanced next to the occlusion balloon. The presence of the balloon allows the sclerosant to dwell longer and prevents reflux into the systemic or portal system. Balloon occlusion is maintained 4 to 24 hours, and re-imaging is then performed prior to balloon deflation to confirm obliteration. The efficacy is 91% to 100% in patients with gastrorenal shunts. However, it can result in increased PHT and esophageal varices if they are not treated first.[11,41]

Balloon-occluded antegrade transvenous obliteration (BATO) can also be used alone to treat bleeding gastric varices or with BRTO if it fails. The goal of BATO is to occlude portosystemic

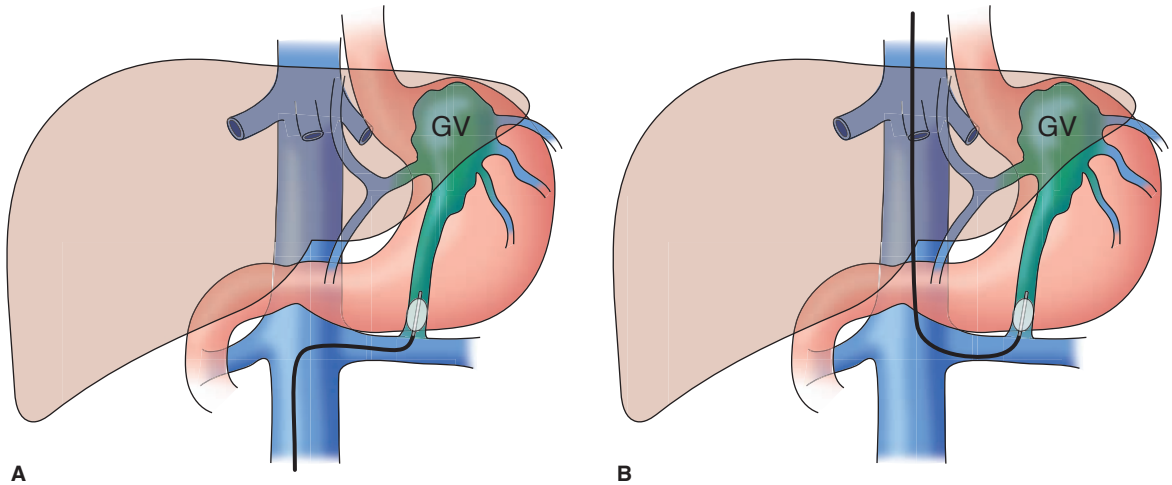

Figure 164.1 Balloon-occluded retrograde transvenous obliteration (BRTO): Illustration demonstrating the basic transfemoral (A) and transjugular (B) approaches for conventional BRTO of gastric varices *(GV)*. BRTO is approaching the GV from the systemic venous side. Balloon-occluded antegrade transvenous obliteration is approaching the gastric varices from the portal venous side. (From Saad WE, Kitanosono T, Koizumi J. Balloon-occluded antegrade transvenous obliteration with or without balloon-occluded retrograde transvenous obliteration for the management of gastric varices: concept and technical applications. *Tech Vasc Interv Radiol.* 2012;15[3]:203-225.)

collaterals from the portal system via the gastric veins or to occlude them in an antegrade fashion. BATO utilizes a portal venous approach in one of three ways, percutaneous transhepatic obliteration, an existing TIPS, or trans-ileocolic vein obliteration. The percutaneous transhepatic obliteration approach is technically similar to that of performing a percutaneous transhepatic cholangiogram, except that the target is the portal vein rather than the bile ducts. TIPS is only utilized if already present, or if the planned treatment for the patient includes TIPS. Trans-ileocolic vein obliteration is used mainly to treat mesenteric varices and is rarely done.

The technique for BATO (Fig. 164.2) is similar to BRTO. When a TIPS is present, BATO can be used routinely with BRTO as the portal vein access is already established.[42] BATO has been shown to increase the technical success of BRTO alone from 84% to 98% to 98% to 100%.[43]

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunts, commonly referred to as TIPS, are performed for refractory variceal bleeding and refractory ascites.[44,45] The TIPS procedure (Figs. 164.3 and 164.4) has been well described, and in high volume institutions, the technical success reaches 97%. The rate of major complications is low (<3%). The procedure is initiated via either internal jugular vein using ultrasound guidance. The right hepatic vein is then selected with a 5 French curved catheter,

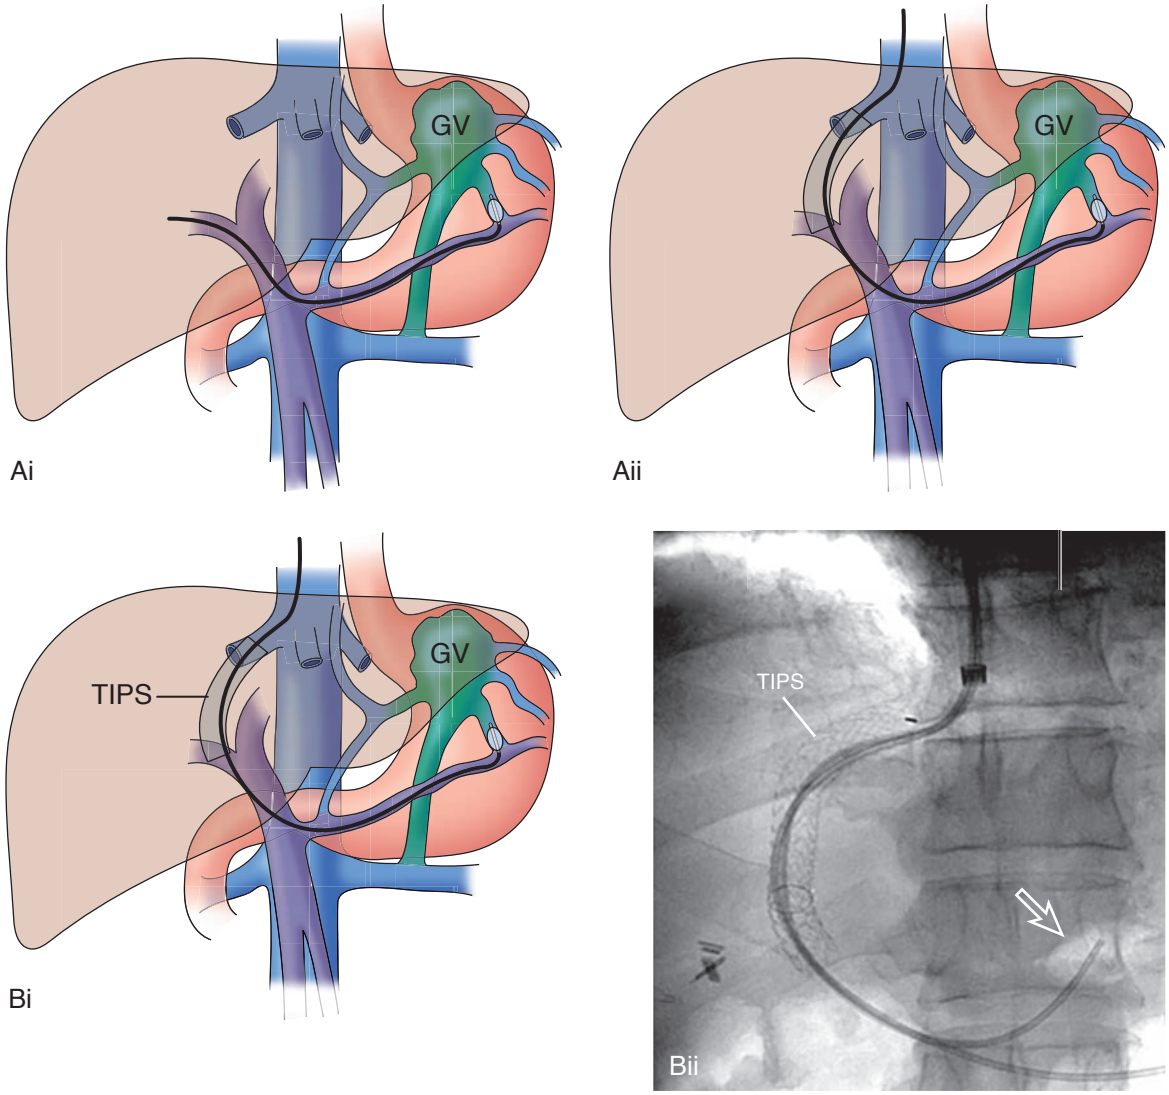

Figure 164.2 (A) Balloon-occluded antegrade transvenous obliteration (BATO): Illustration demonstrating BATO and its subclassification into percutaneous transhepatic obliteration (PTO, panel Ai) and trans-TIPS (transjugular intrahepatic portosystemic shunt, panel Aii) obliteration. Figure 164.3 Determining the Shunt Length. (A) Wedged CO_2 contrast portogram. (B) Portography with additional contrast injection through 10 Fr sheath located at the right hepatic vein inferior vena cava junction to measure required length of endograft. (C) Portography after 7 cm covered length Viatorr endograft deployed. (Schematic of transjugular intrahepatic portosystemic shunt [TIPS.jpg]—figure 2 from Keller FS, Farsad K, Rosch J. The transjugular intrahepatic portosystemic shunt: technique and instruments. *Tech Vasc Interv Radiol.* 2016;19:2-9.)

as it has the best trajectory for portal vein access. The left or middle hepatic veins can also be used, but are technically more difficult. A balloon catheter is used to perform a wedged hepatic venogram to opacify the portal vein target. The catheter is then aimed toward the portal vein. A 10 French guide catheter is directed against the hepatic vein wall, and a locked trocar stylet and 5 French catheter are passed through the liver parenchyma and into the portal vein target. The stylet is removed, and the 5 French catheter is aspirated to confirm placement into the portal vein with adjustment as necessary. Once there is blood return, contrast is used to confirm placement. A guidewire is then advanced into the portal vein, and the access set and 10 French guide catheter are advanced into the portal system. Once in place, the inner components of the set are removed and a marker catheter is used to define the anatomy of the splenic and mesenteric vessels. The larger sheath is then also withdrawn leaving the marker catheter for pressure measurements. The large sheath is passed over a wire into the portal vein once again and is used to aid in deployment of a covered stent graft across the newly created channel. After deployment, the stent is angioplastied. Repeat pressure measurements are taken to confirm a decrease in the portosystemic gradient to less than 12 mm Hg.[46]

The hepatic venous pressure gradient can be used as a predictor of rebleeding after an episode of acute bleeding. A hepatic venous pressure gradient ≥20 mm Hg is associated with failure of treatment, greater transfusion requirements, more admissions to the intensive care unit (ICU), and decreased survival. Early TIPS placement in high risk patients reduces treatment failure, in hospital mortality, and 1 year mortality.[47] These patients have better outcomes with prophylactic TIPS performed after an initial acute variceal bleed to prevent further complications from rebleeding.[44]

In the event of gastric and ectopic variceal bleeding, TIPS has been shown to stabilize and prevent rebleeding after acute gastric bleeding and has a lower recurrence rate than BRTO. However, in cases of refractory gastric bleeding, BRTO can be used subsequently to embolize larger gastric veins, which facilitates flow toward the TIPS. BRTO can be used primarily in the treatment of gastric varices if patients are not candidates for TIPS due to hepatic encephalopathy or marginal liver function. In general, the literature lacks direct comparisons of TIPS to BRTO in the treatment of gastric varices. Severity of PHT, hepatic reserve, and complications of liver cirrhosis should be considered when deciding which procedure to proceed with in the management of gastric varices.[48]

Recently, there has been a report of using Paclitaxel-coated balloons to treat in-stent stenosis after TIPS. This technology is promising in terms of improving secondary patency.[49]

Secondary Prophylaxis

Mortality associated with rebleeding of varices approaches 40%, and most commonly occurs within the first 5 days after the initial episode. Without adequate prophylaxis, the risk of rebleeding approaches 80% at 1 year.[50]

The mainstays of therapy for secondary prophylaxis to prevent rebleeding are nonspecific beta blockade and EBVL. The combination of both treatments is more efficacious than either treatment alone, resulting in a rebleeding rate of less than 50%.[9] TIPS has been shown to reduce rebleeding by approximately

The transjugular intrahepatic portosystemic shunt: technique and instruments. *Tech Vasc Interv Radiol*. 2016;19:2-9.)

30% compared with endoscopic treatment alone, but is associated with increased encephalopathy.[51]

Treatment of Ascites

Spironolactone and furosemide remain the most commonly used treatments for ascites, given their efficacy and lack of adverse consequences. Initial doses are 100 mg of spironolactone and 40 mg of furosemide daily; these can be increased to a maximum of 400 mg and 160 mg, respectively. Spironolactone alone is effective in promoting weight loss, but the addition of furosemide is protective against hyperkalemia. Patients in whom these medications are ineffective or not tolerated are candidates for paracentesis or TIPS.[9]

Treatment of Encephalopathy

Encephalopathy is treated by correcting inciting conditions, including variceal bleeding, infection, and electrolyte imbalances, and by restricting the production and absorption of ammonia. Lactulose is effective in preventing ammonia absorption and increasing fecal nitrogen excretion.[52]

Neomycin is also effective in the treatment of encephalopathy, but side effects (nephrotoxicity and ototoxicity) limit its use.[53]

Hepatic and Portal Vein Recanalization

In patients with PHT complicated by portal or hepatic vein thrombosis, recanalization of these veins has the potential to reduce symptoms and complications. A recent retrospective study performed in the United Kingdom reported the results of endovascular recanalization of the hepatic vein in patients with Budd Chiari syndrome.[54] The study evaluated outcomes in 63 patients treated with venoplasty of the hepatic vein ± stent placement over a 27-year period. The efficacy of the treatment was compared with a previous report using TIPS published by the same investigators.[55] Access was established via the femoral or internal jugular vein. In the event the hepatic vein could not be accessed via the inferior vena cava, a percutaneous transhepatic approach was used. Once the wire was in place, it was snared using the jugular approach, and the rest of the procedure performed from the jugular route. A large balloon catheter was used to dilate the obstructed hepatic vein. If balloon dilation was ineffective, a bare metal stent was deployed. Technical success was reported as 100%, with symptom resolution in 73%. Patency rates were similar between the patients undergoing recanalization and the historical TIPS group, ranging from 70% to 90% at 1 year and 60% to 80% at 10 years. Survival rates were also similar, but procedural complications (9.5% vs. 27.1%) and hepatic encephalopathy (0% vs. 18%) were significantly lower in patients treated with vein recanalization. The authors concluded that TIPS should be reserved for failure of recanalization.[54]

Portal vein recanalization has also been used in conjunction with TIPS to improve candidacy for liver transplant in patients with portal vein thrombosis. The procedure is performed via access from the internal jugular and splenic veins. After the TIPS stent is deployed, the confluence of the stent and the portal vein is venoplastied. This technique generally opens the portal vein without further intervention. Embolization of existing varices and/or splenorenal shunts is sometimes performed to improve patency of the portal vein.

In one study, the initial success rate approached 100%, and the patency rate was 92% at 17 months. Twenty-three of 61 patients enrolled in the study underwent successful liver transplantation.[56]

SURGICAL TREATMENT OF PORTAL HYPERTENSION

Portosystemic bypasses were first used to treat variceal bleeding with promising results; the recurrence rate was less than 3%.[57] These bypasses were then studied as prophylaxis to prevent variceal bleeding. However, prophylactic shunting did not demonstrate a benefit over medical therapy in survival rates, and demonstrated an increase in the incidence of severe hepatic encephalopathy when compared with medical therapy alone. Because of this, surgical shunting is not recommended as prophylaxis.

Portosystemic shunting has also been studied with respect to quality of life and survival. Studies demonstrated that while the rebleeding rate was greatly reduced, there was no long-term survival benefit.[58] In emergency situations with acutely bleeding varices, portosystemic shunting has been shown to stop bleeding and prevent rebleeding. However, mortality is high, and it is generally not recommended given the efficacy of nonsurgical options.[59,60]

There are two types of shunts: selective and nonselective shunts. A selective shunt preserves blood flow to the portal vein while decompressing esophageal varices. Nonselective shunts drain all portal blood flow to the caval system. The most commonly performed selective shunt is a distal spleno-renal shunt. Nonselective shunts include the portocaval shunt and mesocaval shunt. Selective shunting procedures were initially proposed in an attempt to lower the incidence of hepatic encephalopathy and liver failure associated with nonselective shunts, and early results demonstrated promise.[61]

Portocaval shunts can be performed in end-to-side and side-to-side fashion. The benefit of one technique over the other has not been demonstrated.[62] Anatomic limitations include the diameter of the portal vein as well as a history of portal vein thrombosis and recanalization. The portal vein should be at least 1.0 cm in diameter, and previous thrombosis/recanalization is a relative contraindication, as rethrombosis rates are high in these patients. The approach can be via a midline incision or a right upper quadrant subcostal incision. The duodenum is mobilized, and the IVC is exposed to the level of the hepatic veins. The portal vein is mobilized from the surrounding bile duct and hepatic artery and controlled. If performing an end-to-side anastomosis, the portal vein is divided, and the hepatic end ligated. The IVC is then clamped with a side biting clamp, and the portal vein is anastomosed to the IVC. Portal pressures should be measured and decrease by at least 50%. In the

side-to-side anastomosis, a greater length of both the IVC and portal vein is exposed to bring the two vessels in proximity for the anastomosis. Portal pressures should decrease by 50% after it is completed. An effective side-to-side portocaval shunt can also be created with a large diameter expanded polytetrafluoroethylene (ePTFE) graft.[63]

Mesocaval shunts have been used in cases of refractory variceal bleeding to control hemorrhage, as well as in patients with massive ascites, an obliterated portal vein, extreme obesity, and Budd-Chiari syndrome.[64-66] Mesocaval shunts are technically easier to perform than portocaval shunts. The procedure is performed via a midline laparotomy. The transverse colon is elevated and retracted superiorly, and the small bowel is retracted inferiorly to expose the root of the small bowel mesentery. The root of the transverse mesocolon is opened to expose the superior mesenteric vessels. The superior mesenteric vein (SMV) lies anterior to the artery. The surface of the IVC is then found in the retroperitoneum after mobilizing the duodenum. The IVC is isolated to allow for placement of a side-biting clamp. A bypass is then created between the SMV and the IVC using a large-caliber (18 to 20 mm) prosthetic graft. The IVC anastomosis is created first. When the shunt is opened, portal pressure should decrease by 50%, and there should be a palpable thrill within the graft.[65]

Selective shunting refers to creation of the distal splenorenal shunt. The goal of this shunt is to decompress esophageal varices without diverting portal-splanchnic flow. The procedure is performed via a bilateral subcostal incision. The splenic vein is identified by opening the lesser sac. The right gastroepiploic vein is divided, and the short gastric veins are preserved. The pancreas is rotated anteriorly to expose the splenic vein in its entirety; connections to the pancreas are ligated. The renal vein is isolated by dividing the ligament of Treitz and rotating the fourth portion of the duodenum inferiorly. The splenic vein is then divided, and the portion attached to the SMV ligated. A side-biting clamp is placed on the renal vein, and an end-to-side anastomosis is created between the splenic vein and the renal vein. Pressure measurements are then taken from the SMV, renal and splenic veins. The splenic vein pressure should decrease by 60% to 70%, allowing for preferential drainage of the esophageal varices. All collaterals between the portal-azygous and portal-mesenteric system must be also be divided, and care must be taken to divide the left gastric vein, umbilical vein and falciform ligament as well.[59]

Several randomized controlled studies evaluated the efficacy of the selective distal splenorenal shunt compared with the nonselective portocaval shunt for the management of patients with PHT and bleeding from esophageal varices. In one study, 88% of patients maintained portal hepatic flow in the selective shunt group compared with 5% in the nonselective group. Hepatic function was preserved and encephalopathy improved in the selective shunt group. There was no difference in rebleeding or survival between the two groups.[67] The findings of a second study showed that patients undergoing distal splenorenal shunts had a statistically significant lower incidence of hepatic encephalopathy and liver failure when compared with the nonselective group (18.7% and 62.5%, respectively). Both perioperative and late mortality were reduced in the selective shunt group.[61] In a third study, encephalopathy was decreased in the selective shunt group, but there was no difference in late mortality between the selectively shunted and nonselectively shunted groups.[68] Findings of other studies have mostly confirmed a lower rate of encephalopathy in selectively shunted patients, but whether a significant difference in mortality exists between the two groups remains unclear.[69-71]

There have been many studies comparing portosystemic shunting to endoscopic therapy for treatment of variceal bleeding in patients with cirrhosis and PTH. Twenty-two trials were included in a review from the Cochrane database. Shunt procedures significantly reduced the risk of rebleeding when compared with endoscopic therapy, but significantly increased acute hepatic encephalopathy and chronic encephalopathy. There were no differences in mortality and duration of hospital stay.[72]

TIPS was compared with selective distal splenorenal shunting in a randomized trial for control of variceal bleeding. There were no significant differences in rebleeding, first encephalopathic event, or survival at 2 and 5 years between the groups, but thrombosis, stenosis, and reintervention rates were significantly higher in the TIPS group (82% vs. 11%). The authors concluded that treatment choice should depend on available resources and expertise.[73]

Endoscopic sclerotherapy was compared with portacaval shunting in a randomized trial in cirrhotic patients presenting with acutely bleeding esophageal varices. Both techniques controlled active bleeding in most patients, but surgery was significantly more effective in terms of permanent control of bleeding (100% vs. 20% respectively), episodes of encephalopathy, and overall survival.[74]

A recent retrospective study compared outcomes of surgical shunts versus TIPS for the treatment of complicated PTH over a 20-year period. Shunt failure occurred more frequently after TIPS (16 of 31 vs. 6 of 31), and "shunt failure free" and overall survival rates were higher in the surgically treated patients.[75]

Taken together, the results of these studies suggest the continued benefit and role of operative shunting in the acute and long-term management of bleeding varices and PHT.

Liver Transplantation

Liver transplantation is indicated for end-stage liver disease and not necessarily for management of PTH or variceal bleeding. However, transplantation may be the endpoint of treatment for these patients. In general, the available data suggest that patients who undergo surgical shunt for variceal bleeding have higher survival rates after transplantation than patients treated with endoscopic procedures. In some patients, surgical shunting appeared to eliminate the need for transplantation.[76-78]

INTRODUCTION

The left renal vein as it lies between the aorta and the superior mesenteric artery resembles a nut between the jaws of a nutcracker.

—JCB Grant, 1937

The anatomic configuration resulting in outflow obstruction and subsequent dilation of the left renal vein (LRV) has more colloquially been referred to as the "nutcracker syndrome" (NCS) if presenting with a constellation of symptoms, or "nutcracker phenomenon" (NCP) if LRV compression is found incidentally in otherwise asymptomatic patients.[1,2] A host of other names have been applied to this anatomic scenario, including "LRV entrapment syndrome," or "mesoaortic compression" of the LRV. However, the unique phrasing of this anatomic phenomenon was originally coined after the anatomist Grant likened compression of the LRV between the aorta and superior mesenteric artery (SMA) to that of a nut in a nutcracker in pathologic specimens from the 1930s.[3] Clinical reports of the syndrome were initially reported by the Egyptian urologists Mina and El-Sadr in 1950[4] and followed by venographic characterization by Chait et al. in the early 1970s.[5] It was eventually de Schepper's association of LRV compression, pelvic/perirenal varicosities, and hematuria in the early 1970s that completed the characterization of the syndrome and yielded further interest in the disease process.[6] Initial reports proposing surgical repair through transposition of the LRV were described shortly thereafter by Pastershank in 1974.[7] These initial accounts have given rise to numerous small case series and intermittent case reports in the timeframe since.[8-38]

Unfortunately, there remains a paucity of larger studies and thus no consensus over the optimal management of NCS, including patient selection and procedure of choice. As a result, there remains much controversy regarding the optimal diagnostic and therapeutic approach to NCS. Largely, this can be attributed to several factors, including the rarity of NCS, the nonuniformity in patient symptomatology with diagnostic uncertainty and concomitant delays in diagnosis, varying opinions of the optimal surgical approach and lack of consensus data on the durability and longevity of these different approaches, and the involvement of a host of specialists and subspecialists in the care of these patients. This chapter will focus on the anatomic, diagnostic, and therapeutic strategies with which to approach this rare, albeit challenging, disease process.

BACKGROUND

Demographics and Risk Factors

The true prevalence of NCS is unknown, and, although not limited to a specific age range, it is thought to affect females and the young more frequently, with a secondary peak in the second or third decades of life and an additional peak in middle age.[8,39] However, one study demonstrated a 10.4% prevalence of NCP on evaluation of abdominal computed tomographic

Abstract

Nutcracker Syndrome (NCS) occurs when the left renal vein (LRV) undergoes external compression, most commonly from anterior compression by the superior mesenteric artery, and less commonly when a retroaortic LRV is compressed between the aorta and the spine (posterior compression). The most common presenting symptoms are hematuria and left flank pain. In advanced cases, pelvic compression develops with concomitant lower extremity, posterior thigh, and gluteal varicosities, varicocele in men (typically left sided), as well as vulvar/labial varices in females. The diagnosis is usually made from typical symptoms together with duplex ultrasound, computed tomography, or magnetic resonance imaging. In some cases, LRV compression is diagnosed incidentally when no symptoms are present; this is referred to as "nutcracker phenomenon." Treatment is recommended in symptomatic cases only, and has traditionally consisted of surgical procedures such as LRV transposition or vein bypass, with good outcomes. Endovascular treatment with LRV stenting has been used successfully more recently, although no long-term outcomes data are available.

(CT) scans detected for other purposes, with no difference in the prevalence of NCP by gender alone.[40] Owing to causes elaborated upon later, a lower BMI has been shown to have a correlation with NCS.[41] A large proportion of the nutcracker literature stems from Asia, although it should be noted that no true population-based studies have been performed to determine if there are any ethnic or racial risk factors for NCS. Finally, as reported in the literature, there does not appear to be a hereditary link in the inheritance of this phenomenon, although there is a single case report in which it was demonstrated in two young siblings.[42]

Anatomy

A host of anatomic configurations extrinsic to the anatomy and angulation of the SMA may result in symptomatic compression of the LRV, although whether they can be truly considered as causes of the nutcracker "syndrome" is up for debate. These include compression by pancreatic neoplasms, paraaortic lymphadenopathy, retroperitoneal tumors, an overarching testicular artery, fibrolymphatic tissue or "webs" between the SMA and aorta, as well as compression of larger veins by a gravid uterus.[17,27,43,44] However, in most scenarios, NCS is thought to stem primarily from one of two anatomic variants—anterior or posterior compression of the LRV—resulting in what has been classified as "anterior" or "posterior" NCS, respectively. The normal size of the area between the SMA and aorta has been noted to average 4 to 5 mm in distance at the level of the LRV. LRV diameters average approximately 1.2 ± 0.2 cm (1.1 cm proximal segment; 1.2 cm distal segment) in cadaveric studies, with ultrasound studies showing slightly smaller diameters of LRV size in normal patients (4-5 mm).[45-47]

Anterior NCS results from compression of the LRV between the aorta and SMA (Fig. 165.1A) and can result in dilation and engorgement of the gonadal vein, as well as a preponderance of pelvic collaterals easily visualized with cross-sectional or angiographic imaging. Anatomically, there are a variety of explanations as to the mechanism of anterior compression of the LRV, including a more acute angle between the aorta and SMA (<16 degrees; normal range: 35-40 degrees), which is often attributed to a paucity of retroperitoneal or mesenteric fat, wasting of the paraspinal muscles, as well as profound weight loss.[44,48] The paucity of retroperitoneal fat correlates well with the observation that NCS is oftentimes seen in those with a particularly thin body habitus.[44] Posterior ptosis of the left kidney resulting in abnormal angulation and subsequent stretching and compression of the LRV has also been implicated as a possible cause of extrinsic LRV compression. Additional anatomic variants resulting in anterior NCS include aberrant branching of the SMA and an abnormal, particularly cephalad course of the LRV.[45,49,50]

Posterior NCS occurs most commonly in the setting of a retroaortic LRV, with resultant compression of the LRV between the aorta and vertebral column (see Fig. 165.1B). Although prior studies have demonstrated that posterior NCP may be similar in prevalence to anterior NCP,[40] there are far fewer reports in the literature of the management of posterior NCS patients, although their symptomatology is noted to be no different from that of their anterior NCS counterparts.[20] In truth, a retroaortic LRV remains an uncommonly observed anatomic phenomenon, with a recent study showing a prevalence of 0.77% to 3.18%, with only a minority of those symptomatic (6.5%).[51,52]

Although quite rare in the literature, it should be noted that there exists what could be considered a third anatomic category for NCS, that of "atypical" variants. This atypical anatomic variant class includes the scenario of the circumaortic renal vein and truncular vascular malformations—that is, the left-sided inferior vena cava (IVC).[40,53] In addition, right-sided NCS, although possible, is even more infrequently reported in the

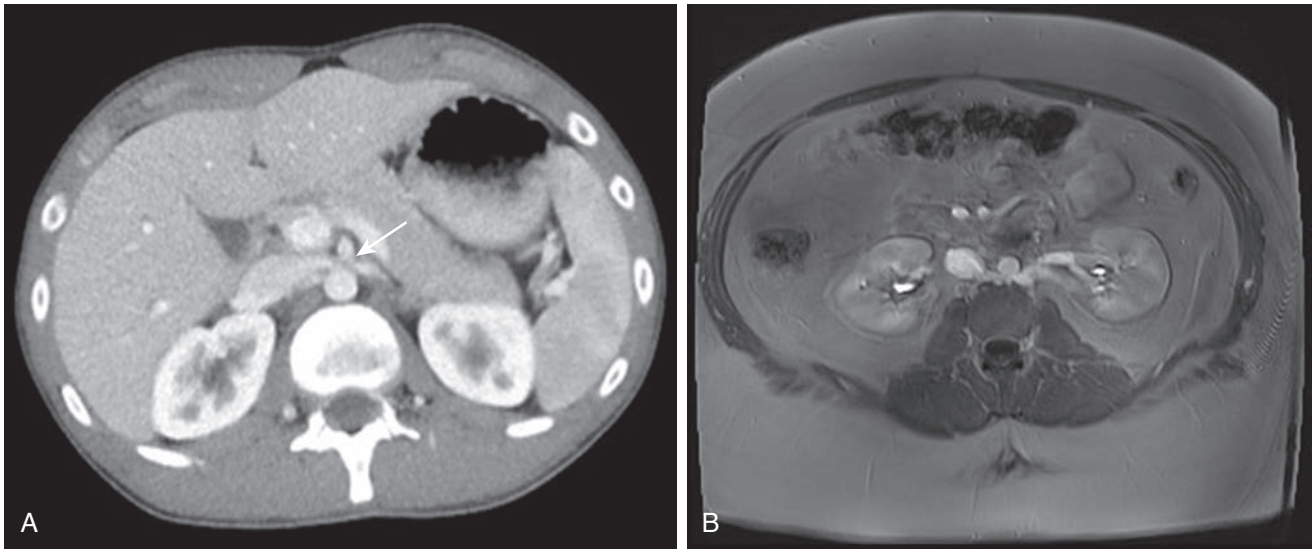

Figure 165.1 Cross-sectional imaging demonstrating (A) anterior nutcracker syndrome with compression of the left renal vein *(arrow)* between the aorta and superior mesenteric artery as observed by computed tomography, and (B) posterior nutcracker syndrome with a retroaortic renal vein as observed by magnetic resonance imaging.

literature and oftentimes results from the condition of left-sided IVC and the unique combination of left-sided IVC, hemiazygos continuation, and persistent left SVC.[54]

DIAGNOSIS

The question of why NCS exists has been posited by many, stemming from the fact that NCP exists, by definition, without symptomatology. Further skepticism around the syndrome and pathophysiology is generated by the fact that the LRV is stretched in instances of a "prominent aorta" and in abdominal aortic aneurysms (AAAs), as well as the fact that the LRV is often ligated without apparent detrimental effect during AAA repair. Although uncertain, hypotheses as to why NCS does not occur in these scenarios include a genetic propensity to the development of venous wall weakness, along with the timeframe with which collaterals are allowed to develop in NCS versus acutely as in AAA.[9] In addition, other similar venous compression syndromes, most notably May-Thurner syndrome, may be found incidentally without clinical sequelae.

Clinical Presentation

The constellation of signs and symptoms that has traditionally defined NCS (Box 165.1) is quite variable, and it is this variety along with ambiguity of symptomatology that has led to diagnostic uncertainty and delays in diagnosis. The most commonly reported symptoms have traditionally been left flank pain coupled with either gross or microscopic hematuria.[55] As compression of the LRV progresses over time and pelvic collaterals form, a host of symptoms related to pelvic congestion syndrome (PCS) may develop, such as dyspareunia, dysuria, and/or dysmenorrhea. Physical exam findings may include lower extremity, posterior thigh, and gluteal varicosities, varicocele in men (typically left sided), as well as vulvar/labial varices in females. It should be noted that there are no true physical exam findings that are pathognomonic for NCS.[56] However, a constellation of any of the previous findings in concert with hematuria and flank pain are strongly suggestive for the diagnosis of NCS.

Proteinuria
Abdominal pain

Hematuria is the most commonly described clinical feature of NCS[56] and can be either gross or microscopic in presentation, oftentimes resulting in further workup for urologic causes of bleeding. Microscopic hematuria is several times more common in presentation than gross hematuria.[19] Authors have described hematuria that may be isolated to the left ureteral orifice on cystoscopy, although hematuria in concert with flank pain can be due to a variety of causes that must be excluded prior to the diagnosis of NCS. The pathophysiology resulting in hematuria is not completely understood but thought to revolve around the obstruction of LRV outflow, with subsequent left renal venous hypertension leading to the diffusion of red blood cells and proteins into the glomerular filtrate.[57,58] In addition, LRV hypertension has been postulated to result in the development of thin-walled varices and valveless collaterals which are prone to rupture into the neighboring collecting system itself, resulting in microhematuria or in more severe cases macrohematuria, or in the communication of dilated venous sinuses with adjacent renal calices.[59,60] Orthostatic proteinuria has likewise been described as a common finding in patients with confirmed NCS, and NCS was once thought to result in chronic fatigue syndromes in children.[16]

Symptoms of pain are ascribed to the passage of blood or clots through the collecting system[43] and as such are typically isolated to the left flank given the propensity of NCS to affect the left side. However, more generalized abdominal pain has been demonstrated in NCS, and left flank pain has likewise been ascribed to the gonadal vein syndrome, in which abdominal or flank pain radiates to the posteromedial thigh and buttock.[30,43] In addition, although the two clinical entities are often confused, nutcracker anatomy (i.e., LRV compression) may be a cause of PCS, in which the accumulation of blood in the pelvis from reflux or obstruction of gonadal, gluteal, or periuterine veins results in a chronic pain syndrome associated with perineal or vulvar varices.[61] This pain is manifested as dyspareunia, dysmenorrhea, and/or dysuria, none of which are typical presentations of NCS. We should also note that symptoms such as scrotal/vulvar varices and pain are exacerbated with standing, physical activity, or orthostasis, because this position results in increased venous filling and distension of collateral drainage pathways.[9,30]

Imaging

If there is clinical suspicion of LRV compression and no prior imaging is available, further imaging should be performed to exclude nonvascular etiologies of LRV compression, as well as to further define the anatomy of the LRV compression. This is due to the fact that potentially treatable etiologies of LRV compression such as neoplasm require referral to a specialist other than a vascular surgeon. The utility of imaging adjuncts in the diagnosis is proven, although a dedicated clinical history is of utmost importance in workup of this syndrome and should be mandatory as the initial and primary diagnostic "test."

Historically, authors favored initial use of left renal venography with measurement of the gradient between the LRV and IVC, but this has been supplanted by noninvasive cross-sectional imaging modalities. Although there is some controversy in terms of which imaging modality is preferentially used in the initial diagnosis, both are needed as they provide different diagnostic information, as outlined later.[47]

Oftentimes, duplex ultrasonography (DUS) serves as the initial imaging modality if NCS is suspected, because it is noninvasive, lacks radiation exposure, and is readily available across most institutions. Ultrasound has the advantage of being able to delineate vascular anatomy and determine basic flow and velocity characteristics of the LRV. However, this modality is limited by patient anatomy and habitus, overlying bowel gas, and interoperator variability. In "good hands," DUS has demonstrated a sensitivity and specificity of 78% and 100%, respectively, in diagnostic accuracy for NCS and has been noted to be particularly useful when coupled with the observation of gonadal and retroperitoneal collateral veins, which demonstrate characteristic aberrant flow in a direction away from the LRV.[62] However, this observation is limited by the fact that the presence of collaterals occurs only after long-standing NCS and hence may not be detected early in the course of the syndrome. Absolute size criteria of the LRV as observed during DUS has been noted by several authors to be of particular diagnostic futility, because larger LRV diameters can be variants of normal and limited by the sonographer, patient positioning, and hydration status.[47,63,64] However, particular utility of DUS has been observed when the diagnostic criteria uses the ratios between anteroposterior diameters and flow velocities at the narrowed proximal and distended distal portions of the LRV, comparing the two to obtain a ratio (>5.0 diagnostic of NCS).[19,47,62] However, errors are rife in DUS due to upright versus supine positioning with subsequent changes in mesoaortic angles, variation of vessel diameter during systole and diastole, as well as intrinsic errors in measurement of velocities and flows.[65,66] Others have used the ratio of the anteroposterior diameter of the LRV between the most dilated and the most narrow portions as diagnostic criteria in adults (>3.7) and children (>4.3).[47,62,67] However, it should be noted that children may form a special class of NCS patients because they are in many cases observed effectively without intervention, owing to the eventual development of mesenteric and retroperitoneal fat. This allows for the widening of the mesoaortic angle and subsequent relief of LRV compression, resolution of hematuria, and improvement in LRV to velocity/flow ratios.[68] In addition, early DUS results were obtained in concert with venography to confirm diagnoses because there was uncertainty and lack of data behind the validity and applicability of DUS in diagnosis at the time of studies. Currently, DUS remains an adjunct for diagnosis in concert with other, cross-sectional imaging modalities, as described next.

In the current era, axial imaging with magnetic resonance imaging (MRI) or contrast CT has gained increasing importance in the initial imaging workup of NCS.[69] The utility of these tests is comparable and can demonstrate a characteristic "beak sign" (as defined by narrowing of the LRV in a triangular shape between the SMA and aorta), as well as the unique circumstance of the retroaortic/circumaortic LRV, retroperitoneal masses, pelvic or periaortic collaterals, and dilation of the gonadal vessels.[70] Critically important in axial imaging is the visualization of pelvic collaterals. If none are present, then the diagnosis of NCS is essentially eliminated as the cause of the patient's symptoms. According to one study, beak sign as delineated by CT imaging demonstrated the highest diagnostic accuracy as compared with LRV hilar/aortomesenteric diameter ratio and mesoaortic angle (<41 degrees), with a sensitivity of 91.7% and specificity of 88.9%.[71] Other diagnostic cutoff values have been established using CT with three-dimensional reconstruction, including an LRV hilar-aortomesenteric cutoff ratio of 4.9 and a <41 degree angle between the SMA and aorta as measured by imaging.[72] The diagnostic accuracy of MRI in relation to NCS has not been examined in the literature but, as others have noted, yields similar anatomic assessment as CT without the expense of contrast media or radiation exposure and can also give unique insight as to stagnation of flow in the LRV, which is seen with compression of the vessel observed in NCS.[73]

Axial imaging alone does not provide the necessary hemodynamic data for the diagnosis of NCS—namely, whether reflux into the gonadal and pelvic circulation is present and severe. Venography allows for the measurement of the renocaval pressure gradient (i.e., "pullback"), while also allowing for the visualization of mesoaortic-induced LRV narrowing, dilation of the LRV, reflux and opacification into the collateral pelvic network (including the gonadal, lumbar, adrenal, and other veins), and the sluggish passage of contrast through the LRV (Fig. 165.2).[70] Many of the criteria for venographic diagnosis/confirmation of NCS arise from an initial study performed by Zerhouni et al., which demonstrated a renocaval gradient of 0 to 3 mm Hg in a normal population.[74] This work was subsequently challenged by Beinart,[59] who demonstrated that 98% of normal subjects had a renocaval pressure gradient less than 1 mm Hg,[74] with later studies demonstrating a range of renocaval pressure gradients, yielding subsequent debate as to the utility of absolute cutoff values for pressure gradients versus symptomatology. A standard of sorts was established when Nishimura and colleagues demonstrated a cutoff value of ≥3 mm Hg as diagnostic of LRV hypertension, which was observed in concert with hematuria and opacification of collaterals in their cohort,[75] and subsequently propagated by Takebayashi et al.[62] In the study by Takebayashi, left renocaval pressure gradients were defined as: normal (<1 mm Hg), borderline hypertensive (1-3 mm Hg), and hypertensive (≥3 mm Hg). However, as noted in other studies, the renocaval gradient may range from 3 to 10 mm Hg in normal patients, and in those with NCS these values range from 2 to 14 mm Hg, representing an overlap and area of diagnostic uncertainty if one were to attempt to diagnose NCS by the renocaval pressure gradient alone.[45,72] It should also be noted that in those with long-standing NCS, the high renocaval gradient typically observed may not be present, due to compensation by collateral circulation and decompression of the proximal LRV obstruction, which can result in low gradient values. In addition, these values may be erroneous in the face of positioning and hydration status.[28,45]

Figure 165.2 Selective Left Renal Venography Demonstrating Characteristic Findings in Anterior Nutcracker Syndrome. Note the vast network of perirenal and pelvic collateral vessels, a dilated and incompetent gonadal vein *(long arrow)*, and stagnant flow in the left renal vein *(short arrow)*.

Historically, other imaging modalities have been reported, such as intravenous urography, retrograde pyelography, and IVC phlebography, although they are not of current diagnostic utility and hence will not be described here. Cystoscopy, which many patients receive as part of the diagnostic workup for hematuria of unknown cause, is efficacious in localizing hematuria to the left ureteral orifice and hence the left side. However, no features on cystoscopy are pathognomonic for NCS, and as such, this invasive technique remains only indirectly diagnostic.

MANAGEMENT

Although the prompt recognition of the symptomatology and the subsequent diagnosis of NCS are important, patient selection and the operative strategy used are both critical to patient outcomes. Unfortunately, there remains a marked lack of concordance regarding when/which patients should be treated and the optimal operative technique. The mere presence of radiographic compression (i.e., "bird beak") is not a sufficient indication to operate, with requirements including hematuria, the presence of collaterals, and pelvic and/or flank pain (Fig. 165.3). Ideally, interventions are directed toward reducing the hypertensive state of the LRV induced by its compression, but as authors have noted, many procedures are performed as a result of symptoms of unrelenting and disabling pain or gross hematuria resulting in anemia.[12] We have elected not to describe the "conservative" management of NCS because this treatment strategy is more suited to children presenting with hematuria and found to have NCS, as further development and weight gain can, as mentioned, result in widening of the acute aortomesenteric angle and hence relief of LRV compression.

Open Surgery for Anterior Nutcracker Syndrome

There have been a host of methods described to treat anterior NCS in an open fashion. These have included LRV transposition ± patch venoplasty, patch venoplasty alone, LRV transposition with a saphenous vein cuff, gonadal vein transposition, saphenous vein bypass, gonadocaval bypass, resection of fibrous tissue with placement of a "wedge" at the aortomesenteric angle, SMA transposition, left renal autotransplantation, nephrectomy, external stenting of the LRV, and nephropexy.[27,34,37,50,76] In this section, we will briefly describe some of the more commonly performed open surgical techniques.

The most commonly reported technique to surgically manage anterior NCS is LRV transposition (Fig. 165.4A). This technique is performed transabdominally via a midline mini-laparotomy, with cephalad and rightward retraction of the small bowel, entrance into the retroperitoneum, and subsequent mobilization of the LRV. This technique requires ligation of the gonadal vein, and frequently ligation of the adrenal and lumbar veins as additional mobilization of the LRV becomes necessary. The LRV is reimplanted into the IVC in a more caudad location, effectively avoiding the area of compression and hence relieving it. In some instances a saphenous vein patch may be required in concert with transposition of the LRV (see Fig. 165.4B). This is especially important in the case of long-standing NCS, when permanent fibrotic distortion of the LRV may occur secondary to the sequelae of LRV hypertension on the endogenous structure of the vessel wall. A great saphenous vein patch, despite requiring an additional groin incision, is preferred as it is typically readily available in this younger cohort (i.e., not expended from prior cardiovascular surgery) and carries a lower risk for infection versus synthetic graft material.

Patch venoplasty without LRV transposition is not frequently reported in the literature but is an option in those in which transposition is not feasible owing to a short LRV, an "overstretched" LRV, or in instances where the extrinsic compression of the LRV would not be alleviated by merely transposing the vein.[72] Overstretching of the LRV is a unique scenario likely resulting from a prominent aorta (as seen in AAA) or an extremely ptotic kidney. Likewise, if the anatomic limitations of the LRV transposition result in an anastomosis in which tension is unavoidable, a tension-free anastomosis can be created by employing a saphenous vein cuff directly to the IVC (see Fig. 165.4C).

An additional surgical alternative is that of gonadal vein transposition (see Fig. 165.4D). This technique is feasible as in many cases of NCS, the gonadal vein has markedly dilated, and through division of this vessel low in the pelvis, symptoms of pelvic congestion can be relieved. Additional advantages of this approach include the fact that it can be used to treat patients with posterior NCS, avoids renal vein clamping or transection, requires only a single anastomosis, and avoids saphenous vein

harvest. For this technique to be used, the gonadal vessel must be large enough in diameter to effectively decompress the LRV and must be long enough to reach the IVC without tension. These features of the gonadal vessel are easily determined by preoperative imaging. Gonadal vein transposition is performed through a mini-laparotomy, with Kocherization and cephalad retraction of the viscera, with exposure of the retroperitoneum allowing for intraoperative confirmation of the feasibility of this approach (assessment of the gonadal and renal veins). If the gonadal vein size is acceptable, mobilization of the gonadal vein with ligation of small side branches easily yields enough length to transpose the vessel. Heparin is administered, and a partially occlusive ("side-biting") clamp is used on the IVC with proximal control obtained on the gonadal vein. A simple running anastomosis is preferred to construct the new gonadocaval anastomosis.

Owing to these features and the applicability of gonadal vein transposition to both anterior and posterior NCS, this has become our preferred strategy for the surgical management of NCS. Our experience has demonstrated symptom resolution in 100% of patients treated using this strategy (n = 4). The relatively limited operation (in comparison to LRV transposition) and potential for decreased morbidity and hospital stay, coupled with excellent outcomes, have led our institutional practice pattern to prefer a "gonadal vein transposition first" type strategy, although this is limited in the face of the anatomic features, as mentioned previously.

A final surgical strategy for the treatment of either anterior or posterior NCS is that of saphenous vein bypass (see Fig. 165.4E), which like gonadal vein transposition avoids clamping or transecting the LRV. Great saphenous vein bypass is used in those infrequent situations where transposition of either the LRV or gonadal vein is not feasible. However, in addition to requiring saphenous vein harvest, this procedure requires two anastomoses and clamping of the LRV.

Outcomes with open surgery for anterior NCS are well documented and are overall satisfactory. In one of the larger and more recent contemporary cohorts as reported by Erben et al. from the Mayo Clinic, the authors report contemporary outcomes using an "LRV transposition-first" strategy of sorts over a 20-year period.[12,15] The authors show a low perioperative complication and reintervention rate, along with high patency of the LRV at discharge in 37 consecutive patients in their series.[15] However, over a median follow-up of approximately 37 months, it was determined that approximately one-third of patients required reintervention of some form—stenting of the transposed LRV in most instances—although symptom resolution was noted to be 87% over follow-up. The authors report a 24-month primary patency and freedom from reintervention of 74% and 68%, respectively. Symptoms of NCS may recur if the bypass or transposed segment becomes occluded, which mandates reintervention. Endovascular rescue has been described in this setting.[77]

Other postoperative complications of open surgical procedures for NCS are relatively uncommon and include deep venous thrombosis, retroperitoneal hematoma, paralytic ileus, and the development of chylous ascites.[12,14] The perioperative mortality rate is exceedingly low, likely due to a young and otherwise morbidity-free patient population. We recommend that, in the postoperative phase, 30 days of anticoagulation with novel agents or warfarin should be instituted, with further benefit potentially derived from additional antiplatelet agents (aspirin, clopidogrel), although this has not been examined in the literature to date.

Open Surgery for Posterior Nutcracker Syndrome

Posterior NCS is challenging from an open surgical perspective because the retroaortic position of the LRV means that the LRV must be anteriorly transposed if using LRV transposition. Dissection in the narrow window between the vertebral column and aorta poses particular hazard from difficult to visualize lumbar, perirenal, and other collateral vessels. Additional difficulties may result from neglected or unseen damage to the numerous lymphatic channels along the aorta in the retroperitoneum, mandating careful ligation to prevent lymph leak and its subsequent morbidity. Much like renal vein transposition as described previously for anterior NCS, anterior LRV transposition may also require a vein patch in the face of long-standing, fibroproliferative disease. In addition, careful attention must be paid because the retroaortic LRV is particularly friable and prone to damage during its dissection and mobilization.[72] Successful laparoscopic techniques for LRV transposition in anterior and posterior NCS have been described[23] but are not recommended for routine application, owing to the expertise required to perform a delicate anastomosis in a minimally invasive fashion.

Other strategies used for the open surgical management of posterior NCS include saphenous vein bypass, aortic transposition,[78] as well as gonadal vein transposition. Again, much as in the scenario for anterior NCS, gonadal vein transposition (if applicable) has the potential to obviate most of the hazards of dissection in the area of the renal vein. This is magnified in the instance of a retroaortic LRV. The approach to performing gonadal vein transposition is the same as in anterior NCS.

Complications for the open treatment of posterior NCS are the same as those for anterior NCS. Although a retroaortic renal vein may be a more frequent anatomic variant than originally thought,[51] treatment of symptomatic posterior NCS is rarely reported in the literature and is limited to case reports and intermittent case series.[20,23,26,78-87] As such, there remains a marked lack of long-term follow-up and description of patient outcomes, with no consensus as to optimal treatment strategies.

Endovascular Treatment of Nutcracker Syndrome

As with virtually all vascular pathologies, endovascular solutions to NCS have been proposed and attempted. However, as with other compressive entities (i.e., thoracic outlet syndrome), endovascular options have been met with limited success. Initially described by Neste et al. in 1996,[13] the utility of endovascular therapy is typically described as stenting of the LRV. The bulk of the available data describing endovascular treatment of NCS is in the form of case reports.[14,33,88-90] More recently several

larger case series have been described.[10,11,91] The largest case series to date is that reported by Chen et al., with 61 patients undergoing LRV stenting with a median follow up of 66 months.[91] The authors reported an overwhelmingly positive response in terms of outcome and symptom resolution, as well as a low perioperative complication rate. Complications included maldeployment of a stent requiring open reintervention and stent migration to the right atrium, which was particularly troublesome as it mandated open cardiac surgery. The authors report that the ideal stent should have the properties of high radial strength, conformability, and minimal shrinkage in length, all of which allow for ideal stent positioning. In fact, the propensity for these devices to migrate in this location has led some authors to recommend both the oversizing and positioning of stents from the first division of the LRV.[72] Unfortunately, recent larger series using an "endovascular first" strategy to the treatment of NCS, with longer follow-up times, have demonstrated a 6.7% migration rate of stents, which is higher than initially hypothesized using midterm follow-up data.[88] When considering these stents can migrate to the right-sided circulation or lungs, this migration rate, as reported, is quite worrisome. The types of endovascular devices used in the larger case series are overwhelmingly self-expanding and include the Wallstent, Palmaz, SmartControl, and self-expanding SMART stents. Other complications from endovascular therapy for NCS include in-stent thrombosis and fracture. Stent protrusion into the IVC, which was initially thought to be concerning, has been demonstrated to be safe.[14]

Antiplatelet medications are a necessity in the postoperative period to prevent thrombotic complications in relation to the stent. Despite the report of adequate long-term outcomes using an "endovascular-first" strategy to treat NCS,[88] a major limitation of this strategy remains the absence of direct comparisons between open and endovascular therapy for NCS performed in the same era at a single institution, raising additional concerns about the durability of these procedures. Moreover, as the cohort of patients treated for NCS are oftentimes in their second or third decades of life, the duration of imaging follow-up required has yet to be established and remains lifelong at this time. Although there are many limitations to this technology as described previously, newer venous-specific endovascular devices are likely to emerge in the near future and improve outcomes in the endovascular treatment of NCS, which could therefore serve as a treatment alternative to open surgery in poor open surgical candidates.

SUMMARY

NCS has much potential to inflict lifestyle-limiting morbidity in the form of debilitating pain, hematuria, and disfiguring varices in the lower extremities and scrotal/vulvar region. This syndrome is the result of anatomic compression of the LRV, with much speculation as to the reasons it may occur in some but not others with anatomic LRV compression. NCS is often misdiagnosed or at best is diagnosed in its later stages, after the development of renal venous hypertension, which in concert with pain and hematuria mandates operative repair. Diagnosis is most efficiently achieved through dedicated clinical examination and characteristic findings on cross-sectional imaging and venography. Although there are a variety of operative strategies applicable to this condition, much of this is dictated by the subclass of NCS (anterior or posterior), as well as intraoperative anatomy. Relief of pain and hematuria is easily achieved with decompression of the LRV. Endovascular strategies have been used and reported more frequently in the recent era, although long-term data are still necessary to prove their efficacy as a treatment modality.

CONCLUSION 2179

INTRODUCTION

Aneurysms are abnormal dilations of blood vessels and occur most commonly in arteries. Venous aneurysms are rare but have been reported throughout the veins in the body, including the extremities, head and neck, and abdomen.

When defining venous aneurysms, Gillespie et al. state: "The definition of a venous aneurysm has been controversial. A venous aneurysm is best described as a solitary area of venous dilation that communicates with a main venous structure by a single channel, and it must have no association with an arteriovenous communication or a pseudoaneurysm. Most importantly, it should not be contained within a segment of a varicose vein."[1] In general, venous aneurysms can be defined as an area of dilation 2 to 3 times the surrounding normal vein.[1,2] They are rare and generally asymptomatic; thus the true incidence is unknown.

Venous aneurysms can be classified as primary (congenital) or secondary (acquired). Primary, or congenital, aneurysms are caused by a weakness in the venous wall secondary to inherited conditions such as Klippel-Trénaunay syndrome, neurofibromatosis 1(NF-1), and Parkes Weber syndrome (discussed more fully in Chapter 171).[3] Secondary, or acquired, venous aneurysms arise from etiologies such as trauma, inflammation, degenerative processes, mechanical stress, and venous hypertension. Some case reports describe a correlation between pregnancy and venous aneurysm formation, but no causative factors have been elucidated.[4] Scientific publications identify the presence of estrogen receptors in venous vascular tissue, and although it is tempting to hypothesize causality, this has not been established.[5-7]

Histologically, the intima of venous aneurysms may be thickened and fibrosed. In addition, the media may be attenuated or absent and display a paucity or total lack of smooth muscle cells. Matrix metalloproteinases (MMPs) have been noted to be expressed at higher levels in venous aneurysms compared with normal venous tissue. The established relationship between MMPs and arterial aneurysms is long standing, but more research is needed to document this relationship in venous aneurysms.[8]

Clinically, patients with venous aneurysms are usually asymptomatic; however, complications can occur and include thrombosis, embolization, rupture, local mass effects with or without edema, and localized pain or tenderness. Diagnosis may be made with physical examination in the case of superficial venous aneurysms; however, they are often misdiagnosed as soft tissue masses or even hernias.[1] Diagnostic confirmation can be performed using duplex ultrasound (DUS), computed tomography, or magnetic resonance imaging. Venography is not indicated for primary diagnosis. A thorough history should be elicited from the patient, specifically inquiring about family history of aneurysmal or connective tissue disease and any recent or remote trauma to the region. In addition, physical examination should identify any sequela of arteriovenous fistula, with imaging studies performed if needed.

Abstract

Venous aneurysms are rare and poorly characterized. Popliteal venous aneurysms warrant intervention if symptomatic or greater than 20 mm. Other venous aneurysms are usually observed if asymptomatic. Interventions include tangential aneurysmectomy, aneurysm resection with primary anastomosis, aneurysm resection with interposition grafting, or ligation of the affected venous segment. Endovascular modalities have been successfully attempted, but no evidence based guidelines exist to guide patient selection.

Keywords

Venous
Aneurysm
Tangential aneurysmectomy
Popliteal
Pulmonary embolus

Treatment of venous aneurysms is performed on a case-by-case basis because there are few evidence-based studies to guide treatment. In general, conservative management is indicated for small and/or asymptomatic aneurysms. Surgical treatment for large aneurysms or those associated with complications consists of tangential aneurysmectomy, aneurysm resection with primary anastomosis, aneurysm resection with interposition grafting, or ligation of the affected venous segment. There is no standard endovascular treatment, but endovascular modalities have been successfully implemented in select patients.[9-11]

LOWER EXTREMITY VENOUS ANEURYSMS

Lower Extremity Superficial Venous Aneurysms

Superficial venous aneurysms are usually visible and present as painless masses, often misdiagnosed as soft tissue masses. Depending on the location, these aneurysms can be confused with hygromas, or even inguinal or femoral hernias.[1] Thorough physical examination may identify a superficial venous aneurysm because the mass is more resistant to compression in the dependent position compared with when the extremity is elevated. DUS can definitively make the diagnosis. Saphenous vein aneurysms have been diagnosed during operative procedures for what were thought to be varicose veins preoperatively. Venous aneurysms on the dorsum of the foot have been described and are usually asymptomatic. Interestingly, all case reports of pedal venous aneurysms involve young women.[12]

Treatment of superficial venous aneurysms involves ligation and excision after ensuring that the deep venous system is intact. If the aneurysm is near the saphenofemoral junction, then a high ligation should also be performed.

Aneurysms of perforating veins in the lower extremity have been described only rarely. This may be secondary to the lack of specific symptoms. Ultrasound is diagnostic when the size of the perforating venous aneurysms exceeds 9 mm. Although these aneurysms are located below the deep fascia, they are included in the superficial venous aneurysm section because they are often treated the same way superficial refluxing veins are treated—subfascial ligation with or without aneurysm excision. Aneurysms are excised if they are symptomatic. Labropolous et al. also noted that these aneurysms are usually fusiform and recommended treatment if perforating vein treatment was undertaken. His group found no relation between the sizes of perforating vein aneurysms and the severity of chronic venous disease.[13]

Lower Extremity Deep Venous Aneurysms

Popliteal venous aneurysms (Fig. 166.1) are the most commonly reported and best studied of all venous aneurysms. Evidence from previous studies suggests that popliteal venous aneurysms are more commonly associated with complications than aneurysms in the superficial systems. These complications include thrombosis, pulmonary embolism, localized pain and swelling, more diffuse lower extremity swelling, and symptoms of chronic venous disease. In a report published in 1993, 24 cases of popliteal venous aneurysm were identified; all patients presented

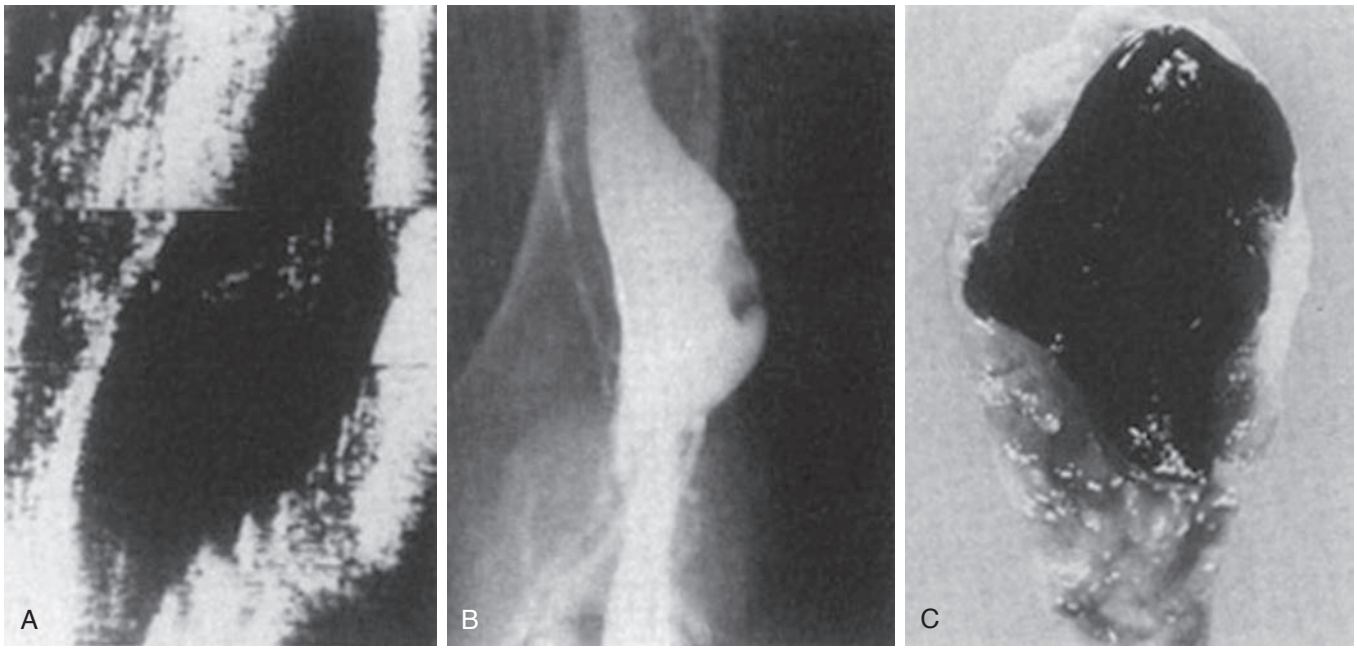

Figure 166.1 (A) Duplex image of popliteal venous aneurysm with intraluminal thrombus. (B) Ascending phlebogram confirming popliteal venous aneurysm with intraluminal thrombus. (C) Resected venous aneurysm sac with intraluminal thrombus. Note appearance of acute, jellylike thrombus despite therapeutic anticoagulation. (From Aldridge SC, Cometota AJ, Katz ML, et al. Popliteal venous aneurysm: report of two cases and review of the world literature. *J Vasc Surg*. 1993;18:708–715.)

with thromboembolic disease. Seventy-one percent presented with pulmonary embolism.[14] Other studies have shown that most popliteal venous aneurysms (45%-80%) are discovered incidentally during work-up after patients have suffered a pulmonary embolism.[15,16]

Asymptomatic patients with aneurysms less than 20 mm can be serially monitored with ultrasound to evaluate for progression. Symptomatic patients (especially those who have suffered a pulmonary embolus) should be treated regardless of aneurysm size. In general, anticoagulation alone is not considered sufficient treatment for popliteal venous aneurysms. Thrombus burden localized to the popliteal venous aneurysm has been shown to predispose to pulmonary embolus even when patients are therapeutically anticoagulated.[17,18] Surgical reconstruction is preferred in these cases and can consist of tangential aneurysmectomy with lateral venorrhaphy, aneurysm resection with primary anastomosis, or interposition grafting with saphenous vein. If no other option is available, a synthetic bypass can be used, but postoperative thrombosis is more common. Tangential aneurysmectomy with lateral venorrhaphy (Fig. 166.2) is the preferred method of reconstruction.[19] Inferior vena cava (IVC) filter placement and catheter-directed lysis should be considered on a case-by-case basis, taking into account patient-specific variables such as ability to tolerate anticoagulation and concomitant extent of ipsilateral deep venous thrombosis. Patients are routinely placed on anticoagulation for 3 to 6 months after all procedures.

Due to their rarity, few studies exist to guide the treatment of femoral and common femoral venous aneurysms. We believe that, extrapolating from the popliteal venous aneurysm literature, symptomatic aneurysms should be treated surgically and asymptomatic venous aneurysms can be monitored for increase in size and/or development of intraluminal thrombus if they are small on discovery.

Iliac vein aneurysms are rare, with only 13 cases reported in the literature. Rupture was reported in one case of a large external iliac vein aneurysm.[14] More commonly these aneurysms are asymptomatic and discovered incidentally or during evaluation for other pathology such as pulmonary embolism. Treatment is best accomplished with tangential aneurysmectomy and lateral venorrhaphy. Ligation of the iliac vein leads to a high rate of chronic lower extremity edema and post-thrombotic syndrome and should be avoided.

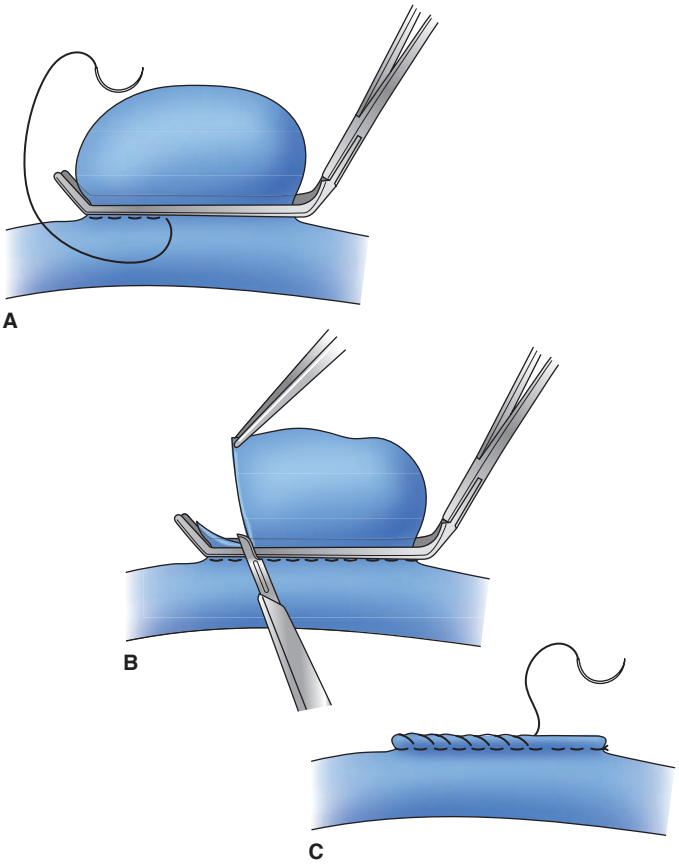

Figure 166.2 (A) Illustration of technique of tangential aneurysmectomy with lateral venorrhaphy. Clamp is placed at base of aneurysm without compromising lumen of popliteal vein. Vein walls are approximated by undersewing clamp with running horizontal mattress stitch. (B) Aneurysm is resected flush with vascular clamp. (C) Second, reinforcing running stitch is placed, approximating vein wall edges external to mattress suture. (From Aldridge SC, Cometota AJ, Katz ML, et al. Popliteal venous aneurysm: report of two cases and review of the world literature. *J Vasc Surg*. 1993;18:708–715.)

ABDOMINAL VENOUS ANEURYSMS

Inferior Vena Cava

The normal caliber of the IVC is 1.5 to 3.7 cm, and the IVC is considered aneurysmal when it exceeds 5 cm. Fewer than 60 case reports addressing IVC aneurysms have been published, which make these rare entities.[20] Clinically, IVC aneurysms are rarely symptomatic and often discovered incidentally on cross-sectional imaging performed for other reasons. In a previous report the most common presentation was iliocaval thrombosis, which occurred in 19%.[21] Gradman and Steinberg created a classification system (Fig. 166.3) defining types of IVC aneurysms, which is shown as follows.[22]

Type 1: suprahepatic aneurysms without obstruction.
Type 2: aneurysms located above or below the hepatic veins with obstruction.
Type 3: infrarenal aneurysms without obstruction.
Type 4: miscellaneous aneurysms.

Although this classification system is not intuitive, it helps to guide management.[22]

Type 1 aneurysms can usually be observed with no adverse outcomes. Types 2, 3, and 4 aneurysms are prone to thrombosis or embolization and, for this reason, are usually treated. Surgical repair is the most common treatment, either tangential excision with venorrhaphy or resection with interposition bypass grafting.[21]

Visceral Venous Aneurysms

Venous aneurysms in the visceral veins, including the portal, mesenteric, and renal systems, are extremely rare. In the only recent systematic analysis, 98 case reports were identified,

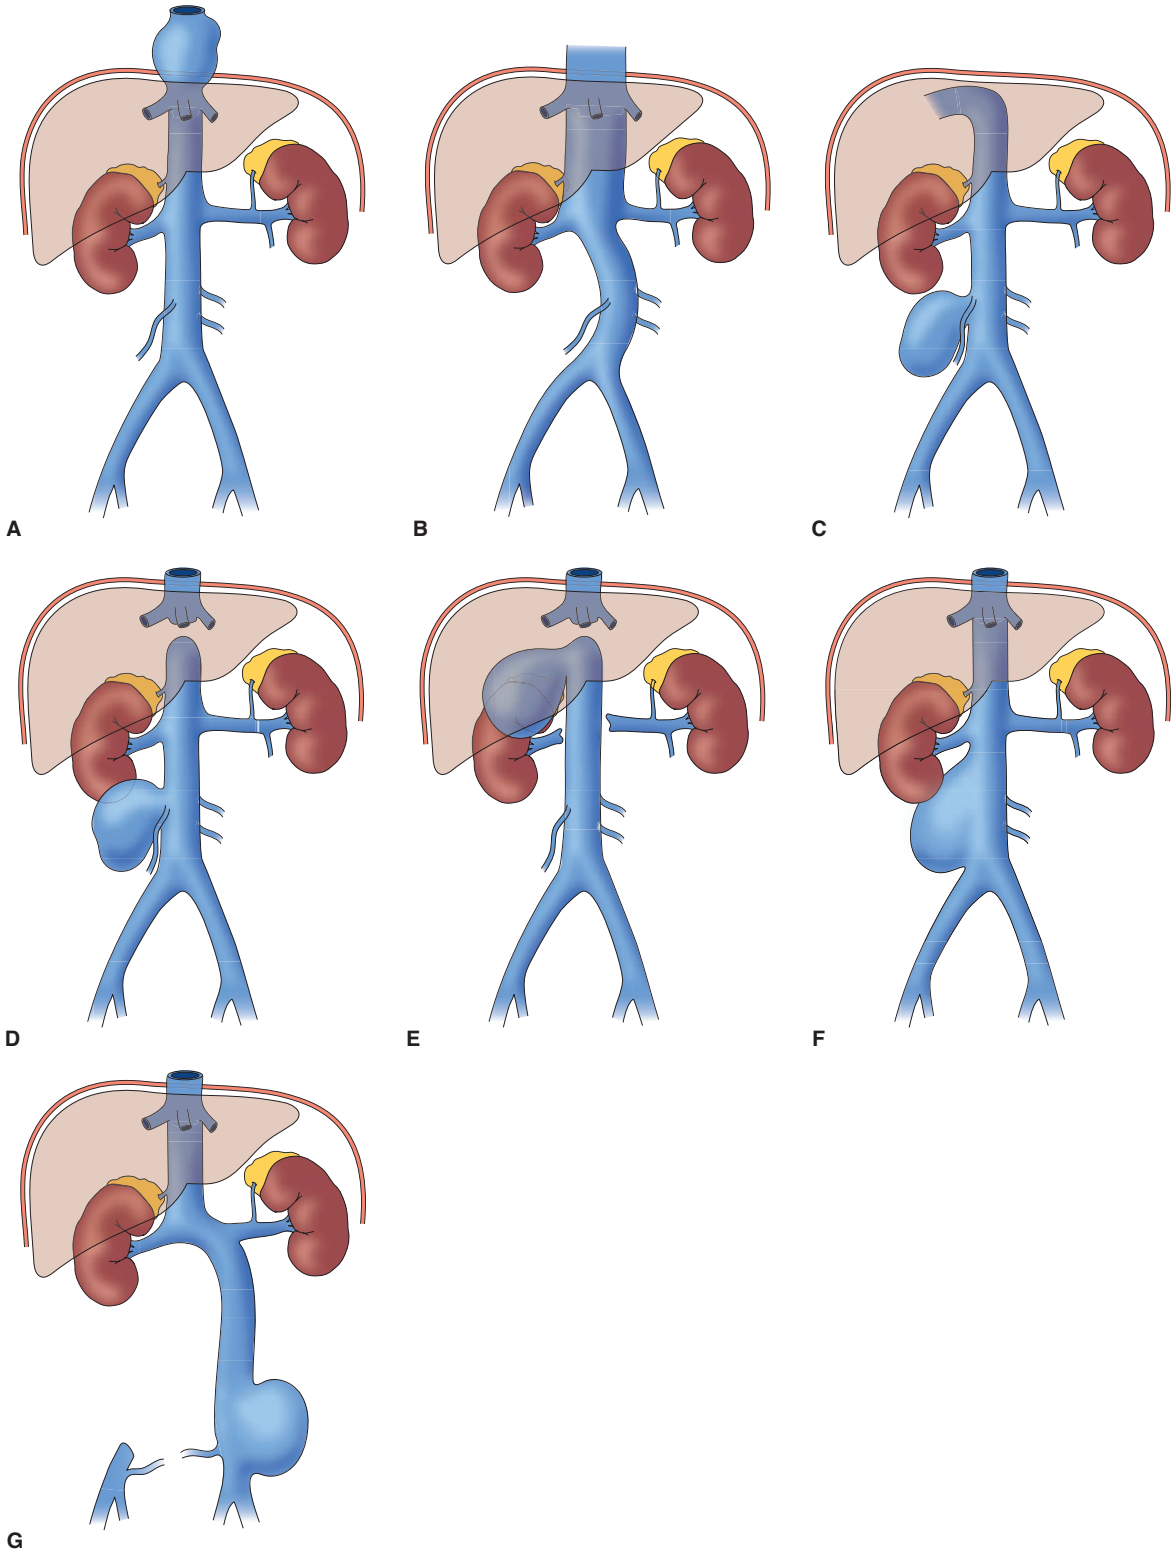

Figure 166.3 (A) Type I aneurysm showing suprahepatic location without obstruction in inferior vena cava (IVC). (B). Type I aneurysm in perihepatic location with left-sided IVC. (C). Type II aneurysm showing supraphepatic interruption of IVC with infrarenal IVC aneurysm. (D). Type II aneurysm with infrahepatic interruption of IVC and infrarenal IVC aneurysm. (E). Type II aneurysm with intrahepatic interruption of IVC, infrahepatic IVC aneurysm, and entry of renal veins into azygous and hemizygous system. (F). Type III infrarenal IVC aneurysm without venous obstruction. (G). Type IV aneurysm of iliac vein with left-sided IVC. (From Gradman WS, Steinberg F. Aneurysm of the inferior vena cava: case report and review of the literature. *Ann Vasc Surg.* 1993;7:347–353.)

including 198 aneurysms in 176 patients. The majority of aneurysms were in the portal vein (191 of 198 aneurysms).

Portal venous aneurysms are defined as a portal vein with a diameter greater than 15 mm, or greater than 19 mm in cirrhotic patients.[23] In the studies reported, one-half of patients presented with nonspecific abdominal pain, 30% were asymptomatic with incidental aneurysm discovery, and 20% of patients presented with thrombosis.[24,25] Rupture was rare.

The congenitally aneurysmal portal vein is thought to arise from incomplete regression of the right primitive distal villetine vein. Acquired portal vein aneurysms form secondary to portal hypertension, trauma, pancreatitis, or local malignancy with venous wall invasion.[26]

Treatment is indicated in portal venous aneurysms greater than 3 cm or smaller aneurysms with complications (rupture, thrombosis, pain, rapid enlargement) in appropriate surgical candidates. Patients without portal hypertension do well with tangential aneurysmectomy and aneurysmorrhaphy, although extensive perioperative bleeding can occur. In patients with concomitant portal hypertension, the treatment should address this underlying condition either through portovenous shunting or liver transplantation. Regression is rare but has been reported.[21]

Mesenteric vein aneurysms are extremely rare and have presented as asymptomatic masses discovered incidentally, or following the development of abdominal pain or thrombosis. In a review published in 2004, 10 cases were identified. The most common presenting symptom was abdominal pain.[27] The majority were treated conservatively, although there is a report of a catastrophic outcome following rupture.[28] It is recommended that surgical treatment be performed in symptomatic patients, or asymptomatic patients with aneurysms greater than 3 cm.

Splenic vein aneurysms are much less common than splenic artery aneurysms, and they have been shown to occur secondary to arterial aneurysm rupture into the splenic vein.[29,25] Treatment is aimed at symptomatic patients, women of childbearing age, or aneurysm size greater than 3 cm.

Renal vein aneurysms are also rare. In a systematic review, five cases were identified. In three cases, abdominal pain was the presenting symptom; the other two patients were asymptomatic. Surgical repair using aneurysmectomy or nephrectomy was performed in the symptomatic patients.[24]

Renal vein aneurysms can be confused with distended renal veins, particularly on the left side. The diagnosis of an aneurysm must not be confused with the nutcracker syndrome. In addition, investigation of a spontaneous splenorenal shunt should be entertained in patients with portal hypertension because this may also contribute to a dilated left renal vein.

UPPER EXTREMITY AND INTERNAL JUGULAR VENOUS ANEURYSMS

Upper extremity and internal jugular venous aneurysms also occur in both the deep and superficial venous systems. They are thought to be less common than venous aneurysms in the lower extremities; in one series, they constituted 23% of 39 aneurysms diagnosed in 30 patients.[1]

Upper Extremity Superficial Venous Aneurysms

Superficial venous aneurysms in the upper extremities often present with pain and/or swelling, but a significant proportion are asymptomatic. In these cases, they are often misdiagnosed and treated as soft tissue masses, with the diagnosis only being made when surgery is performed. This can be avoided with a thorough physical examination which includes compression of the mass with the extremity in both the dependent and elevated positions, and changes can be noted during a Valsalva maneuver. There should be differential filling (fast vs. slow) of the mass depending on the position of the extremity (dependent vs. elevated). DUS scanning is diagnostic and should be routinely used.

Surgical treatment should be directed at aneurysms that are symptomatic or if the patient desires excision for cosmetic reasons. DUS performed immediately before incision is beneficial in identifying all feeding vessels which can then be targeted early in the procedure before the aneurysm sac is excised. The procedure can usually be carried out under local anesthesia.

Pseudoaneurysms frequently develop in arteriovenous fistulae created for hemodialysis access. These are discussed in Chapter 179.

Upper Extremity Deep Venous Aneurysms

Brachial, axillary, and subclavian venous aneurysms are seldom symptomatic and usually present as a painless slowly enlarging mass. If a mass is visible through the skin, physical examination during Valsalva will show enlargement of the mass. In most cases, DUS is diagnostic. Cross-sectional imaging may be considered if adjacent structures are thought to be compromised or for operative planning.

Upper extremity deep venous aneurysms are rarely reported in the literature, and no evidence-based treatment algorithm exists. Although they have been reported to be less likely to be associated with complications, a few case reports have demonstrated pulmonary embolization from these aneurysms.[30,31] Others have reported cases of deep upper extremity venous aneurysms causing localized discomfort.[32] With this in mind, the authors recommend that symptomatic aneurysms be treated with aneurysmectomy and venous reconstruction as needed. Asymptomatic aneurysms can be surgically treated in appropriate risk patients, or serially observed for any change in size or occurrence of symptoms.

Jugular Venous Aneurysms

Venous aneurysms of the jugular veins (Fig. 166.4) are usually asymptomatic and frequently misdiagnosed. The differential diagnosis includes any soft tissue mass of the head and neck, such as lipoma, lymphangioma, malignancy, hematoma, or cystic structures. Congenital venous aneurysms of the external and internal jugular veins presenting in childhood have been described. These aneurysms may also present in adults, although this is rare. There are case reports of patients with NF-1 being predisposed to developing jugular venous aneurysms. Treatment

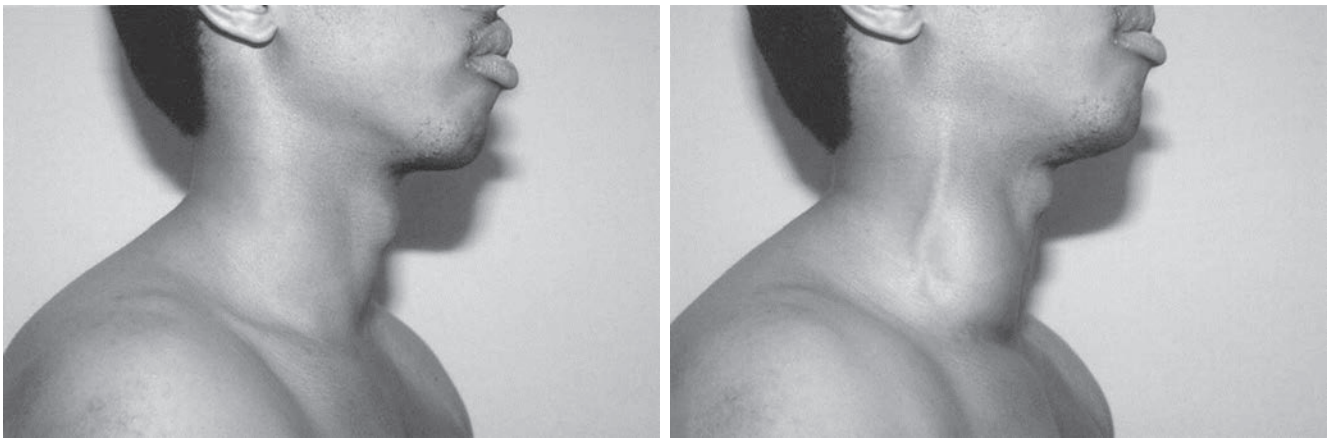

Figure 166.4 Under Valsalva maneuver, aneurysms of the internal jugular vein may become alarmingly large *(right panel).* However, their course is usually benign, and surgical excision is rarely indicated. (From Gillespie DL, Villavicencio JL, Gallagher C, et al. Presentation and management of venous aneurysms. *J Vasc Surg*. 1997;26.5:845–852.)

of these aneurysms involves surgical resection and is performed most commonly for cosmetic purposes because they rarely lead to pulmonary embolization.[33] Ligation of the feeding vessels with aneurysmectomy is frequently performed as long as there is good contralateral venous drainage.

CONCLUSION

Venous aneurysms are rare. They are usually discovered incidentally on cross-sectional imaging or in the work-up for pulmonary embolus. Although no randomized controlled trials are available, best treatment involves surgical consideration for large or symptomatic venous aneurysm, and observation of small and asymptomatic aneurysms. Tangential aneurysmectomy with lateral venorrhaphy is generally the preferred surgical procedure. More studies of these rare entities are needed to develop better treatment algorithms.

SUMMARY AND CONCLUSIONS 2191

INTRODUCTION AND DEFINITIONS

The portal vein and superior mesenteric vein are intrinsically associated anatomically with the pancreas. These blood vessels can become involved with pancreatic tumors and their resection, and reconstruction is becoming a well-established adjunct to pancreatic resection in order to achieve complete tumor resection in patients with localized cancer. Likewise, the inferior vena cava can become involved with tumors or tumor thrombus from a variety of retroperitoneal, abdominal, renal, adrenal, and hepatic tumors. Extensive institutional experience has been amassed establishing the safety and feasibility of portal vein, superior mesenteric vein, and inferior vena cava resection and reconstruction as adjuncts to the resection of certain tumors. In this chapter we discuss tumors involving these blood vessels, the clinical presentation and evaluation of these patients, the surgical approach to tumor resection and vascular resection and reconstruction, methods of vascular resection and reconstruction, the use of adjunctive extracorporeal bypass techniques where available, as well as perioperative and long-term results.

PORTAL AND SUPERIOR MESENTERIC VEIN RECONSTRUCTION

Given the close anatomic relationship between the portal vein (PV), superior mesenteric vein (SMV), and the pancreas, tumors originating from the pancreatic parenchyma may abut or invade these venous structures. Although pancreatic cancer involving these blood vessels was once considered a contraindication to pancreatic resection, the resection and reconstruction of these vessels has been established as a safe and effective method of achieving complete tumor resection in appropriate candidates. Considerable experience has been amassed with PV/SMV resection, and this technique has consequently become regarded as a standard adjunct to pancreatic resection in patients in

Abstract

The performance of venous resection and reconstruction to facilitate oncologic cure is becoming more routine in advanced malignancies of the peri-portal and retroperitoneal territories. Vascular surgeons should aware of the techniques and variations of venous reconstructions, and the options to achieve resection of the nearby malignancies. Additionally, awareness of options for support of venous return during reconstruction of major veins is requisite, and coordination of intraoperative resuscitation and/or extracorporeal bypasses may be considered. As the safety and efficacy of venous reconstruction has been demonstrated in multiple reports, it is likely vascular surgeons will encounter such practice demands in future consultations.

whom a complete tumor resection can be achieved. Whereas there are no prospective data in this area, multiple retrospective reports have examined the outcomes with regard to PV/SMV resection and reconstruction.[1-5] These data are summarized herein.

Tumor Types

Patients undergoing resection of pancreatic malignancies may present with tumor involving the PV and/or the SMV. Although the majority of these patients have pancreatic ductal adenocarcinoma, a minority present with a variety of tumors or diseases of the pancreas that may necessitate PV/SMV resection and reconstruction in order to achieve pancreatectomy. The largest published series of PV/SMV reconstructions performed concomitant with pancreatectomy is the series of 173 patients undergoing portal vein reconstruction out of 6522 patients who underwent pancreatectomy over a 45-year period at the Johns Hopkins Hospital. In this series, 86% of patients had pancreatic cancer and the remaining 14% had other diagnoses.[1] These included solitary fibrous tumor, pancreatic intraepithelial neoplasia (PanIN), gallbladder carcinoma, sarcoidosis, negative final pathology, and complete response to radiation without residual carcinoma present.[1] Since the majority of patients requiring PV/SMV resection have pancreatic adenocarcinoma, we focus here on the indications, approaches, and techniques specifically involving this malignancy.

Clinical Presentation, Evaluation, and Patient Selection

Only 15% to 20% of patients diagnosed with pancreatic cancer have resectable disease at the time of diagnosis.[6] Surgical resection is the only chance for cure. The resectability of pancreatic cancer is assessed based on the presence or absence of distant metastasis as well as the degree of local involvement and invasion of neighboring organs or blood vessels. Although clinical trials focus on the tumor-node-metastasis (TNM) system of classification, a more practical and clinically relevant system by which to categorize pancreatic cancer is as follows: resectable, locally irresectable, borderline resectable, and metastatic.[7] Resectable pancreatic cancer is defined as the presence of a tumor without distant metastasis or involvement of the superior mesenteric artery (SMA) or celiac artery (CA). Locally unresectable cancer is defined by infiltration of the SMA or CA; these lesions are not generally considered amenable to pancreatectomy. Borderline resectable cancer includes tumors with abutment to visceral arteries as well as those infiltrating the SMV or PV.[7] Those in this last category—patients with borderline resectable disease—are potential candidates for SMV/PV resection and reconstruction. Patients with metastatic disease are not candidates for surgical resection.

In the process of diagnosis and workup for pancreatic resection, patients typically undergo multiple imaging and invasive studies. Vascular involvement by pancreatic cancer is best assessed by helical computed tomography (CT) with intravenous contrast imaged in multiple phases to optimize contrast passage through the arterial phase, pancreatic phase, and portal venous phases.[8,9] Assessment of SMV/PV infiltration by a pancreatic tumor is best assessed on the portal venous phase.[9] Imaging findings highly sensitive for detection of PV/SMV invasion include radiologic absence of a fat plane between the tumor and the vessel, length of tumor involvement of greater than 5 mm, venous occlusion with formation of collateral vessels, presence of a "teardrop sign" in the SMV ("tethering" of the SMV by the tumor), and irregularity of the wall of the blood vessel (Fig. 167.1).[8] Imaging findings highly sensitive for unresectability include circumferential involvement of a vessel by more than 180 degrees (see Fig. 167.1).[8] Once a determination has been made regarding vascular involvement and potential for resectability, the technical feasibility of SMV/PV resection and reconstruction is assessed in conjunction with the oncologic surgeon who is managing the patient. A subset of patients requiring SMV/PV reconstruction will have venous involvement discovered intraoperatively despite preoperative imaging studies that do not suggest vascular involvement. Therefore intraoperative consultations for PV/SMV reconstruction are not infrequent.

There remains wide variation in the interpretation of resectability of pancreatic cancer with regard to PV/SMV involvement. A recent systematic review of outcomes from synchronous PV/SMV resection during pancreatectomy for cancer highlights the variability of results achieved with PV/SMV resection but does underscore the finding that PV/SMV resection in conjunction with pancreatectomy can be potentially curative.[10] Multiple recent reports have demonstrated that perioperative morbidity and mortality rates of pancreatectomy with PV/SMV resection and reconstruction are identical to those resulting from pancreatectomy without PV/SMV resection.[11-16] These reports further suggest that complete oncologic resection including PV/SMV resection is associated with improved survival versus those with residual disease after resection.[7] Therefore there has been a trend toward more aggressive PV/SMV resection to facilitate complete tumor removal.

Surgical Approach to Pancreatectomy and Portal Vein and Superior Mesenteric Vein Resection

Resectional techniques for pancreatectomy are well described elsewhere and are not given a full review here. Ductal adenocarcinoma is the most common tumor of the pancreas and is most commonly localized to the head of the pancreas in 78% of cases. Moreover, pancreatic cancers of the body and tail are typically unresectable at presentation. Therefore pancreaticoduodenectomy is the most commonly performed method of pancreatic resection. Indeed, in a systematic review of 1334 pooled patients who underwent SMV/PV resection and reconstruction during pancreatectomy, the extent of pancreatic resection was pancreaticoduodenectomy in 71%, total pancreatectomy in 24%, subtotal pancreatectomy in 3%, and distal pancreatectomy in 2%.[10] Because pancreaticoduodenectomy is the most commonly performed method of pancreatic resection in which SMV/PV reconstruction is required, here we focus

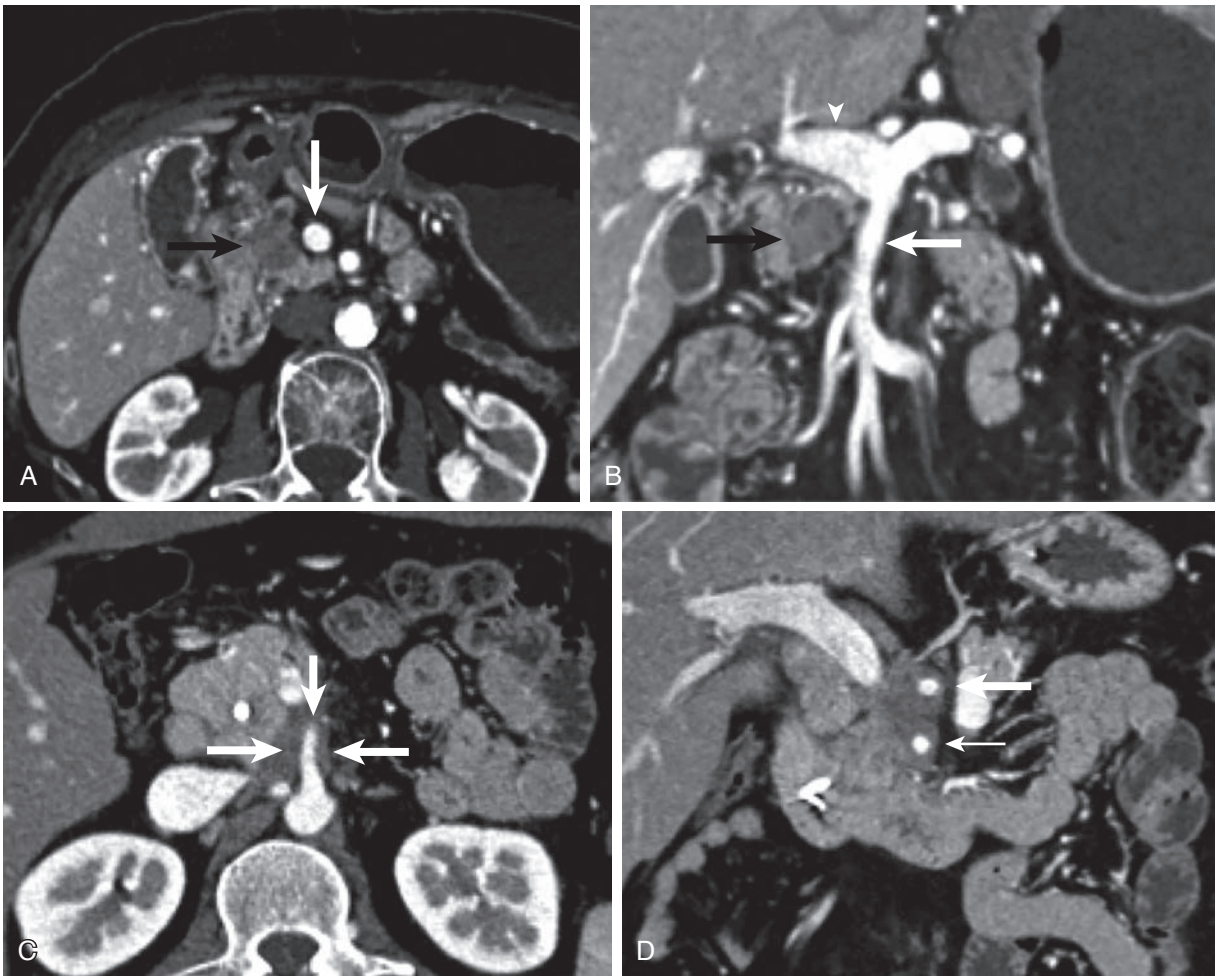

Figure 167.1 Portal Vein Invasion Is Evaluated on Preoperative Computed Tomography (CT) Imaging. (A) Axial slice of CT scan demonstrating a resectable lesion in the head of the pancreas *(black arrow)* with preservation of the fat plane circumferentially around the portal vein *(white arrow)*. (B) Coronal slice of CT scan demonstrating resectable lesion in the head of the pancreas with preservation of the fat plane around the vessel. (C) Axial slice of CT scan demonstrating an unresectable pancreatic mass with greater than 180-degree loss of the fat plane around the portal vein and circumferential encasement of the superior mesenteric artery (SMA). (D) Coronal slice of CT scan demonstrating an unresectable pancreatic tumor with complete encasement of portal vein *(large arrow)* and SMA *(small arrow)*.

briefly on the key steps of this procedure as they relate to SMV/PV resection and reconstruction.

In brief, pancreaticoduodenectomy can be accomplished via midline laparotomy or by bilateral subcostal ("rooftop") or chevron incisions. A critical early portion of the procedure is performing a wide Kocher maneuver, which allows assessment of the tumor and its relationship with the SMA for potential arterial infiltration. Many surgeons perform this portion of the procedure early in order to diagnose SMA or CA involvement, which would preclude pancreatic resection. The lesser sac is then entered by division of the gastrocolic ligament, and the hepatic flexure is mobilized. The gastroepiploic vein is ligated at its base near where it meets the gastrocolic trunk. It is at this point that the SMV is identified and traced to the inferior border of the pancreas. Supraduodenal dissection is then carried out, including cholecystectomy as well as lymphadenectomy of the hepatoduodenal ligament, common hepatic artery, and celiac trunk. The common bile duct is dissected to an extent that facilitates ligation and division. Multiple arteries in the vicinity of the pancreas require ligation, including the right gastric artery, the gastroduodenal artery, and the right gastroepiploic artery. At this point it is necessary to divide the distal stomach or proximal duodenum, depending on the oncologic surgeon's preference regarding preservation of the pylorus. Now the portal vein will be accessible which allows caudal dissection toward the superior border of the pancreas. The ligament of Treitz is mobilized and divided and the proximal jejunum is divided, which allows reflection of the distal duodenum on the specimen side into the lesser sac through a retrocolic window created in the transverse mesocolon to the right of the middle colic vessels. Dissection is then performed to mobilize the specimen off the SMV and SMA. The pancreatic parenchyma is then divided and the specimen is examined for final stages of vascular resection.

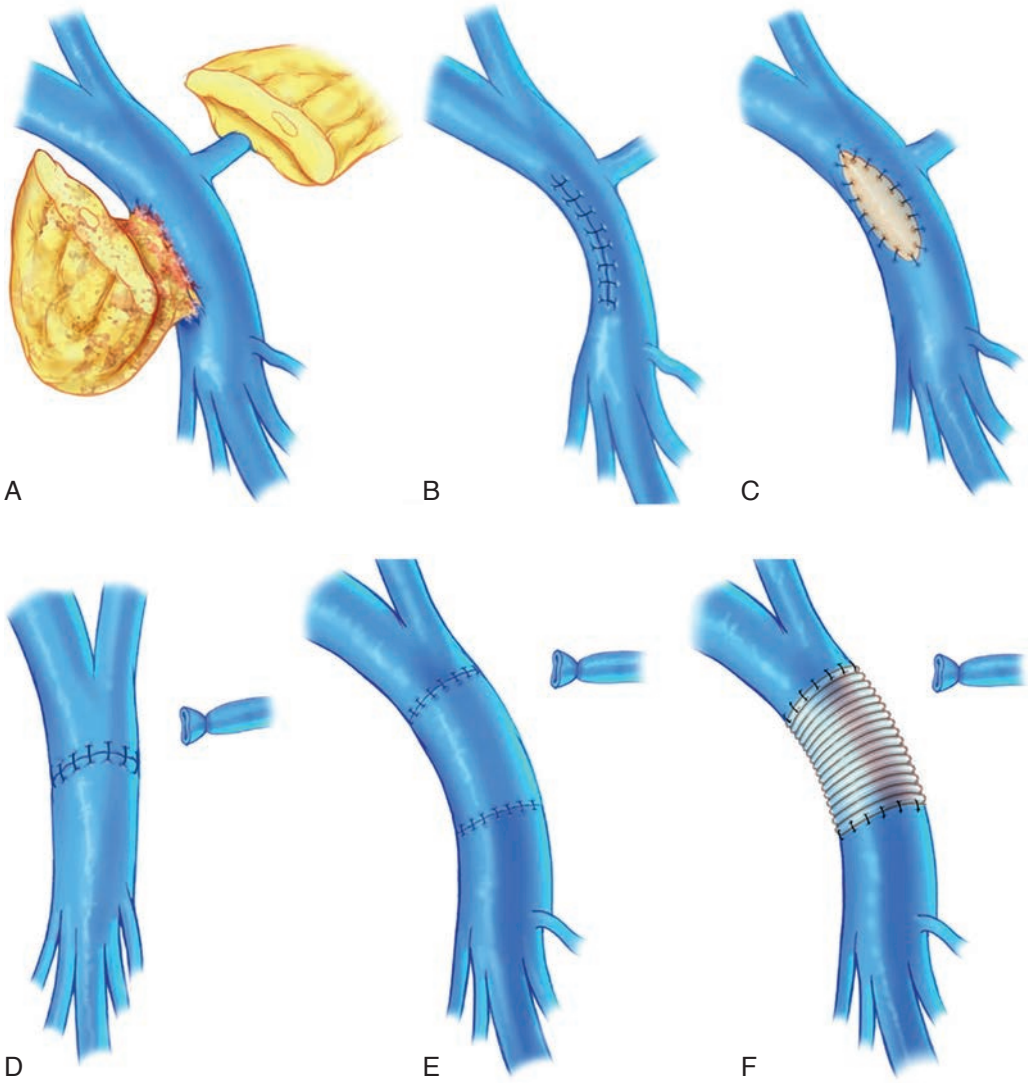

Figure 167.2 Methods of Portal Vein and Superior Mesenteric Vein Resection and Reconstruction. (A) Appearance of the pancreatic parenchyma in relation to the portal vein (PV)/superior mesenteric vein (SMV) illustrating involvement of the blood vessel in the usual anterolateral location. (B) Primary PV/SMV repair using venorrhaphy. (C) Vein patch angioplasty. (D) Primary end-to-end anastomosis. (E) Interposition graft placement using autologous vein. (F) Interposition graft placement using prosthetic.

When PV/SMV resection is required, it is typically performed during the last portion of the pancreatectomy. It is ideal for the rest of the pancreaticoduodenectomy dissection to be complete at this stage so that the specimen may be handed off and venous reconstruction can be performed expeditiously to minimize venous engorgement of the intestines during interruption of flow from the PV. The PV and SMV are circumferentially dissected and encircled with vessel loops to allow vascular control during resection. Depending on the extent and location of SMV/PV involvement, it may additionally be necessary to obtain vascular control of the splenic vein and left gastric vein. After the pancreaticoduodenectomy specimen is mobilized to the greatest extent possible, the SMV, PV, and, if necessary, the splenic and left gastric veins are occluded with vascular clamps and the involved SMV/PV wall is resected. Care is taken to preserve as much normal wall of the SMV/PV as possible in order to minimize the extent of reconstruction required while still achieving negative resection margins with the goal of achieving a complete resection. The most common area of PV/SMV involvement is the right anterolateral wall. If this is the case, the venous resection is best accomplished with the specimen retracted to the patient's right in order to optimize visualization and exposure of the PV/SMV (Fig. 167.2A).

Methods of Portal Vein and Superior Mesenteric Vein Reconstruction

The method and extent of reconstruction are dictated primarily by the anatomic location, circumference, and length of PV/SMV involvement. Reconstruction options include primary end-to-end reconstruction, lateral venorrhaphy, patch angioplasty, and interposition grafting (see Fig. 167.2). An additional factor

influencing the method of reconstruction is the physiologic state of the patient at the point in the procedure when venous reconstruction is performed. The extent of blood loss and degree of physiologic compensation will influence the extent of additional dissection for autologous vein graft procurement and length of additional operative time the patient can tolerate. Intraoperative systemic anticoagulation with heparin is not generally necessary.[1]

Primary venorrhaphy (see Fig. 167.2B) is generally possible when luminal narrowing of 30% or less is expected to result from the reconstruction. This method of SMV/PV reconstruction is both the most expeditious as well as easiest to perform. Primary venorrhaphy was performed in 37% of the SMV/PV reconstructions in our series from the Johns Hopkins Hospital.[1] Patch angioplasty (see Fig. 167.2C) is indicated when 30% to 50% of the PV/SMV circumference is involved and when primary end-to-end reconstruction is not technically feasible. The typical circumstance necessitating this method of reconstruction is a long segment of PV/SMV involvement (>2 cm) with a narrow circumferential involvement by tumor. As such, an ellipse-shaped venectomy is easily reconstructed using this method. Various patch materials have been described, including autologous vein, bovine pericardium, and expanded polytetrafluoroethylene (ePTFE).[1,17,18] We have had similar success with all of these patch materials.[1]

Primary end-to-end reconstruction (see Fig. 167.2D) of the PV/SMV is typically required when the degree of luminal narrowing exceeds 30%. In order to successfully achieve a tension-free primary end-to-end reconstruction, the length of involved vein should measure approximately 2 cm or less. In our reported experience with SMV/PV resection and reconstruction, this method of reconstruction was utilized in 24% of patients. Additional mobilization maneuvers may reduce tethering of the SMV and PV and thereby facilitate this method of reconstruction. These maneuvers can include extensive mobilization of the root of the mesentery, mobilization of the right colon, and mobilization of the liver by dividing its suspensory ligaments.[1]

Interposition grafting of the PV/SMV (see Fig. 167.2E and F) is generally required when the circumference of tumor involvement exceeds 30% and when the length of involved PV/SMV exceeds 2 cm.[1,17] A wide variety of conduits have been described for interposition grafting, including autologous vein grafts (greater saphenous vein, femoral vein, internal jugular vein, left renal vein, splenic vein (see Figs. 167.2E and 167.3), cryopreserved homografts, and synthetic grafts (see Fig. 167.2F), including Dacron and ePTFE (ringed and nonringed).[1,17-19] Conduit choice is influenced by the availability of autologous vein, degree of stability of the patient at the point in the procedure when reconstruction is required, and by size match. Although saphenous vein is an excellent material for patch angioplasty, it is not an ideal conduit for PV/SMV reconstruction owing to size mismatch.[18]

Concomitant splenic vein ligation may be necessary depending on the method and extent of reconstruction required. When lateral venorrhaphy was performed, splenic vein ligation was required in 33% of patients in our series.[1] However, when primary end-to-end reconstruction was performed, splenic vein ligation was required in 78% in our series.[1] When interposition grafting was performed at or above the level of the splenic vein, splenic vein reimplantation was not performed and the splenic vein was ligated.[1]

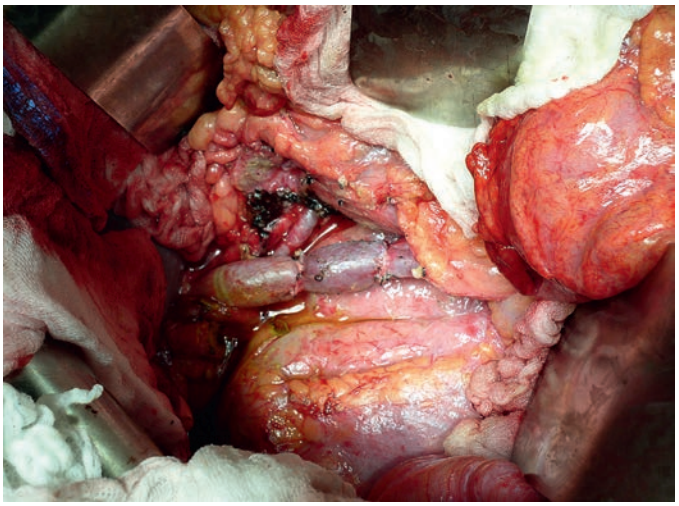

Figure 167.3 Intraoperative photograph demonstrating a portal vein reconstruction utilizing an internal jugular vein interposition graft.

Perioperative Outcomes

Variable rates of thrombosis of the PV/SMV reconstruction of 0% to 17% have been reported in several small retrospective studies examining this procedure.[15,20-25] PV/SMV thrombosis occurs with increasing incidence over time postoperatively in patients undergoing PV reconstruction. In the Johns Hopkins series, routine anticoagulation was not used following PV/SMV resection/reconstruction. Thrombosis developed in 13.3% of patients undergoing PV/SMV reconstruction with follow-up exceeding 1 year. Risk factors for portal vein thrombosis included preoperative chemotherapy, preoperative radiation therapy, long operative time, and use of a prosthetic interposition graft for reconstruction.[1] Similarly, use of prosthetic graft for reconstruction correlated with worse survival at 1 year postoperatively in this series.[1] Whereas other series support the use of ePTFE interposition grafts for PV/SMV reconstruction, the reported graft patency rate of 76% at 14 months is inferior with this modality.[19] PV/SMV thrombosis is associated with the development of ascites.[1,19]

Infectious complications arising from placement of synthetic grafts in the contaminated surgical field associated with pancreatectomy are surprisingly rare. No infectious complications were reported in a series of 33 patients in whom PV/SMV reconstruction was achieved using ePTFE interposition grafts.[19] Anecdotally described techniques employed to prevent ePTFE graft infection include perioperative administration of parenteral antibiotics, graft treatment with antibiotic solution, minimizing enteric and biliary spillage, omental wrapping, and irrigation with antibiotic-impregnated solutions.[19]

As already described, ligation of the splenic vein may be required during PV/SMV reconstruction, particularly when end-to-end reconstruction and interposition grafting are performed. Splenic vein ligation may rarely result in sinistral hypertension with concomitant esophagitis and/or gastritis and gastrointestinal bleeding. This rare complication occurred in only 3.8% of patients undergoing splenic vein ligation in our series.[1]

Long-Term Outcomes

Long-term outcomes in patients undergoing PV/SMV reconstruction are limited primarily by the natural history of pancreatic cancer rather than complications resulting specifically from the method of reconstruction. Although PV/SMV reconstruction has been demonstrated to improve overall survival in selected patients in whom no residual tumor is present and with adjunctive venous resection, the overall survival in this patient population remains poor. In the Johns Hopkins series, patients undergoing PV/SMV reconstruction had a medial survival of 15.5 months.[1] Development of PV/SMV thrombosis did not affect overall survival. Moreover, the method of reconstruction (primary repair, interposition vein graft, interposition prosthetic graft, and patch angioplasty) was not associated with a difference in overall survival, and similar findings have been reported elsewhere.[2,3]

When there is apparent tumor involvement of the PV/SMV upon gross assessment in the operating room, between 25% and 50% of these patients are found to have only a desmoplastic reaction at the interface with the PV/SMV without tumor cell infiltration.[4,21] Patients with tumor infiltration of the PV/SMV have worse survival compared with those with only a desmoplastic reaction at the venous interface.[5] Unfortunately there is no reliable method for differentiating these patients intraoperatively. Therefore PV/SMV resection is currently the accepted treatment of choice for patients with pancreatic cancer with PV/SMV involvement in whom an R0 (complete resection) can be otherwise achieved.

Ascites may develop postoperatively following pancreatic resection as well as PV/SMV reconstruction. The pathogenesis of ascites in these patients is commonly from disease progression in the form of tumor recurrence at the porta hepatis, from PV/SMV thrombosis, or from a combination of these. In our series from the Johns Hopkins Hospital, PV/SMV thrombosis was a risk factor for the development of ascites, although a significant proportion of these patients had recurrence of tumor on follow-up imaging.[1]

INFERIOR VENA CAVA RECONSTRUCTION

The inferior vena cava (IVC) rarely develops primary malignancies. More commonly the IVC may become involved secondarily with malignant tumors originating from the retroperitoneum, kidneys, adrenal glands, liver, and gastrointestinal organs. Whereas surgical resection of many tumors presenting in advanced stages may not be possible, IVC resection and reconstruction can be performed safely in selected candidates and may provide the only opportunity for cure of many of these malignancies. A significant proportion of these patients present with unresectable disease or have a poor performance status, precluding safe IVC resection and reconstruction. Surgical management of these patients is coordinated in collaboration with the medical and surgical oncologists managing their care. There are limited data evaluating outcomes following IVC resection and reconstruction; the existing literature is limited to retrospective series.[26-29] However, this technique is gaining increasing support due to its established safety, success, and ease of execution, particularly with the refinement of venovenous bypass and other extracorporeal techniques of circulatory support.

Tumor Types

Malignancies affecting the IVC may be categorized as primary or secondary. Primary IVC malignancies are extremely rare and will typically be encountered only in tertiary referral centers. Secondary malignancies involving the IVC are more common. These include a variety of renal, adrenal, retroperitoneal, abdominal, and hepatic tumors that may involve the IVC directly or with tumor thrombus. IVC resection and reconstruction may be required for complete tumor clearance in many of these conditions. Although a detailed discussion of indications for surgical resection of these various tumors is beyond the scope of this chapter, several of the more commonly encountered tumors affecting the IVC and requiring concomitant resection and reconstruction are discussed briefly in the following paragraphs.

Primary leiomyosarcoma of the IVC is an exceedingly rare condition. Fewer than 400 cases of resection of this tumor have been reported worldwide. The IVC is the most common blood vessel to be affected by vascular leiomyosarcoma and is the source of more than 50% of cases.[30,31] The mainstay of treatment is complete surgical resection, as this is the only opportunity for cure of the disease and incomplete resection is associated with poor prognosis, as this tumor responds poorly to other forms of therapy.[32] The goal of surgical resection is therefore to achieve negative margins, which has been demonstrated to improve survival.[33] Resection may require en bloc removal of the IVC with neighboring organs, commonly the kidney, adrenal gland, or gallbladder.[26,34] Long-term survival is possible but only with tumor resection.

A host of other retroperitoneal, renal, adrenal, hepatic, and abdominal tumors can secondarily involve the IVC and require concomitant IVC resection and reconstruction. In general, when the IVC is involved, these tumors require complete resection of both the tumor and the involved IVC. Renal cell carcinoma (RCC) is one such tumor that requires surgical resection for cure. In 2% to 16% of cases of RCC, tumor may spread from the lumen of the renal vein into the IVC, a condition termed tumor thrombus.[26-29] Other genitourinary tumors include transitional cell carcinoma and metastatic seminoma.[35] Adrenal tumors include adrenal lymphoma, malignant pheochromocytoma, and adrenal paragangliomas.[18] Liver tumors include hepatocellular carcinoma,[26] cholangiocarcinoma,[26] and metastatic

tumors to the liver, particularly metastatic colon cancer.[26] Other retroperitoneal tumors include liposarcoma, germ cell tumor, malignant fibrous histiocytoma, benign retroperitoneal neurofibroma, recurrent benign intravascular leiomyomatosis, Wilms tumor, teratoma, lymphadenopathy from metastatic melanoma, and duodenal carcinoma.[35,36] Successful IVC resection and reconstruction has been described for all of these tumors.

Clinical Presentation and Evaluation

The workup of patients presenting with malignancies involving the IVC requires a multidisciplinary approach between medical oncologists, surgical oncologists, and vascular surgeons managing their care.[26] Preoperative imaging using CT scanning with intravenous contrast must be performed to establish the presence or absence of distant metastases, the local resectability of the tumor, the degree of IVC involvement, and the presence of absence of IVC obstruction.[26] Particular attention should be paid to the vascular anatomy of the IVC, especially its tributaries and branches, including bilateral renal veins, hepatic veins and their confluence, as well as lumbar and gonadal veins. To this end, CT scans should be performed using arterial and venous phases for purposes of planning surgical reconstruction. Patients may present with chronic IVC obstruction; if so, they typically have well-developed venous collaterals. Imaging modalities employed to this end include a combination of chest roentgenography, CT, magnetic resonance imaging (MRI), and possibly vena cavography when other modalities are indeterminate. In patients with tumor thrombus from RCC, MRI has a high sensitivity for detection of IVC wall invasion and may assist in preoperative planning in these patients.[37]

Intracaval extension of tumor thrombus is present upon diagnosis in up to 16% of patients with renal cell carcinoma, and 1% have tumor thrombus extending to the right atrium.[38,39] The Neves and Zincke classification has been widely utilized to establish the extent of tumor thrombus present (Figs. 167.4 to 167.6).[27] In this scheme, the extent of tumor thrombus is classified according to its most cephalad location. Level I tumor thrombus extends into the IVC less than 2 cm from the ostium of the left renal vein (see Fig. 167.4). Level II tumor thrombus extends into the infrahepatic IVC more than 2 cm above the renal vein (see Fig. 167.5). Level III tumor thrombus extends into the retrohepatic IVC (Fig. 167.7). Level IV tumor thrombus extends into the supradiaphragmatic IVC to involve the right atrium. Patients presenting with tumor thrombus benefit from intraoperative transesophageal echocardiography in order to obtain an accurate assessment of the extent of tumor thrombus present at the time of operation, as tumor thrombus may have progressed since the time of preoperative imaging.[40]

Surgical Approach

The surgical approach for IVC resection is dictated by the location of the tumor and the degree of dissection required for complete vascular control of the IVC. Many cases can be approached through a midline laparotomy; this is the preferred approach if concurrent sternotomy is required for cardiopulmonary bypass (CPB). Alternatively, a chevron incision may be used. If CPB or circulatory arrest is required or if there is tumor thrombus extending to the right atrium, sternotomy or thoracotomy is performed concomitantly. If extensive dissection of the vena cava is required—for example, in the case of a tumor involving the retrohepatic IVC—a right thoracoabdominal approach through the seventh, eighth, or ninth interspace may be preferable as it is allows better access to the retrohepatic and suprahepatic IVC.[26,41]

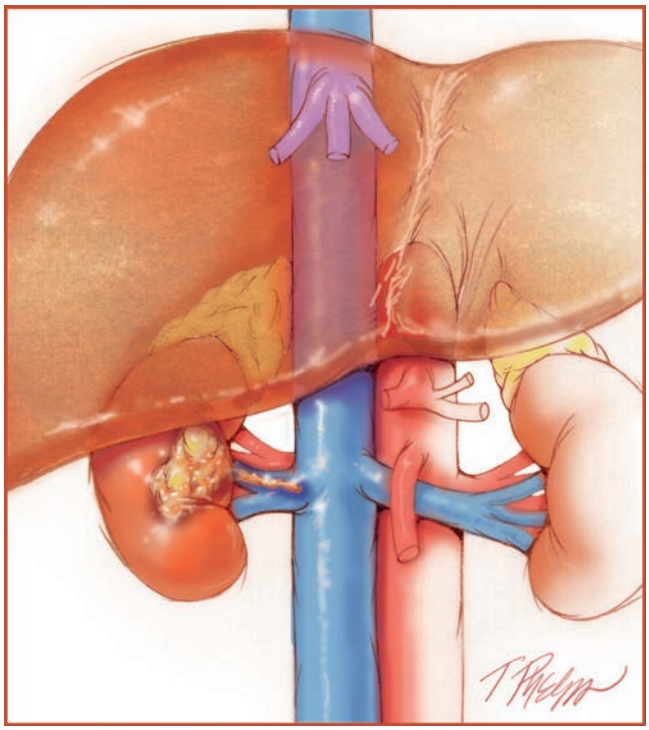

Figure 167.4 Level I Tumor Thrombus. By the Neves and Zincke classification indicating cephalad extent of inferior vena cava tumor thrombus, a level I tumor thrombus is confined to less than 2 cm above the left renal vein.

Upon entry into the peritoneal space, a thorough intra-abdominal exploration is conducted to assess for the presence of regional lymph node or peritoneal metastatic disease. Intraoperative ultrasonography may be employed to assess the relationship of tumor to major vascular structures.[26] The tumor is dissected as extensively as possible prior to IVC resection. In the case of concomitant nephrectomy, it is preferable to complete all portions of the nephrectomy except for renal vein ligation, as this structure is left in place until IVC resection. Vascular control of the IVC is achieved proximally and distally to the tumor, including all venous tributaries in the involved region. Vessel loops or umbilical tapes are placed around the IVC proximally and distally to the involved region. In the case of infrahepatic IVC involvement, control of the infrarenal IVC, renal veins, and suprarenal IVC is adequate. In the case of retrohepatic IVC involvement, total hepatic vascular isolation is necessary, which involves additional control of the suprahepatic IVC and porta hepatis to facilitate a Pringle maneuver. Total hepatic vascular isolation requires mobilization of the suspensory ligaments of the liver. Lumbar veins, if large, must also be controlled as these vessels can cause significant hemorrhage

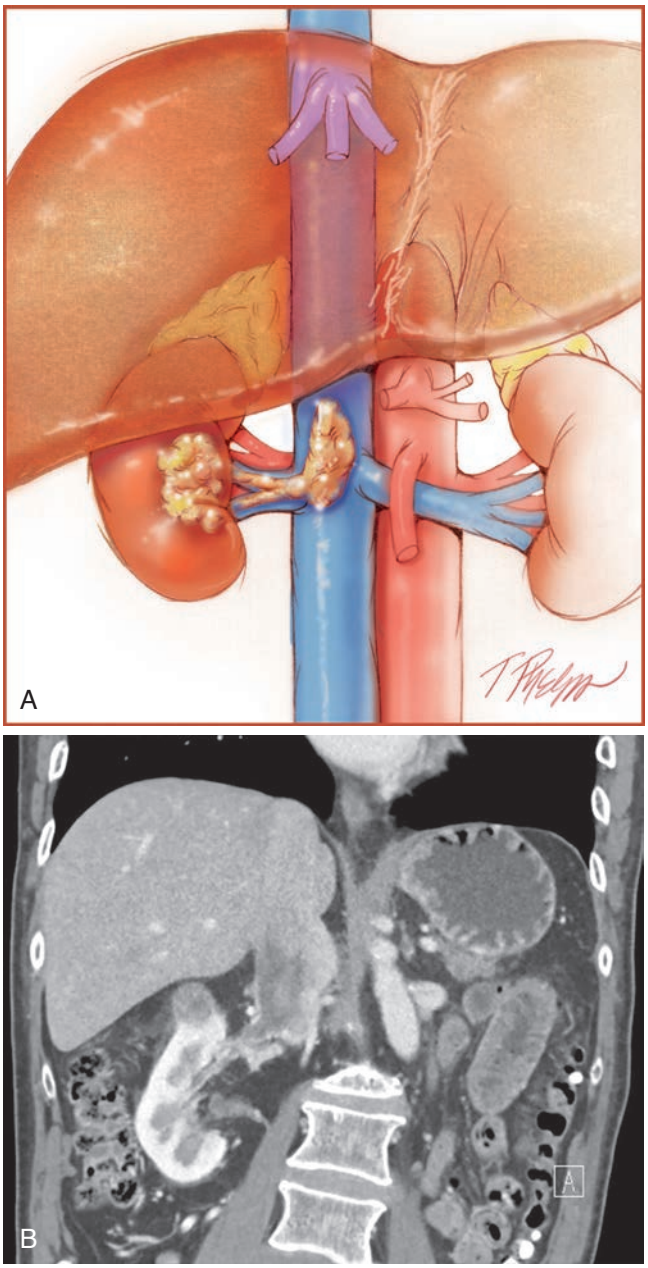

Figure 167.5 (A) Level II tumor thrombus. By the Neves and Zincke classification indicating cephalad extent of inferior vena cava tumor thrombus, level II thrombus extends more than 2 cm above the renal vein, but is still infrahepatic. (B) Representative CT scan of a patient with level II tumor thrombus.

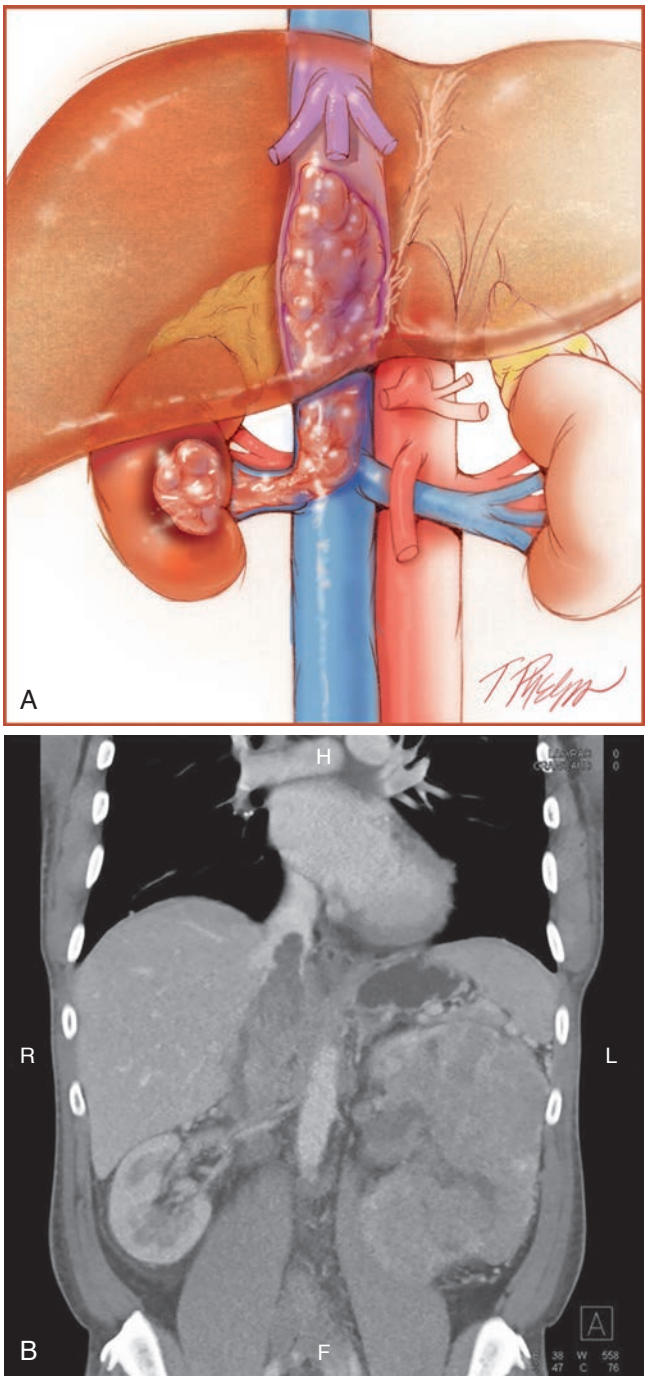

Figure 167.6 (A) Level III tumor thrombus. By the Neves and Zincke classification indicating cephalad extent of inferior vena cava tumor thrombus, level III tumor thrombus is retrohepatic but still remains below the diaphragm without extension into the right atrium. (B) Representative CT scan of a patient with level III tumor thrombus.

from venous backbleeding after IVC venotomy is performed. We routinely administer systemic anticoagulation intraoperatively using intravenous heparin (100 U/kg) administered prior to vascular cross-clamping and dosed to maintain an activated clotting time greater than 250 seconds until restoration of venous flow is achieved.[42,43]

Proper anesthetic management is vital for successful IVC resection and reconstruction. Prior to IVC interruption for resection and reconstruction, temporary IVC occlusion or "test clamping" should be undertaken as a means of assessing whether the profound decrease in venous return resulting from IVC clamping will be tolerated. Patients unable to tolerate test clamping may require more aggressive anesthetic support, including rapid administration of intravenous fluids, initiation of vasopressor support, and Trendelenburg positioning.[40,42] If IVC interruption is still not tolerated, the patient will likely benefit from extracorporeal support with venovenous bypass or CBP. Alternatively, temporary aortic cross-clamping can be performed. However, this maneuver should be minimized to

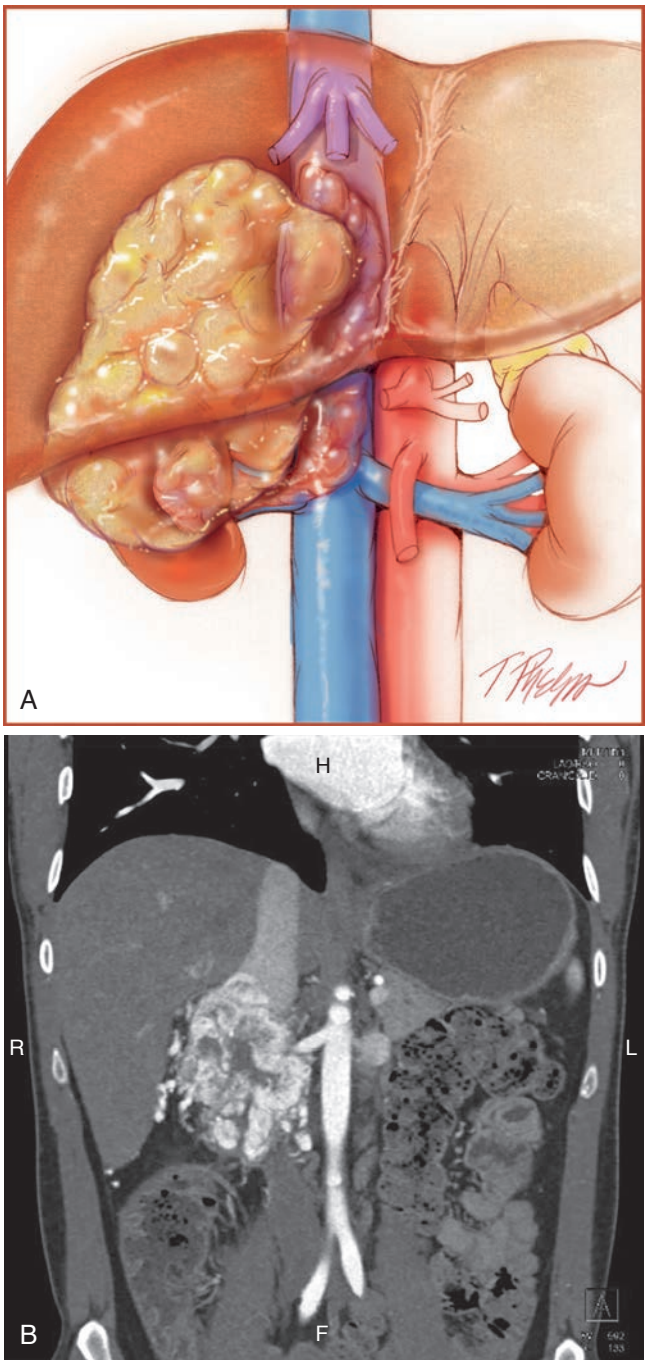

Figure 167.7 (A) Level III tumor thrombus in association with an extensive renal tumor invading the retrohepatic inferior vena cava (IVC), requiring graft replacement of the IVC. (B) Representative CT scan of a patient with adrenal tumor with invasion of the retrohepatic IVC.

30 minutes or less to prevent undue renal and end-organ ischemia; therefore, it may not be feasible during an extensive reconstruction.[44]

Methods of Inferior Vena Cava Reconstruction

The degree of IVC resection is dictated by the degree of tumor involvement of the IVC. In most circumstances, oncologic clearance of tumor requires en bloc resection with the involved portion of IVC. There are several options for reconstruction of the IVC involved by tumor. These include primary repair, patch angioplasty, interposition grafting, and ligation (Fig. 167.8). Primary IVC repair is possible when the IVC wall is partially resected, and primary repair would result in less than 50% narrowing of the vessel (see Fig. 167.8A).[40,42,43] IVC patch angioplasty is indicated when the IVC wall is partially resected, and primary repair would result in greater than 50% narrowing of the vessel (see Fig. 167.8B).[40,42,43] Various materials have been described for patch closure and most commonly include bovine pericardium, but ePTFE and Dacron patch closure may be successfully utilized.[42] Interposition grafting is indicated when the IVC requires circumferential segmental resection (see Figs. 167.8C and 167.9A). Grafts described for use in interposition reconstruction include femoral vein,[26,45] aortic homograft,[46] cryopreserved vena cava,[47] and prosthetic grafts (Dacron and ePTFE). Prosthetic grafts are the most commonly employed type of graft for IVC reconstruction. Most authors preferentially utilize externally reinforced ringed ePTFE, as this widely available graft is theoretically protective against collapse by overlying abdominal viscera in the low-pressure venous system.[18,42,43,48-55] The graft is matched to the size of the recipient IVC, and grafts 14 to 20 mm in diameter are usually appropriate.[26,42,43] In cases of contamination of the operative field by bowel contents, it may be necessary to reconstruct the IVC utilizing autologous vein (saphenous, jugular, or femoral) assembled in a spiral fashion in order to achieve a conduit of adequate caliber to match the native IVC (see Figs. 167.8D and 167.9B).

Patients undergoing interposition grafting during IVC reconstruction may require reimplantation of the renal and/or hepatic veins. In the largest existing series of IVC interposition grafting, renal vein reimplantation was required in 24% of patients, and hepatic vein reimplantation was required in 2%.[56] Renal vein reimplantation, while perhaps unnecessary to achieve adequate renal function postoperatively, certainly enhances flow through the conduit, a factor beneficial in the prevention of graft thrombosis (see Fig. 167.9A). Additionally, intraoperative oliguria or anuria during renal vein clamping may be a harbinger of impending renal failure in the absence of renal vein implantation; if either of these events develops, it would argue for performing renal vein implantation.[49]

Some authors have advocated creation of an adjunctive arteriovenous (AV) fistula in order to augment patency of the IVC reconstruction. Although data in this area are particularly lacking, AV fistula creation may augment patency in select circumstances. This includes patients undergoing reconstruction of the infrarenal IVC due to the relatively lower flow compared with suprarenal reconstructions.[26,41,49,57] An AV fistula may also enhance the patency of long grafts (e.g., in multilevel IVC replacement) or in small-diameter grafts equal to or less than 16 mm in diameter.[26,58,59] An adjunctive AV fistula may be created between the remaining ipsilateral renal vessels, between the renal artery and gonadal vein, or between the superficial femoral artery and greater saphenous vein.[26,41]

Ligation of the IVC is another option for the management of patients presenting with tumors involving the IVC. This method of management should be avoided, if possible, as it is

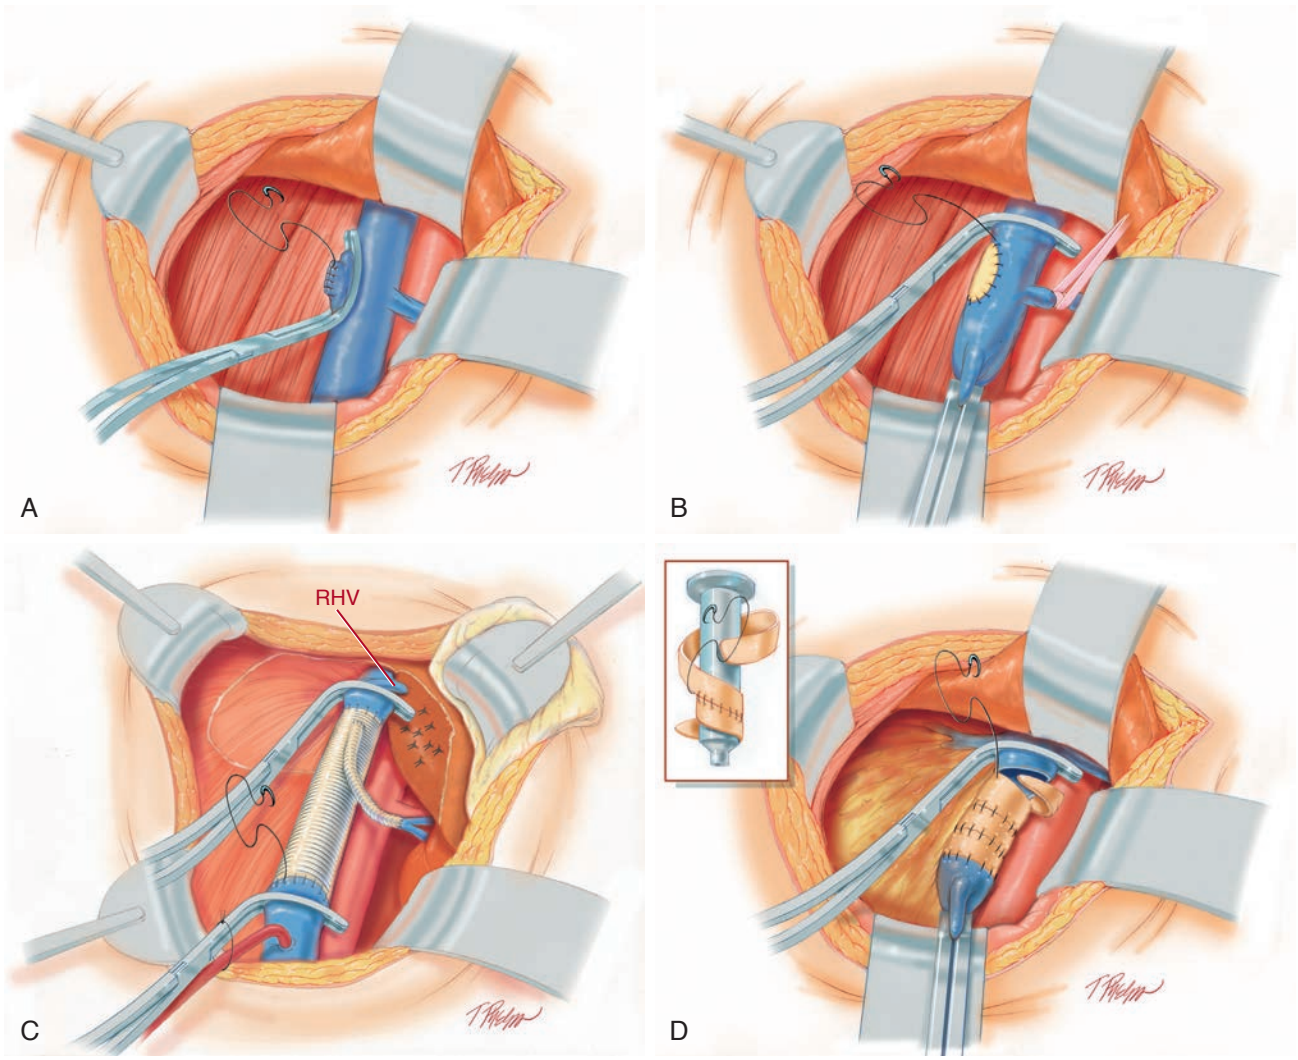

Figure 167.8 Methods of Inferior Vena Cava Reconstruction. (A) Primary repair. (B) Patch repair. (C) Graft reconstruction. (D) Spiral vein graft reconstruction. *RHV,* Right hepatic vein.

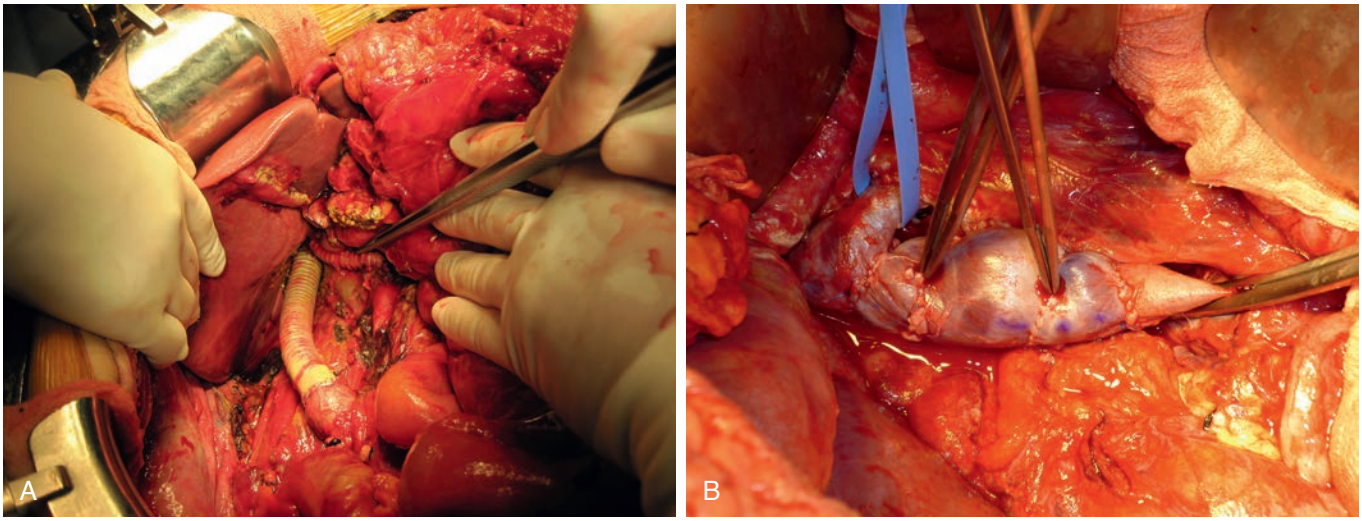

Figure 167.9 Intraoperative photographs of inferior vena cava reconstructions performed including (A) prosthetic interposition graft with reimplantation of left renal vein and (B) spiral vein reconstruction using an autologous vein graft.

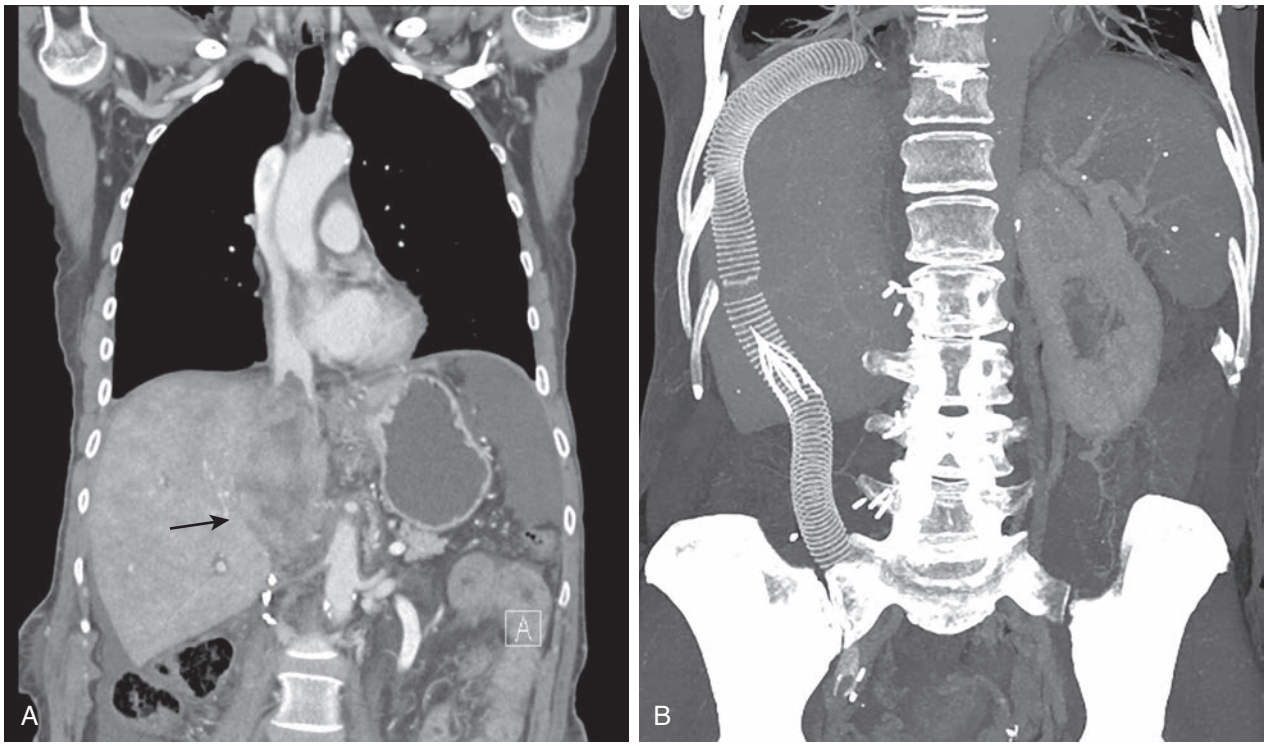

Figure 167.10 Palliative inferior vena cava (IVC) bypass may be utilized selectively in patients with unresectable tumors and/or tumor thrombus causing IVC obstruction. (A) CT scan of a patient with unresectable recurrent renal cell carcinoma involving the IVC, with tumor thrombus causing IVC obstruction *(arrow)* and resulting severe lower extremity edema. (B) This patient underwent a palliative bypass from the right common iliac vein to the suprahepatic IVC using a ringed polytetrafluoroethylene graft with an IVC filter placed within the bypass conduit for thromboembolic protection.

associated with significant morbidity.[41] Acute renal failure and severe postoperative lower extremity edema develop in up to 50% of patients undergoing IVC ligation,[33,41,60] and lower extremity DVT have been reported to occur in close to one-third of patients.[61] Although it is efficient and technically simple, IVC ligation is best reserved for patients with chronic IVC obstruction with the presence of well-developed collaterals who cannot tolerate reconstruction concomitant with tumor extirpation and IVC resection.[18,62] Even in patients with well-developed collaterals whose venous return is compensated preoperatively without venous hypertension, the extensive retroperitoneal dissection associated with removal of these neoplasms significantly disrupts existing venous collaterals and predisposes to postoperative venous hypertension.[36,49] Therefore when IVC ligation is performed, care must be taken to preserve these collaterals.[45] While some series report IVC ligation as a routine method of managing IVC tumor involvement,[60] it is our experience and that of others that IVC ligation is rarely if ever necessary and that safe IVC reconstruction is routinely possible, and indeed preferable, in most circumstances.[18,26,35,36,42,43,63,64]

Improvement in chemotherapeutic and biologic antitumor agents has extended the life expectancy of many patients with unresectable tumors and indolent progression of disease. Palliative IVC bypass is an additional option for the management of select patients with disabling lower extremity edema due to IVC occlusion in whom the primary tumor and/or tumor thrombus are unresectable. Palliative IVC bypass may be safely performed with excellent long-term results (Fig. 167.10). This procedure is best performed via right thoracoabdominal exposure through the seventh, eighth, or ninth intercostal space. The optimal choice of bypass conduit is ringed ePTFE measuring 12 to 18 mm. The proximal anastomosis may be constructed at the most cephalad extent of patent iliac vein or IVC. The distal anastomosis is best constructed at the suprahepatic IVC; it may also be constructed at the right atrium. In the latter circumstance, cardiopulmonary bypass must be instituted. Placement of an IVC filter in the bypass conduit is recommended in order to prevent pulmonary embolism.[42]

Adjunctive Extracorporeal Bypass Techniques

Venovenous bypass (VVB) is a necessary adjunct during IVC resection and reconstruction in several circumstances. These include patients unable to tolerate IVC clamping due to tenuous cardiopulmonary status or old age, level III extension of tumor thrombus, complex multilevel IVC involvement, need for full graft replacement, and those in whom an adequate oncologic resection cannot be achieved without the institution of bypass support.[42,48] The technique of VVB includes placement of a 24-Fr arterial perfusion cannula for VVB outflow. The infrarenal IVC may be cannulated directly or the femoral vein may be isolated via a groin cutdown to allow for cannula placement

outside the operative field. The cannula is then connected to the bypass circuit, which consists of a perfusion pump. Inflow to the circuit is via a "Y" connector to two cordis cannula placed into the right internal jugular (IJ) vein. VVB is then initiated and performed in a normothermic fashion with flow rates maintained at 750 to 1500 mL/min to support a mean systemic perfusion pressure of 60 to 80 mm Hg. At cessation of bypass, the inflow cannula is removed with venous repair as appropriate and the outflow tubing is disconnected from the IJ cordis cannula.

The presence of level IV tumor thrombus requires CPB. To perform this, the superior vena cava (SVC), IVC, and ascending aorta are isolated. The ascending aorta and SVC are cannulated using intraoperative transesophageal echocardiographic guidance using a 19-Fr percutaneous venous cannula. CPB is commonly performed under mild hypothermia to 32°C. When deep hypothermic circulatory arrest (DHCA) is utilized, cooling to 25°C is typical. Arterial inflow is adjusted to maintain a perfusion pressure of 60 to 80 mm Hg.[42]

Perioperative Outcomes

The performance of IVC reconstruction and resection is inherently high risk for the development of venous thromboembolic (VTE) events, as the IVC is a low-pressure system with potential for stasis. Moreover, the presence of malignancy inherently increases the risk of hypercoagulability. Perioperative VTE developed in 22% of patients in our series from the Johns Hopkins Hospital; 9% of patients developed isolated DVT and 12% developed pulmonary embolism (PE).[43] The median time to diagnosis of VTE was 6 days postoperatively in our series. Risk factors for VTE in our series were large tumor size, reimplantation of one or more renal veins, and blood product transfusion. Prosthetic graft reconstruction, preoperative IVC thrombus, and history of VTE were not associated with the occurrence of postoperative VTE. Of note, the VTE events in our series did not result in fatality, and only half were symptomatic. Intraoperative pulmonary embolism during IVC reconstruction has also been described and may require emergent pulmonary embolectomy.[65]

In our experience with IVC resection and reconstruction for malignancy, patients were given postoperative prophylaxis for deep venous thrombosis (DVT) with heparin administered subcutaneously (5000 U) every 8 hours. Antiplatelet drugs were administered if patients were taking them preoperatively. It is not our practice to administer postoperative systemic anticoagulation unless patients are diagnosed with VTE. Some authors advocate the use of selective postoperative anticoagulation in patients with a history of VTE or atrial fibrillation.[35] Others advocate routine postoperative anticoagulation with warfarin, given a high reported incidence of postoperative thrombosis of the IVC reconstruction. The Mayo Clinic group uses routine anticoagulation in patients undergoing IVC reconstruction with prosthetic graft interposition; they report a somewhat lower rate of VTE events, including a 7% rate of graft thrombosis and 3% rate of DVT.[26] Although VTE rates are lower with the routine use of systemic postoperative anticoagulation, the rate of postoperative bleeding is higher.[26,63] Even when postoperative anticoagulation is routinely administered, up to 25% of patients have been reported to develop thrombosis of the graft or of associated iliac vein graft limbs in some series.[41] Therefore it is our practice not to administer postoperative anticoagulation unless VTE is diagnosed.[42,43]

Use of adjunctive bypass support, including VVB, CPD, and DHCA, involves greater surgical complexity and therefore is associated with an increased rate of perioperative morbidity but not perioperative mortality. Utilization of bypass support is associated with increased bleeding and subsequent requirement for perioperative transfusion, coagulopathy, prolonged operative time, longer postoperative ICU length of stay (LOS), and overall hospital LOS.[29,38,42,66,67] Whereas utilization of bypass support is associated with an overall increased risk of perioperative complications, its use does not have an effect on long-term outcomes or survival.[42]

Long-Term Outcomes

Circumferential IVC resection with placement of a prosthetic interposition graft is associated with good long-term patency in several series. Patency rates of 80% to 100% at 9 months to 5 years have been reported in multiple small series, and these results were achieved utilizing postoperative anticoagulation.[26,35,48,68] In a large multi-institutional series involving the placement of prosthetic interposition grafts for IVC reconstruction, outcomes in 102 patients over a mean follow-up of 56 months were reported. These authors report excellent IVC graft patency rates of 95% at 1 year, 92% at 3 years, and 92% at 5 years.[56] Graft infection and tumor recurrence have been demonstrated to correlate with graft thrombosis.[26] Graft infection with subsequent thrombosis has been reported in several series but is still relatively rare; this event occurred in 1 of 14 patients in the Johns Hopkins series,[42] 1 of 27 patients in the UCLA series[35] and 1 of 16 patients in a series from Heidelberg.[68] Reported risk factors for IVC graft infection include duodenal leak, bile leak, and perforated diverticulitis.[26,68]

SUMMARY AND CONCLUSIONS

The PV, SMV, and IVC may be safely and expeditiously resected as an adjunct to tumor resection in appropriate surgical candidates. The safety and feasibility of these techniques have been well established on the basis of institutional experiences from multiple centers. PV/SMV resection is now a routine intraoperative technique to facilitate R0 resection for pancreatic tumors. Indeed, multiple lines of evidence are establishing that this technique facilitates a higher rate of complete resection without increasing the morbidity and mortality of pancreatectomy. Likewise, IVC resection provides the only chance for cure of a variety of retroperitoneal, renal, adrenal, hepatic, and abdominal malignancies. The best data suggest that this technique does not negatively influence survival or mortality in the long term. On the contrary, IVC resection may also provide the only chance for cure of a whole host of malignancies, and without employing this technique these tumors would otherwise

be unresectable. A variety of adjunctive bypass techniques increase the technical feasibility of IVC resection without negatively affecting long-term results. In both of these areas, future prospective or multi-institutional retrospective studies will elucidate the most successful methods of reconstruction and postoperative management, including the ideal method of anticoagulation for optimum graft patency.

Lymphedema is the term used to characterize the various pathologic conditions in which there is progressive accumulation of protein-enriched interstitial fluid. Collectively, these forms of edema arise as a consequence of relative impairment of lymphatic vascular function. Lymphatic vascular insufficiency can result from either primary or acquired (secondary) lymphatic defects. Cryptogenic forms of lymphedema are often presumed to represent primary lymphatic dysfunction. Although impaired lymphatic function can manifest as visceral pathology, particularly in the respiratory or gastrointestinal organs, it is upper or lower extremity edema, with or without visceral involvement, that is the most common presentation of lymphatic impairment.

PATHOPHYSIOLOGY

Impairment of lymphatic outflow leads to the pathologic consequences of lymphedema. In high-input failure, such as that which occurs in venous edema, increased pressure at the venous end of the capillary leads to the accentuated production of interstitial fluid through increased capillary filtration; if the production of lymph exceeds the maximal transport capacity of the lymphatic conduits, lymphedema will ensue, even if these structures are anatomically and functionally normal. By contrast, low-output failure ensues when some pathologic condition compromises lymphatic flow. Lymph stasis can accompany lymphatic hypoplasia or aplasia, functional

insufficiency or anatomic absence of lymphatic valves, or, conceivably, blunted lymphatic contractility.[1]

Because the lymphatic circulation is responsible for the return of interstitial fluid and protein to the central circulation, lymph stasis creates an accumulation of protein and cellular metabolites in the extracellular space; with the ensuing increase in tissue colloid osmotic pressure, there is water accumulation and elevation of the interstitial hydraulic pressure (see Chapter 10).

Impaired lymphatic transport leads to the accumulation of hyaluronan and other glycoproteins within the extracellular space. This is followed by a secondary increase in the fibroblast, keratinocyte, and adipocyte content of the affected tissues along with the accumulation of mononuclear cells, including macrophages. Ultimately, an increase in collagen deposition occurs, typically accompanied by an overgrowth of connective tissue and adipose elements in the skin and subcutaneous tissue.[2] Although the contributory mechanisms are still not well understood, there is a tendency for these processes to lead to progressive subcutaneous fibrosis.

CLASSIFICATION AND STAGING

Standard clinical classifications distinguish lymphedema on the basis of cause (primary vs. secondary). Primary lymphedema is further classified on the basis of genetics (familial vs. sporadic) and time of onset (congenital, praecox, tarda).[3-5] Although these systems are useful for categorizing lymphedema, they do not address the clinical severity of the disease and are usually not relevant to therapy. More recent classifications focus on the clinical stage of lymphedema, or emphasize the causal anatomic or functional lymphatic abnormality, in an attempt to predict natural history and to identify the best therapeutic approach.[1,6,7]

Primary Lymphedema

The prevalence of the heritable causes of primary lymphedema is difficult to ascertain, and estimates vary substantially. Primary lymphedema is thought to occur in approximately 1 of every 6000 to 10,000 live births. On the basis of data collected by the Rochester group study, it affects 1.15 per 100,000 persons younger than 20 years.[8] Females are affected 2- to 10-fold more commonly than males, and the incidence peaks between the ages of 12 and 16 years.[6,9]

Of 125 patients with primary lymphedema treated at the Mayo Clinic, 97 (78%) were female and 28 (22%) were male, yielding a female-to-male ratio of 3.5:1.[10] The ratio of unilateral to bilateral lymphedema was 3:1. Congenital lymphedema occurred more frequently in males than in females. In these patients, the edema was usually bilateral and involved the entire lower extremity. In contrast, the typical patient with lymphedema praecox was female and had unilateral involvement, with swelling usually extending only to the knee.

Primary lymphedema represents a heterogeneous group of disorders; therefore, its classification schemes are numerous. Affected individuals can be classified by age at onset, morphology, or clinical setting.

Classification by Age at Onset and Inheritance

The term *congenital* is applied when lymphedema is present at birth or is recognized within the first year of life. *Lymphedema praecox* most commonly appears at the onset of puberty, but it may be delayed until the third decade of life. *Lymphedema tarda* typically begins after the age of 35 years.

Congenital. Congenital lymphedema can occur in a sporadic fashion; however, when clusters of cases occur in families, an autosomal dominant pattern of transmission is frequently observed.[11] In addition to isolated causal mutations, there is a strong association between intrauterine and congenital lymphatic dysfunction and the presence of chromosomal abnormalities, including Turner's syndrome, Klinefelter's syndrome, and trisomy 21, among others. In congenital lymphedema, the swelling can involve only a single lower extremity, but edema of multiple limbs, the genitalia, and even the face can be seen. Bilateral leg swelling and involvement of the entire lower extremity are more likely in congenital cases than in other forms of primary lymphedema.[10]

Lymphedema Praecox. Lymphedema praecox is the most common form of primary lymphedema, accounting for up to 94% of cases in large series. The name *Meige's disease* has historically been reserved for a specific familial form of lymphedema and typical onset at puberty. Lymphedema praecox displays a marked gender imbalance, with an estimated 10:1 female-to-male prevalence.[2] The edema is usually unilateral, and is limited to the foot and calf in the majority of patients.[10] Estrogenic hormones may play a role in the pathogenesis of this form of primary lymphedema.[10]

Lymphedema Tarda. Lymphedema tarda is relatively less common. Appearing after the age of 35 years, it typically accounts for an estimated 10% of cases of primary lymphedema.

Classification by Morphology

It has been suggested that a morphologic classification of primary lymphedema might provide more useful prognostic information than classification by age at onset (Fig. 168.1).[2] This alternative classification scheme relies on an anatomic description of the lymphatic vasculature.[3,11]

Aplasia. In aplasia, no collecting vessels can be identified.

Hypoplasia. In hypoplasia, a diminished number of vessels are seen.

Numerical Hyperplasia. In numerical hyperplasia (as defined by Kinmonth[3]), an increased number of vessels are seen.

Hyperplasia. In addition to an increase in number, the vessels have valvular incompetence and display tortuosity and dilation (megalymphatics, lymphangiectasia). Megalymphatics and lymphatic hyperplasia are less common than hypoplasia or aplasia. This pattern demonstrates a male predominance. These patients most often have unilateral edema involving the entire lower extremity. Cutaneous angiomas and chylous reflux also can be seen (Fig. 168.2). Megalymphatics are associated with a greater extent of involvement and a worse prognosis.

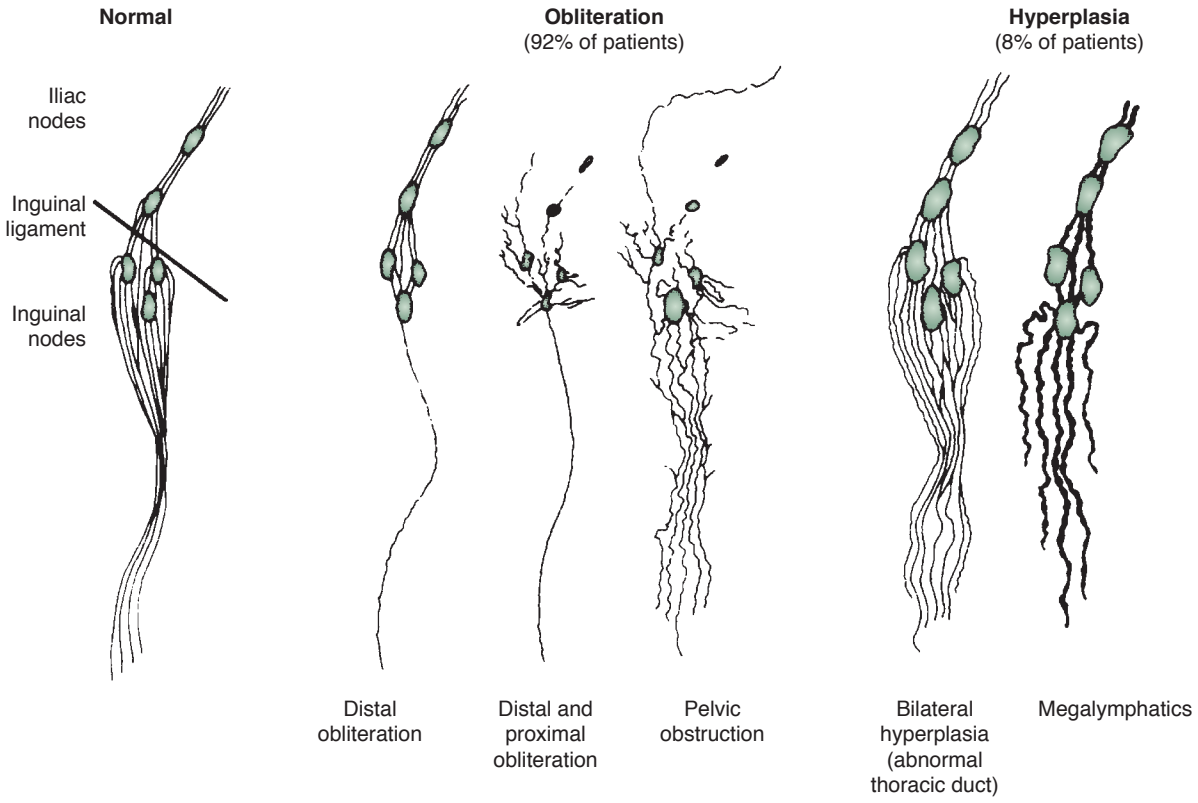

Figure 168.1 Lymphangiographic patterns of lymphatic morphology in a normal lower limb and in patients with different types of primary lymphedema. Obliteration of the lymphatic pathways may be due to aplasia, hypoplasia, or obstruction of the lymphatic channels and nodes.

Figure 168.2 Primary lymphedema of the right leg caused by hyperplasia of the lymphatics and valvular incompetence. Mid-calf skin vesicles contain a milky fluid because of lymphangiectasia and reflux of chyle.

Classification by Anatomy

Aplasia and hypoplasia have a different natural history, depending on whether they involve the distal or proximal portion of the leg.

Distal Obstruction. Approximately one-third of all cases result from agenesis, hypoplasia, or obstruction of the distal lymphatic vessels, with relatively normal proximal vessels (see Fig. 168.1).[11] In these cases, the swelling is usually bilateral and mild, and females are affected much more frequently than males. The prognosis is good. In general, after the first year of symptoms, there is little extension in the same limb or to uninvolved extremities. Although the maximal extent of involvement is established early in the disease in about 40% of patients, the girth of the limb continues to increase. Distal hypoplasia or aplasia of the lymphatics most often correlates with the presence of bilateral peripheral edema of the lower extremities. Familial occurrence, female predominance, and indolent progression characterize this pattern of lymphatic disturbance.

Proximal Obstruction. In more than half the cases, the defect primarily involves obstruction of the proximal lymphatics or nodes, with an absence of distal lymphatic involvement. Pathologic studies reveal intranodal fibrosis.[12] In these cases, the swelling tends to be unilateral and severe; there may be a slight female predominance.[11] In patients with proximal involvement, the extent and degree of the abnormality are likely to

progress, potentially requiring surgical intervention. Initially, uninvolved distal lymphatic vessels may become obliterated over time. A minority of patients have a pattern of bilateral hyperplasia of the lymphatic channels. In these less common forms of primary lymphedema, there is a slight male predominance. When isolated proximal obstructive hypoplasia is observed, clinical involvement of the entire limb is more likely, with relentless worsening of edema.

Classification by Clinical Setting

Alternatively, primary lymphedema can be classified by abnormal phenotype or associated clinical anomalies.[13]

Inheritance. Although sporadic cases of primary lymphedema are more common,[11] there is a significant tendency for congenital lymphedema to cluster in families (Fig. 168.3). A familial predisposition for congenital lymphedema, ultimately determined to have an autosomal dominant form of inheritance with variable penetrance, was first described by Milroy in 1892.[14] He reported "hereditary edema" affecting 22 individuals in one family over six generations. Although Milroy studied not only congenital lymphedema but also the praecox and tarda variants of the syndrome that bears his name, lymphedema praecox is better known as Meige's disease.[15]

In general, congenital lymphedema with recessive forms of inheritance is less common than that with dominant forms of inheritance.[11,16,17] Nevertheless, the list of heritable lymphedema-associated syndromes is long and growing.[18,19] Primary lymphedema has been described in association with various forms of chromosomal aneuploidy, such as Turner's and Klinefelter's syndromes; with various dysmorphogenic genetic anomalies, such as Noonan's syndrome and neurofibromatosis; and with a variety of, as yet, unrelated disorders, such as yellow nail syndrome, intestinal lymphangiectasia, generalized lymphatic anomaly (formerly known as lymphangiomatosis), and arteriovenous malformation.[20-25] The association of lymphedema with vascular anomalies underscores the common developmental origin of the lymphatic and blood vasculature.

Associated Disorders. Numerous disorders are associated with heritable forms of lymphedema. Increasingly, these disorders have yielded to chromosomal mapping techniques. Lymphedema-cholestasis, or Aagenaes' syndrome, has been mapped to chromosome 15q.[26] In several family cohorts of Milroy's disease, it has been determined that the disorder reflects missense inactivating mutations in the tyrosine kinase domain of vascular endothelial growth factor receptor 3 (VEGFR-3),[27,28] thus suggesting the likelihood that this condition reflects an inherited defect in lymphatic vasculogenesis. Several additional lymphedema syndromes have recently lent themselves to successful genetic mapping.[7] Lymphedema-distichiasis, an autosomal dominant dysmorphic syndrome in which lymphedema presents in association with a supplementary row of eyelashes arising from the meibomian glands, has been linked to truncating mutations in the forkhead-related transcription factor FOXC2[29]; mutations in *FOXC2* have subsequently been associated with a wide variety of primary lymphedema presentations.[30] Similarly, a more unusual form of congenital lymphedema, hypotrichosis-lymphedema-telangiectasia, has been ascribed to both recessive and dominant inheritance of mutations in the transcription factor gene *SOX18*.[30] It is plausible that further elucidation of the molecular pathogenesis of these diseases linked to *FOXC2* and *SOX18* mutations will lead to enhanced insights into the mechanisms of normal and abnormal lymphatic development.

Secondary Lymphedema

Acquired (secondary) lymphedema is the most commonly encountered form of lymphatic dysfunction (Fig. 168.4). In the United States, iatrogenic causes predominate among the acquired forms of lymphedema owing to the common occurrence of lymphatic trauma after surgery or radiotherapy for cancer.[9,31]

Figure 168.3 (A) Adult patient with congenital lymphedema. In addition to the bilateral arm lymphedema depicted, she has edema of both legs and the face. (B) Upper extremities of this patient's 18-year-old son, who has a similar distribution of lymphedema. This is an example of Milroy's disease.

Figure 168.4 Chronic acquired lymphedema of the lower extremities. Note severe skin changes (A) and swelling of the foot (B) associated with squaring of the toes (Stemmer's sign) and the typical peau d'orange. (C) Severe lymphedema with subcutaneous lymph cysts and chronic verrucous superinfection.

Cancer

Of the various clinical settings that predispose patients to lymphedema, treatment of breast cancer is most commonly associated with acquired lymphatic insufficiency (of the upper extremity). Lymph node dissection and adjuvant radiation therapy independently and synergistically predispose to lymphatic vascular insufficiency.[20]

According to the most recent estimates, 6% to 30% of breast cancer survivors experience clinically significant arm lymphedema after axillary intervention. Despite the benefits of recent surgical and radiotherapeutic enhancements, the problem of lymphedema has not been eradicated.[18]

Similar lymphatic sequelae are encountered in the lower extremities and pelvis after interventions for gynecologic or urologic malignant neoplasms. Malignant melanoma can cause either upper or lower extremity lymphedema when radical dissection is required in the axilla or groin, respectively.

Filariasis

Filariasis, caused by infestation with parasites such as *Wuchereria bancrofti, Brugia malayi,* and *Brugia timori,* is by far the most frequent cause of secondary lymphedema in third-world countries. Of the estimated 90.2 million people in the world who are infected, more than 90% have bancroftian filariasis.[32] The disease is most frequent in subtropical and tropical countries such as China, India, and Indonesia. It is transmitted by various types of mosquitoes, and transmission is closely related to poor urban sanitation.[33]

Perilymphatic inflammation and fibrosis, and sclerosis of the lymph nodes, are caused by the indwelling adult worms. Lymph node fibrosis, reactive hyperplasia, and dilation of the lymphatic collecting channels are caused by the worm products, by physical injury to the valves and vessel walls caused by the live worms, and by the immune response of the host.[34] Eosinophilia is found in the peripheral blood smear, and microfilariae can be demonstrated in peripheral nocturnal blood, centrifuged urine sediment, or lymphatic fluid.[35]

Filarial lymphedema rapidly develops into grossly incapacitating elephantiasis that is extremely difficult to treat.

Other Causes

Lymphedema can also be acquired from other types of lymphatic vascular trauma, including burns and large or circumferential wounds to the extremity. Additional causes of acquired lymphedema include pregnancy, bacterial and fungal infections, infections after snake or insect bites, contact dermatitis, and rheumatoid arthritis.[9] Autoimmune destruction of the lymphatics has been hypothesized but not directly demonstrated.

Clinical Staging

Because none of the classification schemes addresses the clinical stage of the disease, in 1985 the Working Group of the 10th International Congress of Lymphology suggested staging chronic lymphedema, regardless of cause. A latent, subclinical stage and three clinical grades were established,[36] and each grade was subclassified as mild, moderate, or severe:

Latent Phase: Excess fluid accumulates and fibrosis occurs around the lymphatics, but no edema is apparent clinically.

Grade I: Edema pits on pressure and is reduced largely or completely by elevation; there is no clinical evidence of fibrosis.

Grade II: Edema does not pit on pressure and is not reduced by elevation; moderate to severe fibrosis is evident on clinical examination.

Grade III: Edema is irreversible and develops from repeated inflammatory attacks, fibrosis, and sclerosis of the skin and subcutaneous tissue. This is the stage of lymphostatic elephantiasis.

The advantage of this classification is that it permits the evaluation of treatment effectiveness and the comparison of different treatment modalities. One drawback is that appropriate staging may be difficult in some cases without a biopsy of the subcutaneous tissue.

CLINICAL PRESENTATION HISTORY

A careful history frequently reveals the cause of the swelling and suggests the diagnosis of lymphedema. A family history that is positive for leg swelling may indicate familial lymphedema. The development of painless leg swelling in a teenage girl without any identifiable cause strongly suggests primary (idiopathic) lymphedema. A history of diarrhea and weight loss is a clue to mesenteric lymphangiectasia, whereas intermittent drainage of milky fluid from skin vesicles indicates reflux of chyle. In patients with secondary lymphedema, the cause of limb swelling should be evident from the history, such as previous lymph node dissection, irradiation, tumor, trauma, or infection. In patients who have traveled in tropical countries, filariasis is suspected. Although the causes of primary and secondary lymphedema are different, the clinical presentation and characteristic physical findings are frequently similar.

Signs and Symptoms

The clinical signs and symptoms of lymphedema largely depend on the duration and severity of the disease.

Edema

Initially, the interstitial space is expanded by an excess accumulation of relatively protein-rich fluid. The swelling produced by the fluid collection is typically soft, is easily displaced with pressure (pitting edema), and may substantially decrease with elevation of the limb. In the lower extremities, the edema typically extends to the distal aspects of the feet, resulting in the characteristic "square toes" seen in this condition. Stemmer's sign is positive when the skin at the base of the second toe becomes inelastic to the point that the examiner's fingers cannot cause the skin to tent. The dorsum of the forefoot can be involved, resulting in the typical appearance of a "buffalo hump." During a period of years, the limb may take on a woody texture as the surrounding tissue becomes indurated and fibrotic.

Skin Changes

In the early stage of lymphedema, the skin usually has a pinkish red color and a mildly elevated temperature owing to the increased capillary blood flow in the skin. In long-standing lymphedema, the skin becomes thick and shows areas of hyperkeratosis, lichenification, and development of peau d'orange. The term *pigskin* reflects the reactive changes of the dermis and epidermis in response to the chronic inflammation caused by lymphatic stasis.[37] Recurrent chronic eczematous dermatitis or excoriation of the skin may occur, but frank ulcerations are rare. Unlike the situation in venous stasis, the skin maintains a higher degree of hydration and elasticity in lymphedema, and ischemic changes due to high skin tension and disruption of the circulation to the skin and subcutaneous tissue are rare.[38]

Additional skin changes in chronic lymph stasis, primarily in patients with hyperplasia of the lymphatics and valvular incompetence, include verrucae or small vesicles, which frequently drain clear lymph (lymphorrhea). In patients with lymphangiectasia and reflux of chyle, drainage from the vesicles is milky (chylorrhea; see Fig. 168.2).

Primary lymphedema may be associated with yellow discoloration of the nails.[37-39] In the yellow nail syndrome, pleural effusion is also present. The pale yellow color of the nails is most likely caused by impaired lymphatic drainage. Severe clubbing, transverse ridging, friability, and decreased rate of nail growth are also observed.[40,41]

Pain

Although some aching or heaviness of the limb is a frequent complaint, intense pain is rare. If a patient with lymphedema complains of marked pain, infection or neuritic pain in the area of scar tissue or radiation treatment should be suspected. Other possible causes of leg swelling, such as venous edema or reflex sympathetic dystrophy, should also be considered (see the later discussion of differential diagnosis).

Complications

Infection

The propensity for recurrent soft tissue infection[42] is one of the most troublesome aspects of long-standing lymphedema. Accumulated fluid and proteins provide a good substrate for bacterial growth. Lymphatic dysfunction impairs local immune responses, which plays a permissive role in the propagation of bacterial and fungal invasion. Furthermore, once it is established, soft tissue infection exacerbates the existing lymphatic dysfunction, sometimes irreversibly. With recurrent infection, there is progressive damage of lymphatic capillaries. In primary lymphedema, the reported infection rate is as high as 31%.[10]

The clinical presentation of soft tissue infection in lymphedema varies substantially, from the acute manifestation of rapidly progressive infection to only modest exacerbations of edema accompanied by subtle cutaneous erythema in the absence of fever. Recurrent attacks of cellulitis can damage the existing cutaneous lymphatics, exacerbate the skin disease, and further aggravate existing edema.

Malnutrition and Immunodeficiency

Lymphangiectasia with protein-losing enteropathy or chylous ascites or chylothorax may result in severe loss of proteins, long-chain triglycerides, cholesterol, and calcium.[43,44] Loss of lymphocytes, immunoglobulins, polypeptides, and cytokines, coupled with impaired immune trafficking through the lymphatic vasculature, results in a state of immunodeficiency that decreases the patient's ability to resist infections or, potentially, malignant disease.[45]

Malignant Tumors

In rare cases, chronic lymphedema of any cause may be complicated by the development of malignant tumors in the involved limb. Lymphangiosarcoma after long-standing secondary lymphedema, originally described by Stewart and Treves,[46] is a rare malignant disease that frequently results in limb loss or even death. Lymphangiosarcoma is manifested as multicentric lesions with bluish nodules, sclerotic plaques, or bullous changes. Other malignant tumors that appear with increased frequency in lymphedematous limbs include Kaposi's sarcoma, squamous cell carcinoma, malignant lymphoma, and melanoma.

DIAGNOSIS

In most cases of advanced, sustained lymphedema, the characteristic clinical presentation, history, and physical findings establish the diagnosis with near certainty.[47] In more subtle presentations, it may be difficult to distinguish primary lymphedema from other edematous conditions. Additional objective data may be required to confirm the presence of impaired lymphatic flow or the typical pattern of abnormal fluid distribution within tissues. The diagnosis is more difficult to establish in the early stages of disease, particularly when edema is mild or intermittent.

Physical Examination

The physical examination of a patient with lymphedema should include inspection for cutaneous and subcutaneous fibrosis and peau d'orange and attempts to elicit the pathognomonic Stemmer sign in which the examiner is unable to tent the skin of the interdigital webs, based on the characteristic loss of cutaneous elasticity in lymphedema (see Fig. 168.4). In some cases, particularly early in the disease, the pitting edema of this condition may be indistinguishable from other local or systemic causes of edema.

Testing

Objective documentation of lymphatic dysfunction is sometimes useful. Available tests include isotopic lymphoscintigraphy, near infrared fluorescent lymphatic imaging, indirect and direct lymphography, lymphatic capillaroscopy, magnetic resonance imaging (MRI), axial tomography, and ultrasonography. Direct lymphography is rarely used today and should be restricted to those patients who are potential candidates for lymphatic surgery. Lymphatic capillaroscopy is available only in specialized centers.

Lymphoscintigraphy

Isotopic lymphoscintigraphy is a reliable and reproducible[46] method to confirm the diagnosis of lymphedema. A radiolabeled macromolecular tracer is injected intradermally or subdermally within one of the interdigital spaces of the affected limb. The lymphatic transport of the radiolabeled macromolecule is tracked with a gamma camera. The biokinetic behavior of interstitially applied colloid particles depends on their surface charge and particle size. Particles with small diameters are absorbed into capillaries, whereas those in the 10-nm range, such as antimony trisulfide (Sb2S3), are absorbed into the lymphatic system. The time needed for activity to appear in the regional lymph nodes varies according to the physical characteristics of the imaging agent. For example, small particles such as technetium Tc 99m-labeled human serum albumin may appear in the pelvic nodes within 10 minutes,[48] whereas relatively large agents, including rhenium and Sb2S3 colloid, should arrive within 30 minutes[46] to 1 hour,[49] respectively. In most centers, 99mTc-Sb2S3 or 99mTc-labeled human serum albumin is used for lymphoscintigraphy.[50,51-53]

Interpretation. Lymphoscintigraphy provides a semiquantifiable assessment of lymphatic function as well as visualization of major lymphatic trunks and lymph nodes. The data can be recorded in a standardized report format, which is helpful for creating reproducible reports when many physicians review these tracings. A sample report form, shown in Fig. 168.5, is an adaptation of one proposed by Kleinhans and colleagues for the estimation of a transport index.[54]

In normal limbs, lymphoscintigraphy shows several lymph vessels as the tracer is visualized along the anteromedial aspect of the leg. The injection site, because of the relatively large tracer dose given, does not show details, and no information about lymph distribution in the feet is obtainable. Several lymph channels may be identified in the calf. However, in the thigh, the lymph vessels run close to each other, and separate activity in each larger channel is seldom seen on lymphoscintigrams (Fig. 168.6).

Tracer activity is clear in the inguinal lymph nodes by 60 minutes (range: 15 to 60 minutes). A faint hepatic uptake, activity in the bladder, and faint traces in the para-abdominal nodes are visible at 1 hour. Three-hour images show intense uptake in the liver; symmetrical and good uptake in the lymph nodes of the groin, pelvis, and abdomen; and, occasionally, a tracer focus in the left supraclavicular area at the site of the distal thoracic duct.

The qualitative interpretation of images has resulted in moderate sensitivity and excellent specificity for the diagnosis of lymphedema.[52] Quantitative lymphoscintigraphy, with measurement of lymphatic clearance, may improve the detection of early disease,[50] but the results obtained in some studies have been equivocal.[51,52] Neither the image pattern nor the quantitative parameters can reliably distinguish primary from secondary lymphedema.[51,53]

Figure 168.5 Evaluation form for calculation of the lymphatic transport index. (Modified from Kleinhans E, Baumeister RG, Hahn D, Siuda S, Büll U, Moser E. Evaluation of transport kinetics in lymphoscintigraphy: follow-up study in patients with transplanted lymphatic vessels. *Eur J Nucl Med.* 1985;10:349. Courtesy Springer-Verlag.)

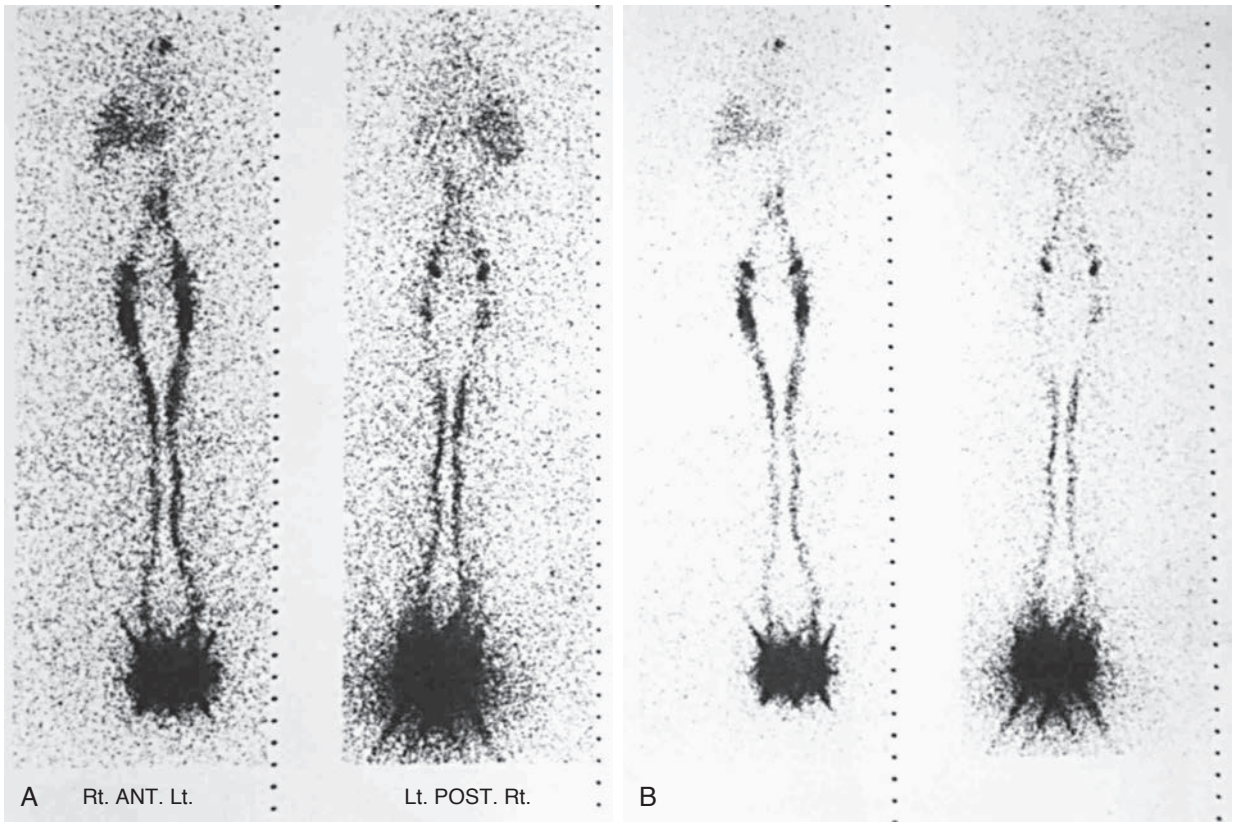

Figure 168.6 Anterior and posterior images in two intensity settings from a total-body scan with a dual-headed gamma camera. (A) Normal lymphoscintigram. (B) Higher intensity settings in the same patient. A large area of high activity and scatter is seen at the feet, where the injection was made. The single well-outlined band in each leg represents the main lymphatic channels. The lymph nodes in the groin and liver, the pelvic and para-aortic nodes, and an area at the site of the upper thoracic duct, are visualized.

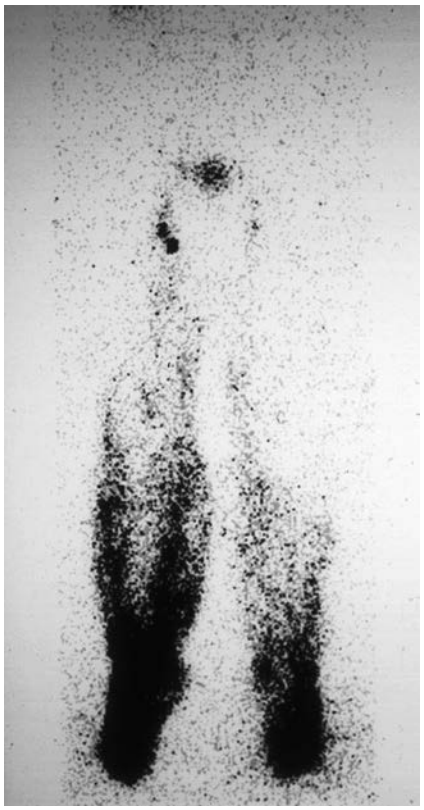

Figure 168.7 Radionuclide lymphoscintigraphy in chronic bilateral lower limb lymphedema. The study demonstrates a dramatic degree of dermal backflow, suggesting the presence of lymphatic hypertension and valvular incompetence.

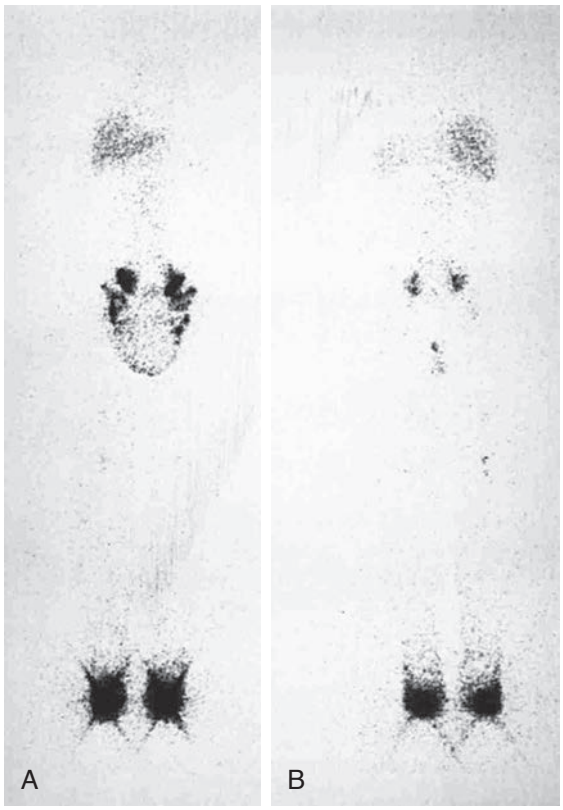

Figure 168.8 Bilateral leg scintigraphy with anterior (A) and posterior (B) views in a 24-year-old man outlines the swollen scrotum in the 6-hour image. Colloid reflux resulted from dilation and valvular incompetence of the lymphatics.

Lymphedema. Typical abnormalities observed in lymphedema include dermal backflow (Fig. 168.7), absent or delayed transport of tracer, crossover filling with retrograde backflow, and either absent or delayed visualization of lymph nodes. In primary lymphedema, channels are obliterated or absent; in a smaller percentage of cases, they become ectatic and incompetent. The asymmetry or delayed appearance of radiocontrast material in the proximal nodal tissue can be used as a semiquantitative measure of the severity of lymphatic vascular insufficiency. The density of subcutaneous accumulation of radiotracer (dermal backflow) can also be quantitated, as can the ratio of radioactivity in ipsilateral versus contralateral nodal tissues in the setting of unilateral limb edema. Quantitation has the greatest utility in predicting the likelihood of a beneficial response to therapeutic intervention.

Lymphangiectasia. Scintigraphic findings in lymphangiectasia consist of dilated lymph channels with only mild or no delay in lymph transport (Fig. 168.8). Colloid injected into the unaffected lower extremity may reflux into the affected lymphedematous leg because of lymphatic valvular incompetence. Similar reflux of the colloid may be seen in the dilated mesenteric lymphatics (Fig. 168.9) or in the retroperitoneum, perineum, or scrotum. Ruptured lymphatics cause extravasation of the colloid into the abdominal cavity or the chest in patients with chylous ascites or chylothorax. The images are generally not helpful in determining the exact site of the lymphatic leak.

Computed Tomography and Magnetic Resonance Imaging

Lymphedema is typically confined to the epifascial space of the skin and subcutaneous tissue, sparing the muscle. This characteristic absence of muscle involvement produces distinctive changes that can be observed with computed tomography (CT) or MRI. These typical imaging features facilitate the differentiation of lymphedema from other edematous entities. In lymphedema, the images reveal a characteristic honeycomb distribution of edema within the epifascial structures along with thickening of the skin. In venous edema, both the epifascial and subfascial compartments are affected, whereas, in lipedema, there is fat accumulation without fluid. MRI is also helpful in the identification of lymph nodes and enlarged lymphatic trunks and in the differentiation of various potential causes of lymphatic obstruction in secondary lymphedema. The anatomic information derived from MRI can complement the functional assessment provided by lymphoscintigraphy.[55] The greatest value of CT and MRI in the evaluation of a patient with a swollen leg is to exclude any obstructing mass in the pelvis that may result in decreased transport capacity of the lymphatic system.

Direct Contrast Lymphangiography

Contrast lymphography is used primarily before reconstructive lymphatic surgery. Imaging is accomplished through the direct

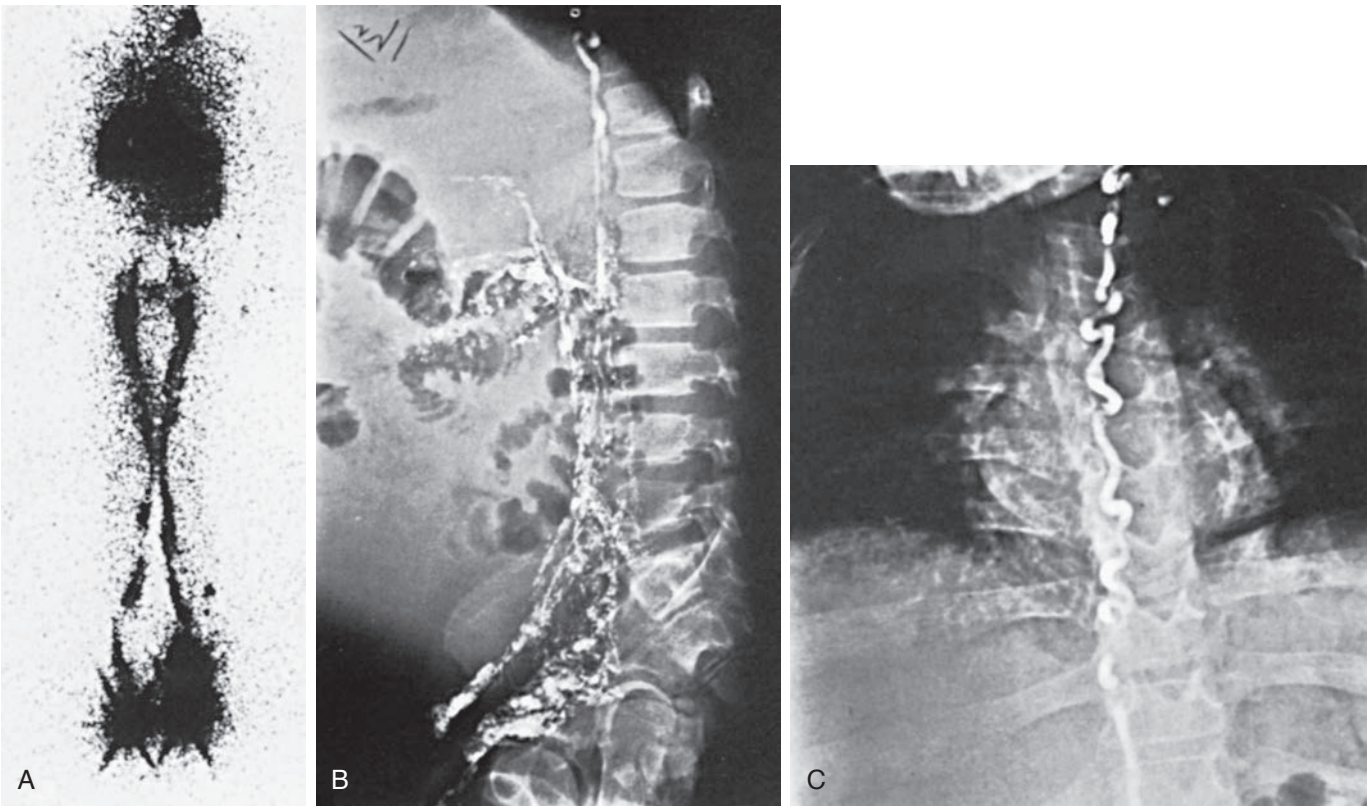

Figure 168.9 (A-C) Lymphoscintigram of an 18-year-old man with lymphangiectasia, protein-losing enteropathy, and chylous ascites. Note the large leg lymphatics (A) and reflux of colloid into the mesenteric lymph vessels (B), filling almost the entire abdominal cavity. Note the large thoracic duct (C).

injection of iodine-based, lipid-soluble agents into the subcutaneous lymphatics, which are first identified by the subcutaneous injection of dye (methylene blue) and then cannulated. Contrast lymphography poses distinct technical difficulties and may, in fact, exacerbate lymphatic malfunction through the accumulation and pooling of the oil-based contrast medium. For these reasons, its use should be limited to preoperative evaluation in specialized centers.

Differential Diagnosis

The differential diagnosis frequently includes lipedema; a lipodystrophy that typically causes symmetrical enlargement of the lower extremities, particularly in obese females; and venous insufficiency, a hydrostatic cause of lower extremity edema. In lipedema, there may be a component of pitting edema; however, in contradistinction to lymphedema, there is sparing of the feet despite pronounced enlargement of the calves and thighs. Venous stasis has relatively distinctive cutaneous attributes, including chronic deposits of hemosiderin in the skin. The patient's history and the clinical setting often determine the degree to which chronic venous insufficiency plays a role in the differential diagnosis. However, even when the clinical setting and physical examination suggest the presence of venous stasis, the accompanying venous hypertension may chronically elevate the lymphatic load and thus predispose to the secondary development of lymphatic edema. Therefore, in practice, such patients often have a mixed lymphatic-venous form of chronic edema.

Systemic Causes

During the evaluation of patients with chronic limb swelling, a systemic cause should be excluded first. Underlying cardiac diseases, such as congestive heart failure, chronic constrictive pericarditis, and severe tricuspid regurgitation, are the most frequent systemic causes leading to pitting or bilateral leg swelling. Hepatic or renal failure, hypoproteinemia, malnutrition, and endocrine disorders (myxedema) are other possible causes of leg swelling. Allergic reactions, hereditary angioedema, and idiopathic cyclic edema are rare systemic causes that should be considered. Chronic use of diuretics may lead to generalized swelling that most frequently affects the extremities and the face. Other drugs that may cause swelling include corticosteroids, some antihypertensive drugs, and antiinflammatory agents.

Venous Insufficiency

Among the local or regional causes of limb swelling, chronic venous insufficiency is much more common than lymphedema. In some patients with chronic iliac or iliocaval obstruction, massive swelling of the entire extremity can develop (Fig. 168.10). The usual causes of proximal venous occlusion are deep venous thrombosis or external compression of the vein by tumor or

Figure 168.10 Right leg swelling due to venous insufficiency, caused by chronic iliofemoral venous thrombosis.

Figure 168.11 Left leg edema associated with a congenital vascular malformation (Klippel-Trénaunay syndrome).

retroperitoneal fibrosis. Whereas lymphedema is usually painless, venous hypertension results in marked pain and cramps after prolonged standing or at the end of the day. Patients with proximal venous obstruction may complain of typical claudication, which is manifested as throbbing pain in the thigh or calf after walking. The pain resolves with rest, although elevation of the extremity provides the fastest relief. The presence of varicosity, pigmentation, induration, or venous ulcers makes the diagnosis of venous insufficiency easier. Chronic inflammation in the subcutaneous tissue due to venous stasis may result in destruction of the collecting lymph channels; a mixed venous-lymphatic edema develops in these patients.

Vascular Malformation

Patients with congenital vascular malformations frequently have a larger than normal extremity that may be difficult to distinguish from lymphedema (Fig. 168.11). An increase in the length of the affected extremity, the presence of atypical lateral varicosity, and a port-wine stain with underlying developmental abnormality of the deep venous system are characteristic of Klippel-Trénaunay syndrome.[56] Although hypertrophy of the soft tissues and bones is caused by an abnormality in mesenchymal development, congenital lymphedema may also be present in these patients. In patients with high-shunt, high-flow arteriovenous malformations, the extremity is larger than normal, and is frequently longer.[57] A bruit and thrill are present; the superficial veins are dilated and frequently pulsatile; and the distal arterial pulses may be diminished.

Lipedema

Lipedema is characterized by the deposition of a large amount of fatty tissue in the subcutaneous layers. Most of these patients have morbid obesity; some, mostly females, have fat deposition localized to the lower half of the body. Evaluation of the lymphatic system with lymphoscintigraphy or lymphangiography shows essentially normal findings.

Other Causes

Trauma and subsequent reflex sympathetic dystrophy may result in painful swelling of the extremity. Because of disuse, a varying degree of osteoporosis can be observed, and increased sympathetic activity occurs in the limbs of these patients. The swelling is usually the result of high-output lymphatic failure, and increased lymphatic transport may be demonstrated on lymphoscintigraphy (Fig. 168.12). Baker's cyst, soft tissue tumor, hematoma, and inflammation, such as tenosynovitis or arthritis, are additional local causes of limb swelling, which should be considered in the differential diagnosis of lymphedema.

DECISION MAKING

Clinical examination of the patient frequently reveals the correct cause of limb swelling. Initial laboratory examinations should include routine blood tests to look for signs of renal or hepatic failure, eosinophilia, or hypoproteinemia. Urinalysis may indicate proteinuria. Once a systemic cause

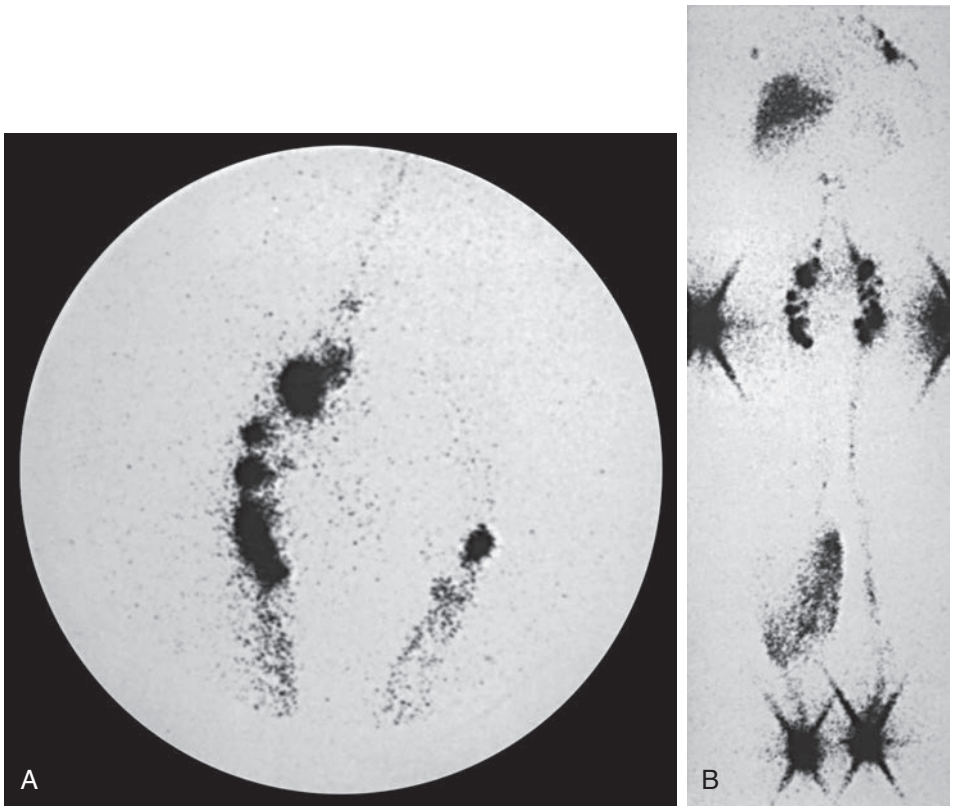

Figure 168.12 Lymphoscintigraphy in high-output lymphatic failure due to reflex sympathetic dystrophy of the right leg. (A) Fast lymphatic transport in the affected right leg compared with the normal left leg is evident in the image of the inguinal nodes 20 minutes after injection. (B) Total-body image at 3 hours shows a dermal pattern on the right, but no evidence of proximal lymphatic obstruction.

of edema is excluded, the local or regional cause should be confirmed.

Patients at risk for the development of secondary lymphedema (e.g., cancer survivors) pose a distinct challenge for decision making, because there is an imperative to recognize the evolving condition at its earliest stages. Within the last decade a new technology, bioimpedance spectroscopy, has been introduced, which provides the requisite sensitivity and specificity to detect stage 0 disease.[52] Increasingly, this technique, which is rapidly and efficiently performed at the bedside, will have applicability to the serial monitoring of the patient's treatment response as well.[58] There may also be an evolving role for the prospective analysis of body fluids to determine lymphedema risk in evolution.[59]

Venous duplex scanning confirms or excludes venous occlusion or valvular incompetence in the leg. CT has become routine for most adult patients with leg swelling to exclude underlying malignant disease. MRI provides the most accurate information in patients with clinical signs of congenital vascular malformation, soft tissue tumor, or retroperitoneal fibrosis.

Lymphoscintigraphy is the test of choice for the confirmation of lymphedema, and a normal finding on lymphoscintigraphic examination essentially excludes the diagnosis of lymphedema. Patients with chronic venous insufficiency may have abnormal results on lymphoscintigraphic examination, with delayed transport because of mixed lymphatic and venous edema. As mentioned earlier, direct contrast lymphangiography should be performed selectively and should not be part of the routine evaluation of patients with chronic limb swelling. Increasingly, near-infrared fluorescent lymphography is incorporated into the pre-surgical evaluation of lymphedema, when reconstructive approaches are contemplated.[60]

For all patients with chronic lymphedema, conservative management through physical means is the mainstay of therapy.

PROSPECTS FOR MOLECULAR THERAPY

Although current therapeutic strategies for lymphedema effectively reduce excess volume, minimize complications, and optimize function, the disease currently lacks a cure. For these reasons, there has been an emphasis on the possible application of effective molecular therapies. Among these, one of the most exciting prospects is therapeutic lymphangiogenesis, a molecular approach based on growing insights into the mechanisms of lymphatic vascular development.

Among the biological factors that initiate and regulate the growth of vascular structures, the vascular endothelial growth factor (VEGF) family plays a central role.[61,62] VEGF-C and VEGF-D direct the development and growth of the lymphatic

vasculature in embryonic and postnatal life by binding to VEGFR-3, which is nearly exclusively expressed on lymphatic endothelia.[63,64] In transgenic mice that overexpress VEGF-C, the lymphatic vessels demonstrate a hyperplastic, proliferative response, with secondary cutaneous changes.[65] Exogenous administration of VEGF-C upregulates VEGFR-3, leading to a lymphangiogenic response.[66,67]

These molecular observations have helped elucidate the mechanisms that contribute to disease expression in the most common heritable form of lymphedema, the autosomal dominant condition known as Milroy's disease. In many affected family cohorts, this disease has been linked to the flt4 locus, encoding VEGFR-3.26. Disease-associated alleles contain missense mutations that inactivate the tyrosine kinase signaling mechanism, thereby preventing downstream cellular activation. It is believed that the mutant form of the receptor is not only functionally inactive, but also excessively stable, serving as a potential "sink" for activating ligands. Thus, the normal signaling mechanism is blunted, leading to hypoplastic development of lymphatic vessels.[68,69]

The prospects for therapeutic lymphangiogenesis in human lymphedema have been underscored by the recent description of a mouse model of inherited limb edema that features a mutation in the VEGFR-3 signaling mechanism, and a pathologic process that resembles human disease.[63] In this model, the therapeutic overexpression of VEGF-C with the use of a viral vector induces the generation of new functional lymphatics and the amelioration of lymphedema. Similarly, in a rodent model of acquired postsurgical lymphatic insufficiency (resembling postmastectomy lymphedema), the exogenous administration of human recombinant VEGF-C restores lymphatic flow (as assessed by lymphoscintigraphy),[70,71] increases lymphatic vascularity, and reverses the hypercellularity that characterizes the untreated lymphedematous condition.

Intensive future investigation will be required to verify the therapeutic potential of such approaches, and to establish dose-response relationships and the durability of the therapeutic response. As with other forms of angiogenic therapy, the relative virtues of growth factor therapy versus gene therapy must be established.[72]

INTRODUCTION

What comes to mind when we mention that the circulatory system is the blood vessels and somehow we forgot the unique system of lymphatics? Most of our research has been focused on veins, arteries, and their related pathophysiology—mainly thrombosis and atherosclerosis. In this chapter, we will examine the lymphatic system and its malfunction with significant attention to current nonoperative approaches to treat lymphedema. Details of diagnosis and surgical approaches have been outlined in other chapters. We will examine the pathology that contributes to the malfunctioning lymphatic system. The pathology of the lymphatic system is linked mainly to lipid and protein malabsorption, defected immunologic response, accumulation of protein-rich interstitial fluid, and the inability to return lymph back to the systemic circulation leading to the development of lymphedema. Although a nonoperative approach is the main therapy in treating early stages of lymphedema, our interest is to also focus on nonoperative management of advanced incurable lymphedema. It starts with preventive medicine to high-risk patients. If lymphedema diagnosis is established, then attention is directed to the reduction of limb swelling and prevention of secondary infections, which should be the main goal of lymphedema management. Mechanical therapy is the gold standard for established lymphedema, and includes self-hygiene, compression techniques and physiotherapy. Other treatment modalities will be discussed briefly, including, but not limited to pharmacotherapy, laser therapy, and gene therapy. Unmanaged chronic lymphedema eventually results in devastating limb swelling with increasing morbidity, decreased quality of life and productivity,[1] increased risk of infection, and late onset malignancy. Lastly, we will briefly discuss the psychological status of the patients, insurance concerns, and what would be considered the ideal lymphedema clinic. Unfortunately, treatment options for lymphedema remain very limited and largely ineffective.[2]

Abstract

The lymphatic system is an essential component of the human circulatory system. The lymphatic system works in conjunction with the arterial and venous system. It has three main roles, 1) it is part of the immune system, 2) it helps to maintain fluid balance, and 3) it plays an essential part in the absorption of fats and fat-soluble nutrients. Lymphedema is a pathological condition usually associated with a significant swelling of a target body organ. Although, there are many different etiologies that could produce similar pathology, the diagnosis of lymphedema is based on clinical presentation. There are several diagnostic tools such as, magnetic resonance imaging (MRI), computed tomography (CT) and types of ultrasound (US) that can be used to detect the presence of extra fluid in tissues. With all ongoing advances in medical therapy, still lymphedema is deemed to be incurable disease in most part and the main component of therapy is non-surgical interventions. After diagnosis is established, the main components of non-surgical therapy include: Manual lymphatic drainage, compression bandages, compression garments and compression devices. Other non-surgical therapeutic measures include pharmacotherapy, laser therapy, hyperbaric oxygen and intermittent negative pressure. In addition; clinicians should also be aware of possible complications such as skin infection, malignancy and psychological impact of body disfigurement. This chapter is to highlight the most updated medical (non-surgical) interventions for lymphedema and to set an algorithm to guide clinicians in making accurate diagnosis and to establish an effective medical therapy.

Epidemiology

The prevalence of primary lymphedema within North America is estimated to be 1.15 per 100,000 children, and mainly affects the female gender around the menarche time. On the other hand, secondary lymphedema (i.e., arm swelling following breast cancer treatment) reportedly affects 15% to 20% of women receiving axillary dissection and/or radiotherapy as part of their breast cancer therapy.[3] Yet, the prevalence of lymphedema remains under-recognized and under-treated. It has been reported that a significant proportion of wound clinic patients had lymphedema. In addition, the management of lymphedema is difficult due to a lack of resources, a lack of awareness among primary care providers, and a lack of patient adherence to treatment.[4]

Etiology

In general terms, lymphedema is the imbalance between the uptake and the transport capacity of the lymphatic system,[5–7] which leads to an accumulation of protein-rich fluid in the interstitial spaces. This excess fluid occurs as the result of an anatomic or a functional obstruction in the lymphatics or lymph nodes.[8] Nevertheless, the imbalance could happen without even a trigging factor, and it is called primary (congenital) lymphedema. Primary lymphedema is generally related to aplasia, hypoplasia, agenesis, or fibrosis of the lymphatic system.[9] When primary lymphedema appears before the age of 35 it is called lymphedema praecox; if it appears after the age of 35, then it is referred to as lymphedema tarda.[10] As opposed to primary, when there is an identifying cause of the lymphedema it is termed secondary lymphedema, and is generally related to the dissection of lymph nodes, radiation treatment, following a traumatic injury, postinflammatory occurrence, or malignancy (Fig. 169.1). Interestingly, chronic venous disease (CVD) is a common cause of secondary lymphedema; it is sometimes misdiagnosed as primary lymphedema, and patients would not receive optimal treatment.[11]

Diagnosis, Classification, and Clinical Features

Although, not the main focus of this chapter, listed below are the current classification methods for lymphedema. The International Society of Lymphology (ISL)[5] focuses on the fibrotic soft tissue changes with lymphedema. Stage I is reversible, characterized by soft pitting edema, with neither secondary tissue changes nor reduction in swelling after elevation. Stage II is irreversible, characterized by fibrosclerotic changes, inflammation, hardening or thickening, along with nonpitting edema. Stage III lymphostatic elephantiasis is characterized by extreme increase in the size and texture of the skin often with typical papillomas and/or deep skin folds. Stemmer's sign describes the inability to pick up a fold of skin at the base of the second toe, and this is usually a positive sign of lymphedema of the legs (Fig. 169.2). Another classification method considers the malignant versus benign features of the lymphedema (Fig. 169.3).

Lastly, the approach most often used to classify lymphedema is the Common Terminology Criteria for Adverse Events v3.0,

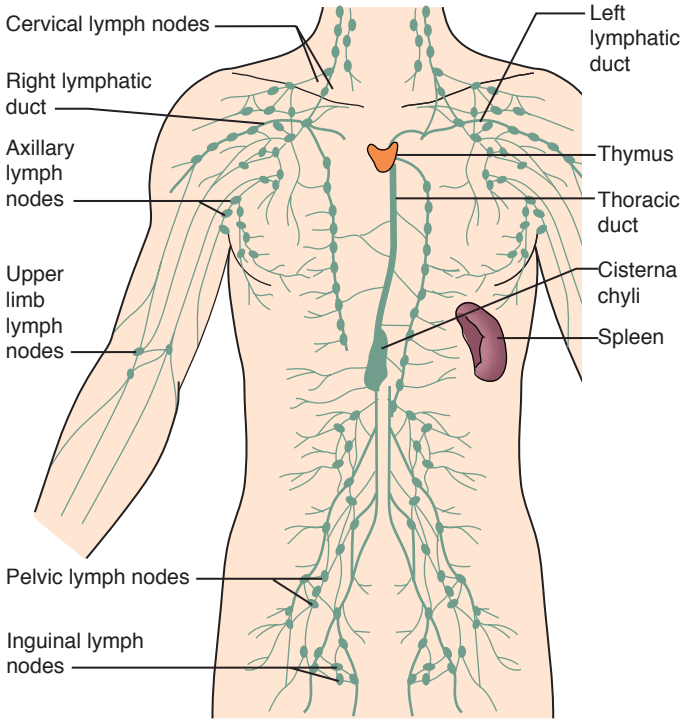

Figure 169.1 Lymphatic System.

which was developed for grading adverse events in the context of clinical trials.[12] This grading system provides not only objective measures (inter-limb discrepancy in volume or circumference), but also subjective and clinical assessments for lymphedema diagnosis (Table 169.1).

PREVENTIVE MEDICINE

Patients at Risk

Identifying patients who are at risk is the essential step for preventive medicine. In undeveloped countries, Wuchereria bancrofti is the most common cause of lymphedema and filariasis. The effort to decrease the transmission in endemic areas may decrease the incidence of lymphedema; the mass administration of diethylcarbamazine plus ivermectin significantly decreased lymphatic filariasis.[13,14] It was reported that higher doses of albendazole did not improve the result, but on the other hand was associated with more severe side effects. It was suggested that alternative regimens could be useful in the later stages of existing programs or to achieve elimination more rapidly in areas where programs have yet to start.[15]

In developed countries, there are two groups of patients who are at high risk of developing lymphedema. The first group contains patients who undergo radiation of a lymph node and/or surgical lymphadenectomy as part of their cancer treatment. Efforts to spare lymph nodes during cancer treatment have proven to be effective. For instance, for patients with breast cancer, the standard of care in staging has evolved from dissection of 2nd ± 3rd level axillary lymph nodes to performing sentinel lymph node biopsy, followed by complete dissection only if nodal metastases are detected; this approach had reduced

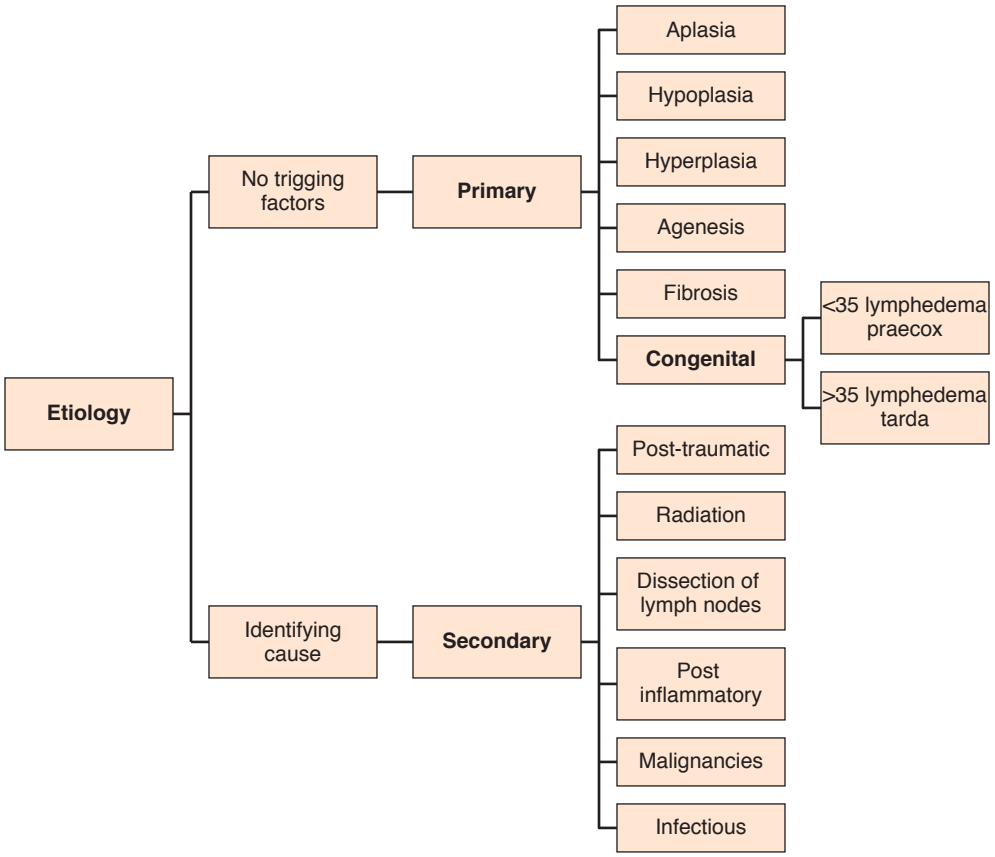

Figure 169.2 Lymphedema Etiology.

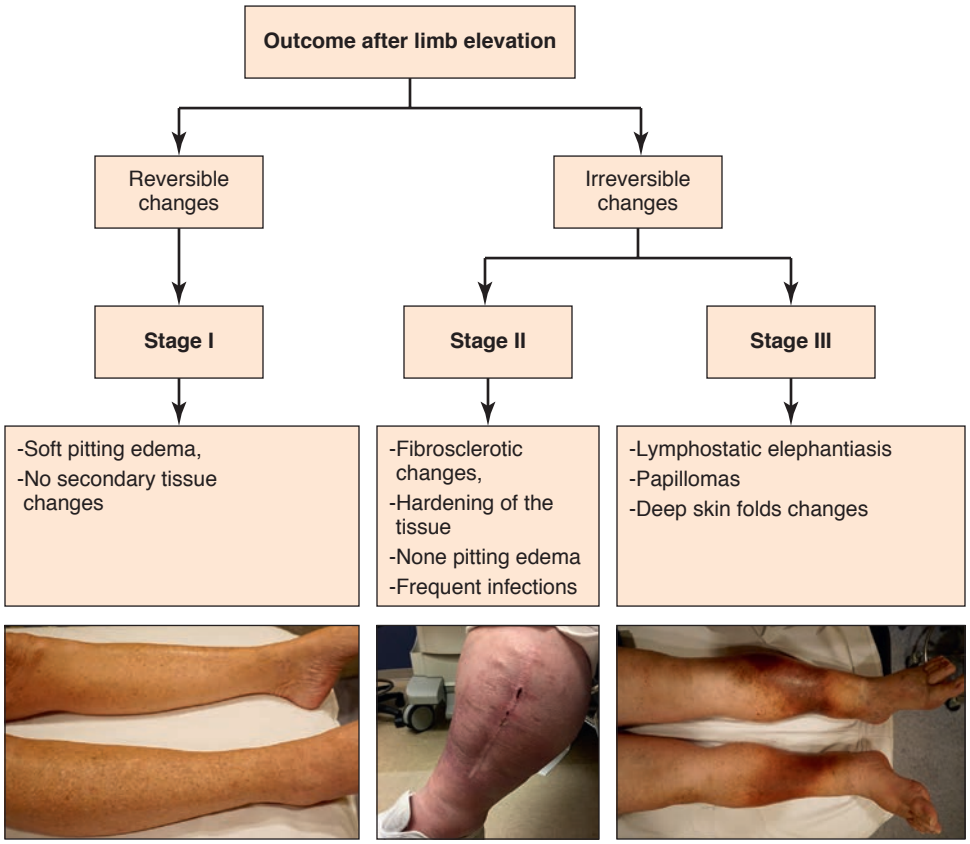

Figure 169.3 Diagnosis, Classification, and Clinical Features.

TABLE 169.1 Common Terminology Criteria for Adverse Events (CTCAE)

Grade	Inter-Limb Discrepancy	Visible Difference
I	5%-10%	Swelling or obscuration of anatomic architecture on close inspection; pitting edema
II	10%-30%	Readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour
III	More than 30%	Gross deviation from normal anatomic contour; interfering with activities of daily living
IV	Progression to malignancy (e.g., lymphangiosarcoma); amputation indicated; disabling lymphedema	

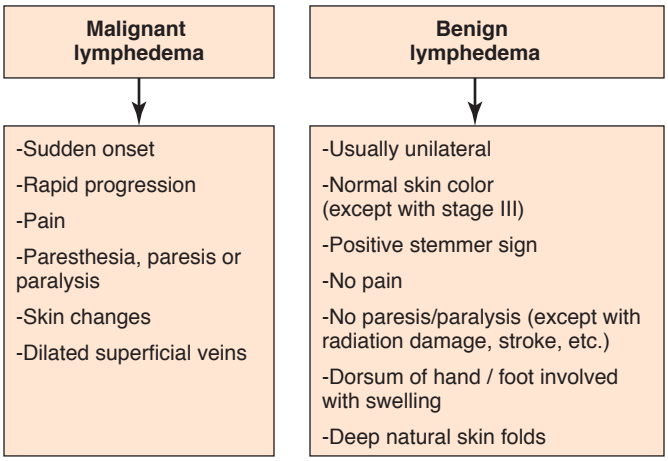

Figure 169.4 Malignant versus Benign Features.

lymphedema incidence by approximately 80%.[16–19] Similarly, the use of sentinel lymph node biopsy to identify lymph nodes involved by metastatic melanoma has significantly reduced the need for extensive inguinal and pelvic lymphadenectomy and has reduced potential lower extremity lymphedema. Interestingly, it also has been reported that being obese or overweight may place women at risk for developing lymphedema following breast cancer treatment,[20] and is considered a major risk factor for lymphedema.[21,22]

The second high-risk group is patients with recurrent cellulitis; a damaged lymphatic system undermines the system's functional capacity, and eventually, causes lymphedema. Recurrent cellulitic infections may cause permanent irreversible lymphatic compromise. Other forms of chronic infection can cause sufficient inflammation to damage the lymphatics.[23] However, because lymphedema is the strongest risk factor for cellulitis,[24,25] at times it is difficult to distinguish between cellulitis as the initial presentation of previously subclinical lymphedema or independently caused lymphedema. The low-grade chronic inflammation produced by rosacea could be caused by the lymphedema of facial structures, particularly the eyelids. The goal of starting prophylactic antibiotics for this group is necessary to prevent recurrent infection. The aim of current therapy should be directed at resolving acute infections and the prevention of recurrent episodes of cellulitis (Fig. 169.4).[26]

Patients with a history of fungal infection, including candidiasis and tinea, should use topical antifungal medications. Routine use of topical clotrimazole cream (1%) or miconazole nitrate lotion or cream (2%) is sufficient for most patients. Oral fluconazole or itraconazole may be needed for recalcitrant or extensive infection. No studies have definitively addressed the efficacy of these treatments in terms of documenting a decreased incidence of lymphedema in those patients.

Edema Preventive Measures

It has been reported that lifestyle modifications, such as changes in diet and increased exercise, have helped to decrease the progression of lymphedema.[27,28] In terms of preventive care, there are several self-care measures that can be practiced to decrease lymphedema, including maintaining daily skin hygiene (e.g., the limbs should be washed regularly with soap and water) and it is important to avoid trauma; either of these can be the nidus of infections.

Other lifestyle or daily habits include elevating the affected limb, modifying dietary intake to include less salt and more protein, wearing properly fitted compression stockings, and walking and performing aerobic exercises to promote lymphatic flow. It is important to monitor and measure limb volume as an objective parameter during the follow-up with patients with lymphedema.[29]

Exercise helps to decrease lymphedema swelling; during the contraction phase of the muscle, the lymph gets pushed to an alternative lymph node through the lymph vessels.[30,31] Historically, patients at risk for developing lymphedema have been advised against "overusing" their at-risk body parts for fear of triggering lymphedema. This recommendation is based on anecdotal associations of the initial onset of lymphedema with episodes of vigorous exercise or sustained, repetitive use of the at-risk extremity. Recently, recommendations against exercise have recently been tempered and re-phrased, based on the results of several randomized controlled trials.[32,33] These trials revealed that a gentle, incremental program of full-body resistive training, started at a low level and increased gradually, did not increase the incidence of lymphedema among at-risk breast cancer survivors, and might have been protective. Similar trials have yet to shed light on the risk-benefit profile of exercise in lower extremity lymphedema.

Exercise routines should include combinations of lymphedema remedial exercises (e.g., active, repetitive, nonresistive motion of the involved body part) along with three main types of exercise (i.e., aerobic, strength, and flexibility). Other possible types of exercise could be considered, but have not been adequately studied in people with lymphedema (e.g., Pilates, yoga, Tai Chi, Qigong, aquatic exercise, trampoline rebounding, breathing exercises, and relaxation). Finally, patients should avoid exposure

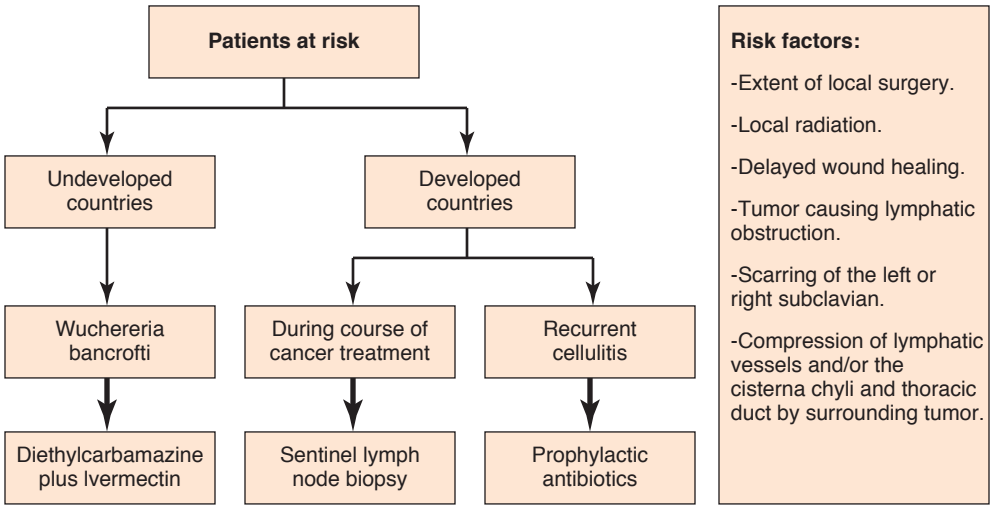

Figure 169.5 Preventive Medicine.

to extreme heat or cold, at least to the extent that tissue injury may occur, such as a burn or frostbite (Fig. 169.5).[34]

MECHANICAL REDUCTION OF LIMB SWELLING

Currently, there is no cure for lymphedema, and management is based on a series of lifelong physical therapies.[1] Practitioners at lymphedema centers or clinics should set specific goals tailored to each patient, while at the same time base treatment on the stage and grade of the lymphedema. The aim of the treatment and goals should be to minimize limb diameter, decrease edema, maintain skin integrity, prevent infection, and encourage patients to use self-care to monitor their skin care and weight reduction.

Complex Decongestive Therapy

The standard of care for lymphedema is commonly referred as complex decongestive therapy (CDT). CDT was popularized in Europe by Földi et al.,[35] Kasseroller,[36] and Leduc et al.,[37] as well as Casley-Smith[38] in Australia, and was introduced to the United States in the early 1990s; CDT continues to be first-line therapy for stage II and III lymphedema. CDT's success has been documented worldwide.[39–43] It is the combination of four components and two phases. The components are: (1) manual lymphatic drainage; (2) compression bandaging; (3) compression garments; and (4) compression devices. Volume reductions were reported after the use of compression garments, pumps, and manual lymphatic drainage. However, the greatest improvements were reported when these treatments were combined in a treatment program.[44]

The two phases are:

1. Initial or reductive phase (phase I); the aim to reduce the size of the affected area and to emphasize proper skin care.
2. Maintenance phase (phase II), which begins immediately after phase I; the main aim is to maintain the gains made during phase I, and requires life-long self-maintenance.

Although very successful, CDT requires a large investment of time from the therapist and patient. Therapists must be specially trained to perform standardized techniques of manual lymph drainage (MLD) and complex multilayered wrapping. Currently, the treatment is offered in specialized practices, but other programs are becoming more widely available. In the United States, there is a voluntary certification process that involves documentation of training, logging treatment hours, and a certification examination to ensure competence. This effort was initiated and coordinated by the Lymphology Association of North America (LANA). Certified therapists are listed on LANA's website,[45] which can be searched by name, state, or zip code. Although phase I CDT can achieve abrupt and dramatic reductions in limb volume, long-term success requires ongoing phase II home-based program maintenance. Without consistent adherence to the program, a patient's lymphedema volume will re-accumulate. The multi-week intensive treatment program also may be limited by insurance coverage in the United States; modified programs, often with inferior outcomes, may be a patient's only option. An alternative program that utilizes home compression bandaging and exercise may achieve comparable results to conventional CDT in some patients with milder (e.g., stage II) lymphedema. Patient compliance and adherence to the therapy is normally 60% to 70%, which in turn, requires trained therapists to have an average volume reduction of 50%.[41,46]

Manual Lymphatic Drainage

First developed by Emil Vodder in 1936,[47] the theory behind MLD is to apply gentle pressure to the skin to stretch the superficial lymphatics, to enhance the contraction and sequestration of lymphatic vessels, and to help the unidirectional flow of lymph to relieve congestion and to minimize subsequent subcutaneous fibrosis. MLD is performed in a series of steps. Before MLD is started, it is beneficial to divide the trunk into six areas (see Fig. 169.1), which correlate to the drainage territories of the cervical, axillary, and inguinal lymph node beds. Treatment is first initiated by massaging an intact section adjacent

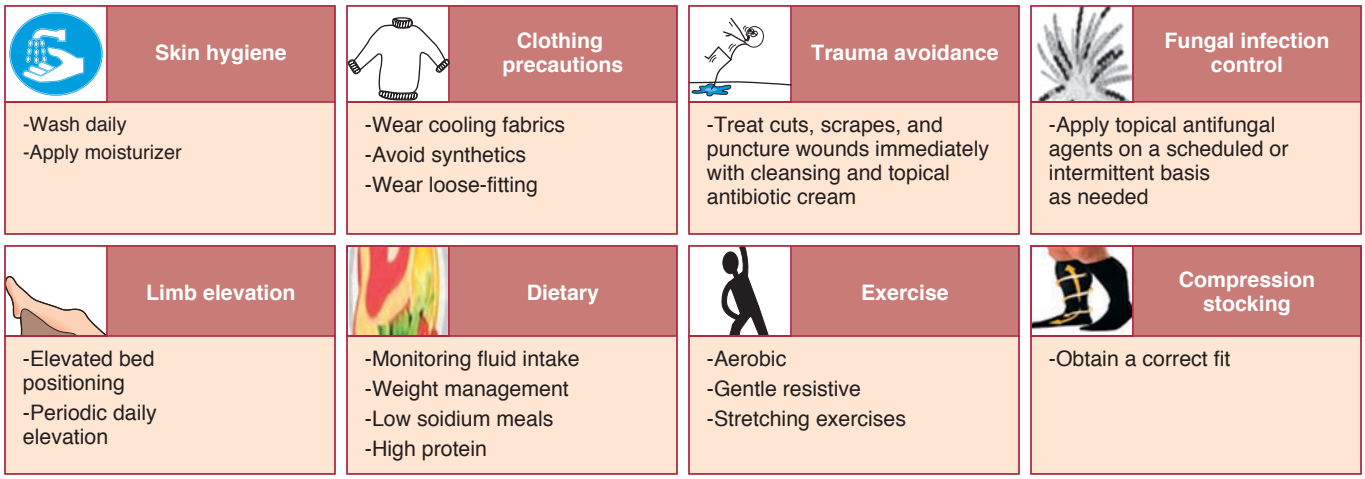

Figure 169.6 Edema Preventive Measures.

to the section that includes the affected limb or body part to prepare the area to receive congested lymph. This maneuver has been shown to redirect lymph fluid toward functioning lymphatic territories.[48] Practiced in this fashion, MLD has been shown to redirect lymph toward functioning lymphatic territories.[48] MLD techniques are particularly of great interest when treating body parts that are not conducive to sustained compression (e.g., face, breast, genitalia, and trunk) (Fig. 169.6). The evidence from a recent systematic review and other studies have shown improvement when combining MLD with compression bandages in treating lymphedema; however, the evidence did not support using MLD by itself—independent from CDT for the purpose of limb volume reduction.[49–51] Yet, Moseley et al., reported that MLD alone did contribute to improvement in self-reported symptoms when used in the palliative care setting.[5,52] In addition, there is some evidence that there are several benefits to practicing standard manual massage with a new device, Linforll.[53]

Compression Bandaging

Elastic wrapping is the principal compression technique used in phase I CDT. Short-stretch bandages have been reported to be very effective in the initial management of arm lymphedema.[54,55] The wrapping requires (1) tubular bandage lining; (2) foam, polyester, or cotton under the cast padding; (3) digit bandages; and (4) multiple layers of short bandages with limited stretch ability when pulled. A recent study described the use of upper extremity compression sleeves among breast cancer survivors whose arm volumes increased by 3% from baseline. Normalization of arm volumes was achieved for the majority of patients after 4 weeks of sleeve use and was maintained for an average follow-up of 4 months. At 1 year following diagnosis, lymphedema incidence was reduced relative to previously reported rates.[56] The goal is to create an internal pump-like action. Two different types of pressures are produced by the bandaging: (1) the low resting pressure (20 to 30 mm Hg),[57] which is the result of short-stretch bandages on the patient during resting; and (2) the high working pressure, which is the result of short stretch bandages on the patient during muscle contraction. The resulting cycling between high-working pressures and low-resting pressure under the bandages in the interstitial fluid areas mimics the action of a pump, which assists the unidirectional flow of lymph to be transported away from the congested area. Inelastic multi-component compression (ICM) bandages normally applied by specialized medical staff are considered the standard of care treatment for compression therapy related to lymphedema of the extremities. However, there are new adjustable compression wraps (ACWs), which can be self-applied by patients. To date, the ACWs have been mainly recommended during the maintenance phase; however, this could be a step toward self-management during the initial treatment phase as well.[58] The technique of applying the elastic wrap is important to achieve an effective compression gradient; short-stretch bandages must be applied with low-to-moderate tension using more layers at the ends of the extremities.[3,59–62] During phase I CDT, low-stretch wraps are worn 24 hours a day (except when the patient is receiving a massage or bathing). In the maintenance phase, a compression garment is worn during the day, and the wraps continue to be worn at night. Compression bandaging is always a part of phase I CDT. Some individuals with more severe forms of lymphedema may need to use home compression bandaging long term as part of phase II. Although somewhat debatable, especially in the past, heating combined with compression bandaging was deemed effective treatment for chronic lymphedema with dermatolymphangioadenitis.[63]

Compression Garments

Compression garments are normally used during all phases of lymphedema treatment, including prophylaxis in at-risk patients. Strict adherence to the daily use of properly fitting and appropriately graduated elastic compression garments are the key components to maintaining limb size for most patients. Fitted elastic knit two-way low-stretch compression garments generate greater pressures more distally than proximally to maintain unidirectional lymphatic flow.[10,64] Normally, compression garments deliver about 20 to 50 mm Hg of pressure (Table 169.2).[5,10] Generally speaking, the highest compression that can be tolerated by the patient is likely to be the most beneficial.[5]

TABLE 169.2 Compression Garments and Their Associated Pressure

Type	Garment Pressure
Over the counter	7-15 mm Hg. Not graduated
Anti-embolism	15-20 mm Hg. Graduated
Chronic venous insufficiency or lymphedema	20-30, 30-40, 40-50, and 50-60 mm Hg
Patients with comorbidities	20-30 mm Hg or less
Upper extremity	20-30 mm Hg
Lower limbs with recalcitrant chronic lymphedema	30–40 mm Hg

Wearing compression bandages or garments that are too tight, restrictive, or not fitting properly may worsen limb condition. When fitted correctly and when properly worn, compression garments may reduce swelling (Fig. 169.7).[52] Support garments come in a variety of sizes, compression strengths, and materials; the different features may be selected to meet the unique needs and dimensions of individual patients (Figs. 169.8 and 169.9). Although off-the-shelf prefabricated garments may fit many limbs, custom stockings may be necessary for significant swelling or an unusual shape. Compression garments should be replaced every 3 to 6 months. Contraindications for the use of compression garments include arterial insufficiency, acute cardiac failure, extreme limb shape distortion,

Figure 169.7 Manual Lymphatic Drainage.

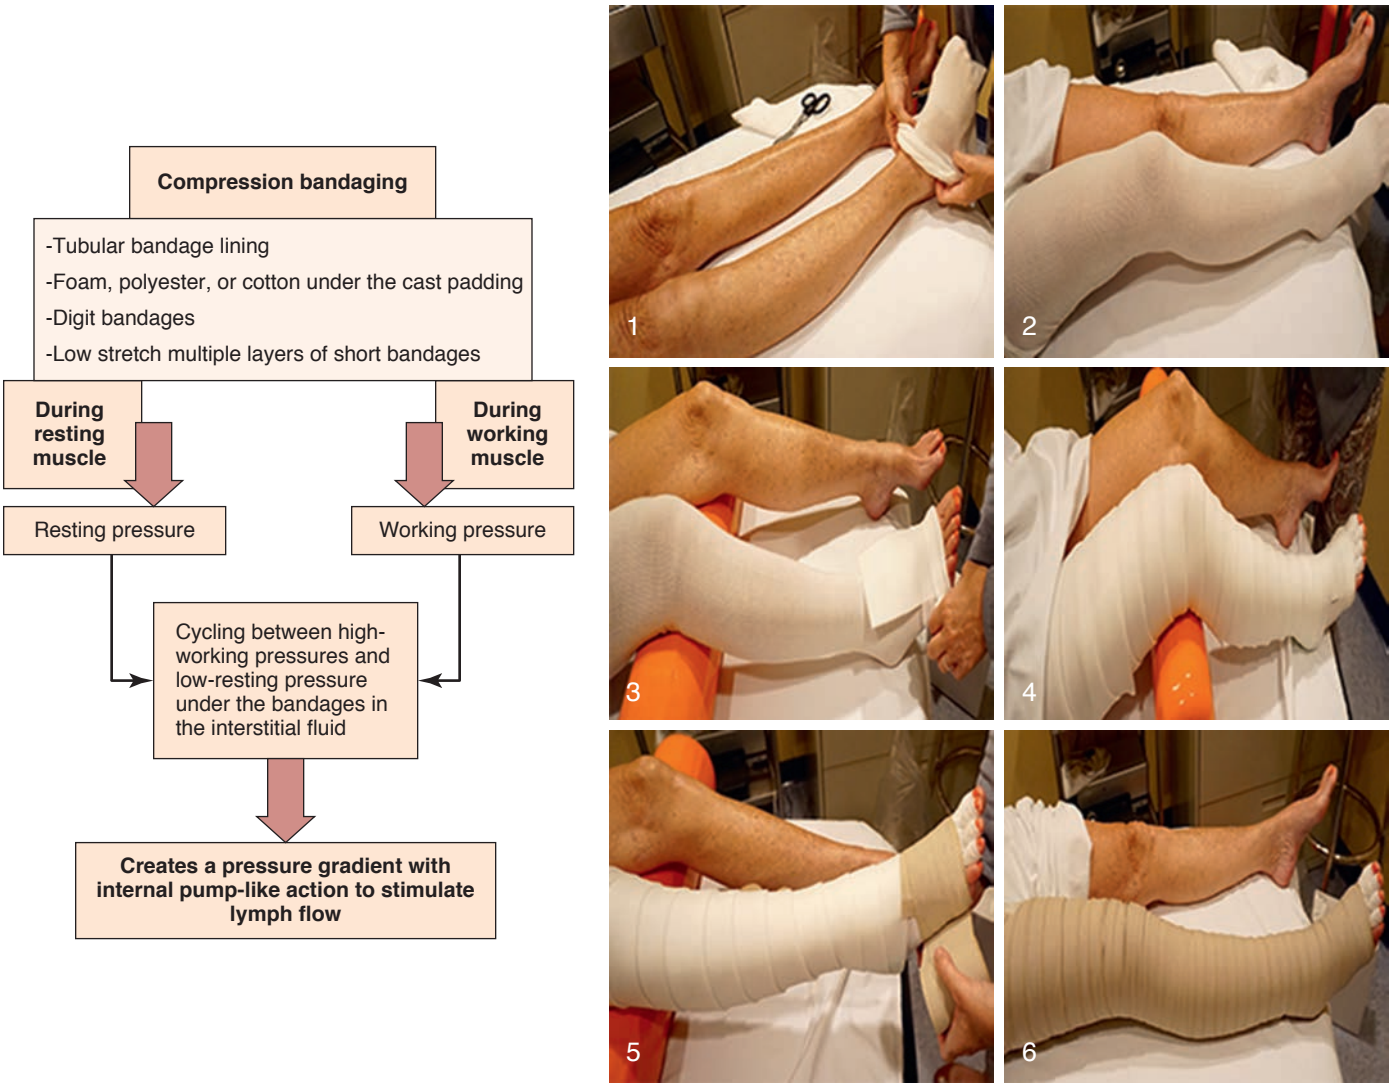

Figure 169.8 Compression Bandaging.

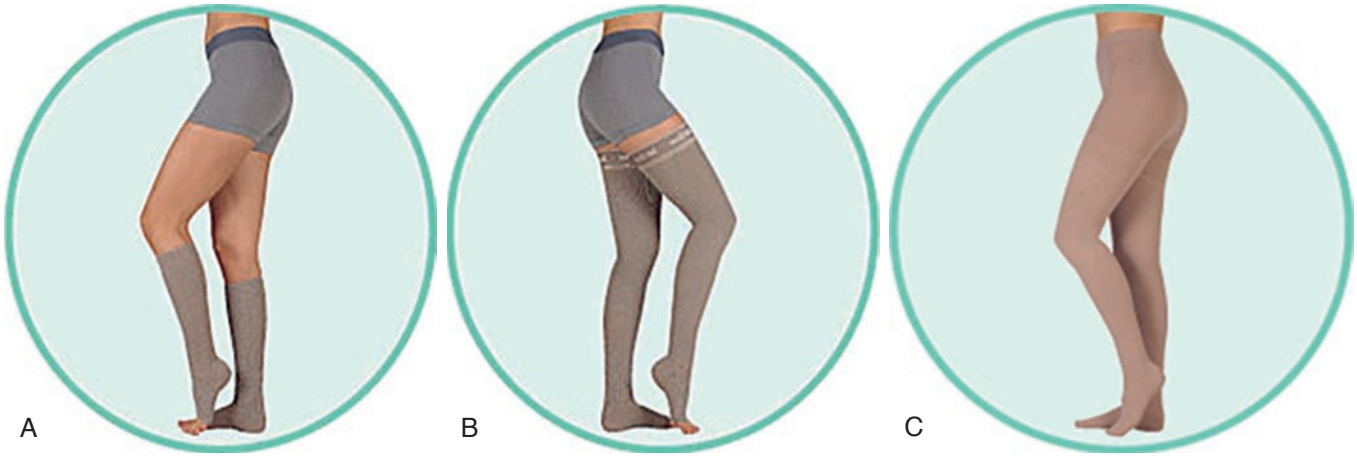

Figure 169.9 Compression Garments Length. **A**, Knee-high; **B**, thigh-high; and **C**, full-length.

very deep skin folds, extensive skin ulceration, severe peripheral neuropathy, and lymphorrhea.[65] There is a lack of evidence suggesting a positive or negative effect from a compression garment use during exercise. The results from current and previous research suggest the recommendation that garments must be worn during exercise is questionable, and its application requires an individualized approach.[66]

Stocking length is frequently an issue. As a general rule, stockings should be long enough to cover the edematous portion of the limb, but patient preference and physical limitations have to be considered. In general, knee-high or thigh-high compression garments with removable proximal pressure support (e.g., biking shorts, sport leotards) are better tolerated than full-length garments. Patient input in selecting among the wide range of options is key to promoting acceptance and adherence. Good garment fit is critical. Garments should never be rolled at the top, creating the possibility of an obstructing tourniquet. Creases at the ankle or in the popliteal or cubital areas can create enough pressure to cause skin breakdown. Skin should be carefully inspected for chafing or irritation after any new garment is worn.

Nonelastic Compression

Commercial nonelastic support devices are well received by patients as an alternative to nighttime wrapping. The Circ Aid (Shaw Therapeutics, Rumson, New Jersey) uses Velcro fastenings to adjust a series of nonelastic support bands around the leg and ankle. Another form of nonelastic support, the Reid sleeve (Peninsula Medical Inc., Scott Valley, California), is a tube of egg-crate foam, surrounded by canvas, with multiple wide Velcro bands to apply compression. Nonelastic compression options are most helpful for patients who are unable to manage a program of complex wrapping by themselves (Fig. 169.10). The efficacy of nonelastic devices has not been prospectively tested.

Sequential Pneumatic Compression

Sequential pneumatic compression (also called intermittent pneumatic compression [IPC]), is another method of compression therapy,[55] which is an ideal alternative to replace MLD for those patients who find difficulty performing the self-care MLD.[67,68] With lymphedema there is no force available to mobilize, isolate, and propel stagnant fluid to the regions where lymphatics absorb and contract; this task needs to be replaced by external massage, of which the most effective seems to be the sequential IPC.[69] The intermittent nature of pulsatile external compression produces beneficial physiologic changes, which include hematologic, hemodynamic, and endothelial effects.[70] The device enhances lymph transport by generating intermittent inflation and deflation over the affected limb, which mimics the action of muscle pump. Basically there are two phases: (1) the preparation phase, where pressure is applied in a distal-to-proximal gradient; and (2) the drainage phase, where pressure is applied in the same manner.[67] IPC also reduces lymphedema by decreasing capillary filtration, and therefore decreasing lymph formation.[71] Also the pump will lead to evacuating the edematous fluid to the area with normal lymph flow through the squeezing effect of the pump.[68] However, the efficacy of IPC may depend on the clinical situation as well as on several variables associated with the devices.[72] Bergan et al.[73] randomized 35 patients with lymphedema to a 2-hour-long treatment session with one of three types of compression pumps: (1) a uni-compartmental pump using 50 mm Hg pressure; (2) a three-compartment pump with segmental pressures of 50 mm Hg in each cell; or (3) a multi-compartmental gradient pressure pump with 10 cells ranging in pressure from 80 mm Hg distally to 30 mm Hg proximally. The mean percentage volume change was +0.4% in the first group, +7.3% in the second, and −31.6% in the third. The authors concluded that multi-compartment sequential compression achieved the best reduction of limb volume after a single treatment for chronic lymphedema.

The IPC devices may be single or multiple chambered,[74] and some pumps permit adjustment of the amount of pressure in a particular chamber; however, for the management of patients with lymphedema, the ideal pressure for the pump is unknown. Some investigators have suggested that a pressure greater than 60 mm Hg may injure lymphatic vessels. The IPC treatment is usually applied daily or 5 times per week; the optimal duration of IPC is also unknown. Among various studies, sessions have

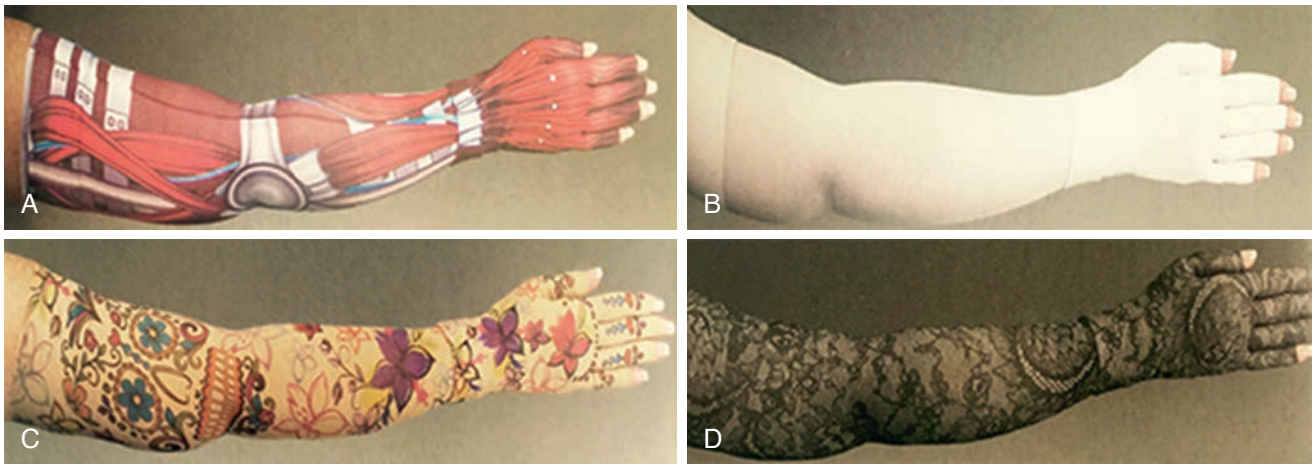

Figure 169.10 Compression Garments Materials. A, Latex; **B,** cotton; **C,** spandex; and **D,** nylon.

varied in length (90 minutes to as long as 6 hours) and duration (2 days to 4 weeks).[75–79]

After external compression therapy, a form-fitting, low-stretch elastic knit sleeve is usually applied to maintain edema reduction.[5] Outcomes of using the pump have been studied, and it was concluded that the pressure generated from the pump at the limb lymphedema tissue will cause formation of tissue channels that will work as pathways to help in clearing the accumulated fluid. The limb circumference is decreased or at least does not further increase, and the elasticity of the target limb is increased and maintained. No local complications in limb texture were observed.[5] The long-term, high-pressure IPC, long-inflation timed therapy can be safely be recommended to patients with lower limb lymphedema.[68] Contraindications to the use of IPC include local or proximal malignancy, infection in the limb, deep vein thrombosis, and patients on anticoagulation medication.[67] Current trials have failed to show the effectiveness of the addition of an IPC to the routine management of breast-cancer-related lymphedema.[80] It has been reported that IPC improved symptom relief, and reduced episodes of cellulitis and ulceration in lower-extremity lymphedema. It was well tolerated and should be recommended as supplemental to standard lymphedema therapy.[81]

Pressure Level

Provided there is no underlying peripheral arterial disease, sustained pressure of 60 to 70 mm Hg has been suggested as a maximum upper limit to treat lymphedema. Therapeutic lower extremity elastic stockings designed for chronic venous insufficiency or lymphedema are available in a variety of lengths and compression strengths (20 to 30, 30 to 40, 40 to 50, and 50 to 60 mm Hg). Lower limbs with recalcitrant chronic lymphedema generally require 30 to 40 mm Hg of compression at the ankle; however, for patients with comorbidities (e.g., diabetes mellitus, arterial occlusive disease, arthritis, or other conditions that limit the use of high-compression garments), stocking pressures of 20 to 30 mm Hg or less may be more appropriate. Upper extremity garments are typically fitted with 20 to 30 mm Hg pressure; however, 15 to 20 or 30 to 40 mm Hg are available, but their use would depend on lymphedema stage and tissue turgor. Previous studies have shown that high-pressure (90 to 100 mm Hg) sequential external pneumatic compression (SEP) reduced both limb girth and volume in a lymphedematous extremity.[82] Good evidence supporting the use of IPC for thrombosis prevention after surgery, in the treatment of post-thrombotic syndrome, and in lymphedema, has been reported.[83]

It also has been reported that IPC use with a pressure of 120 mm Hg inside the chambers effectively reduced a phlebolymphedema. Furthermore, it appeared that treatments with a pressure of 60 mm Hg were ineffective in lymphedema therapy, and perhaps are only useful in antiedematous therapy.[84] Currently, the optimal frequency and duration of IPC therapy is unclear.[74] Little known adverse events have been reported using IPC. In one study, there were no significant adverse events reported; however, there were reports of discomfort in two patients with chronic venous edema treated with IPC at 60 mm Hg, but not at 40 or 50 mm Hg. Another patient reported skin irritation, while three reported discomfort at least once during therapy.[85] Current literature indicates that IPC devices have little detrimental effect on patient safety (Fig. 169.11)[74]

Figure 169.11 Nonelastic Compression.

After reviewing current literature regarding garment characteristics, the authors of this chapter recommend applying nonelastic graduated compression stocking with 60 to 70 mm Hg when appropriate in addition to CDT.

Exercise

Exercise may be beneficial to individuals with lymphedema.[86] It provides an improved life quality[87] and a therapeutic intervention instead of worsening the lymphedema symptoms[88] by enhancing protein resorption[89] and maintaining lymphatic flow.[88,90,91] During the inspiration phase of exercise, there is a decrease in the intrathoracic pressure, which leads to an improvement of infradiaphragmatic lymph flow.[92] It can be concluded that with more exercise there is more pulmonary work, which enhances lymph flow and decreases the lymphedema.[64] Exercise will help weight reduction, which, in turn, will augment the clearance of lymph and decrease the swelling.[64] It is worth mentioning that patients with lymphedema associated with breast cancer may benefit from resistance exercise, and it is safe when it is done under the supervision of an experienced trainer to decrease symptoms exacerbation.[93,94]

Skin Care and Nail Care

Skin and nail hygiene is recommended to decrease the amount of cutaneous fungal and bacterial on the skin. Low pH moisturizers should be applied to keep skin from drying and cracking.[95] Cracks and dry areas of the skin are entry points for bacterial and fungal infections.[96,97] Regular use of a moisturizer can be used to avoid skin cracking. For arm lymphedema, good hand

TABLE 169.3 Therapeutic Approach Based on Clinical Stages

Stages	Duration	Phase I (Decongestion)	Phase II (Maintenance)
Stage I	2-3 weeks	• MLD 1-2× per day • Short-stretch bandages • Skin care • Remedial exercises	• MLD • Compression garments • Skin care • Remedial exercises
Stage II	3-4 weeks	• MLD twice a day • Short-stretch bandages • Skin care • Remedial exercises	• MLD as needed 1-2× per week • Compression garments • Skin care • Remedial exercises • Repeating phase I (1-2×)
Stage III	4-6 weeks	• MLD 2-3× day • Short-stretch bandages • Skin care • Remedial exercises	• MLD as needed 1-2× per week • Compression garments with bandages • Bandages at night • Skin care • Remedial exercises • Repeating phase I (3-4×) • Plastic surgery may be indicated

MLD, Manual lymphatic drainage.

hygiene and softening the cuticles with proper cuticle moisturizer are recommended.[98]

Therapeutic Approach Based on Clinical Stages

Multimodal therapy consists of general measures of self-care applicable for all stages of lymphedema. Treatment should be based on the stage of the disease. The intensity of compression and physiotherapy will also vary by stage. There are two general phases of therapy. The goal of phase I (intensive phase) is to mobilize accumulated protein rich fluid and initiate the reduction of fibrosclerotic tissue (if present), while the goal of phase II is to reserve and improve the success achieved during phase I (Table 169.3).

TABLE 169.4 Level of Evidence for Lymphedema Current Treatments

Therapy	Outcome	Evidence
Manual lymph drainage	Effectiveness not established	(112), (113), (114), (115)
Compression bandaging compression garments	Recommended for practice	(61), (116), (117), (118)
Pneumatic compression	Effectiveness not established	(106), (119), (120)
Exercise	Likely to be effective	(121), (122), (123)
Skin care	Expert opinion	None

Level of Evidence

CDT, including all the components, is recommended for practice.[99–106] Based on recent research, each individual component of CDT has different expected outcomes (Table 169.4).

OTHER TREATMENT

Besides the established therapies mentioned in Table 169.4, the benefits and effectiveness of several other therapies have been investigated. Pharmacotherapy has not shown to be beneficial; neither diuretics nor coumarin alleviate lymphedema. Low-level laser therapy, hyperbaric oxygen, and intermittent negative pressure have limited data to support effectiveness (Fig. 169.12). For example, the results from one low-level laser therapy study indicated edema reduction after treatment, which was sustained for several months.[107] In addition, hyperbaric oxygen therapy studies for breast-cancer-related lymphedema has had mixed results (see Fig. 169.13 for summary).[108,109]

As mentioned below, additional treatments have been investigated. It is likely, in the future, that gene therapy will be used to develop new lymphangioles in the affected limbs, which could be a potential clinical remedy. The potential efficacy of this approach was illustrated in a mouse model with lymphedema acquired by inactivating VEGFR-3 mutation, similar to that in congenital hereditary lymphedema (Milroy disease). Virus-mediated therapy with the gene for VEGF-C, which activates VEGFR-3, led to the generation of functional lymphatic vessels.[110]

Intralymphatic steroid injections also have been used in an attempt to decrease fibrotic occlusion in lymph nodes and to improve lymphatic transport. In a pilot study of 20 patients with primary lymphedema, 8 showed improvement for as long as 9 months after treatment.[111] Yet, to-date, the effectiveness of steroid treatment has not been established; however, investigators in Japan attempted to treat secondary lymphedema by injecting autologous lymphocytes into the main artery of the affected limb. Five of seven patients showed a short-term improvement.[112] In addition, the results of a larger series, which used a combined approach of lymphocyte injection and compression therapy, reported that 34 of 46 patients experienced edema reduction.[113] However, these studies have not been replicated.

Figure 169.12 **Sequential Pneumatic Compression. A,** Basic pump; **B,** Entre system with up to 18 inflatable chambers; and **C,** Flexitouch system with up to 32 inflatable chambers.

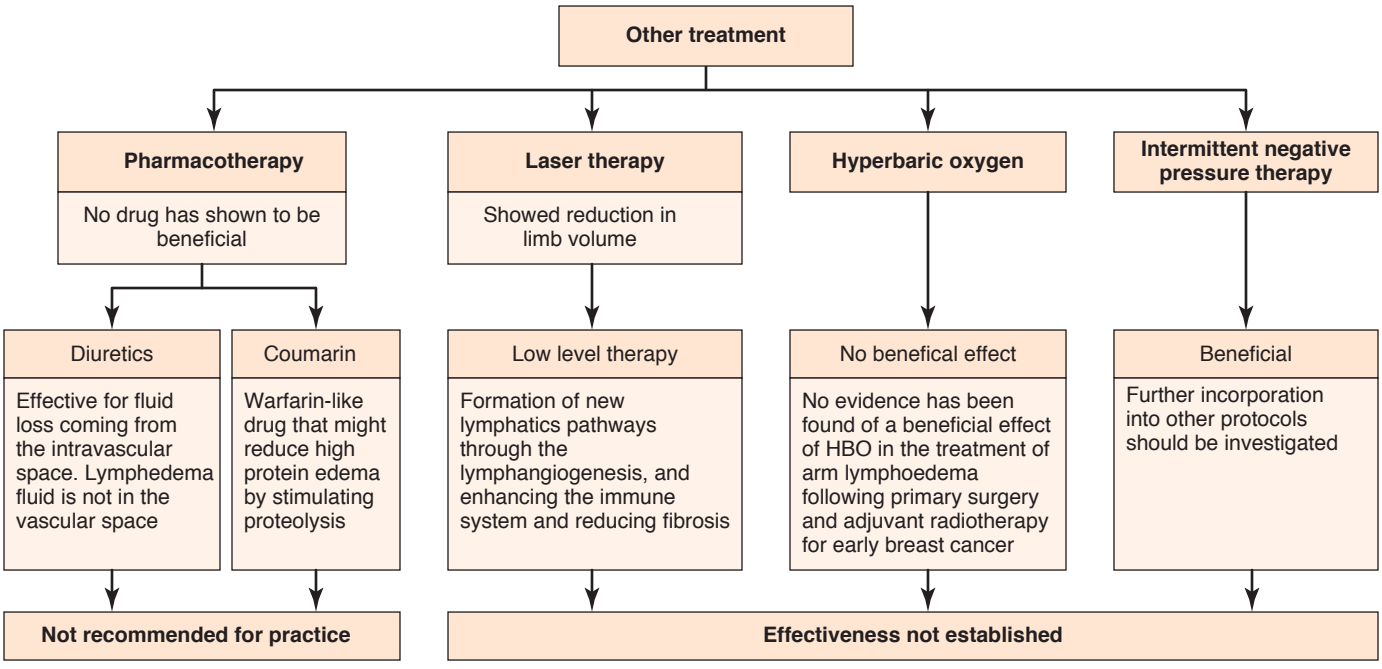

Figure 169.13 Other Treatment.

Researchers found a significant decrease in the thickness of lymphedematous ears in a rabbit animal model following extracorporeal shock wave therapy. The results indicated that there was a significant increase in the density of lymphatic vessels. The authors suggested that extracorporeal shock wave therapy may be a novel, feasible, effective, and noninvasive treatment for lymphedema.[2]

SUPPORTING EVIDENCE

Besides the standard lymphedema management and treatment techniques, there is limited information on the efficacy for other non-traditional therapies (see Figure 169.13). For example, there is little to no evidence that diuretics are effective. There are some reports supporting the use of coumarin[114,115] and laser

therapy.[2,107,116–120] On the other hand, published reports have failed to show any benefit for the use of hyperbaric oxygen[121,122] or intermittent negative pressure therapy.[123]

COMPLICATIONS

Skin Infections

Skin infection itself is a triggering factor for lymphedema, and it can be a complication of untreated lymphedema. Lymphedema is a protein-rich fluid, which is also an excellent medium for bacterial and fungal growth that may contribute to an increasing risk of infection. Lymphedematous tissue serves as an entry site for bacteria and developing erysipelas,[124] recurrent infections, and lymphangitis.[95,124–127] Approximately 20% to 30% of lymphedema patients will develop lymphangitis, erysipelas,[95] and cellulitis, especially those patients undergoing lymph node dissection.[56,128]

Malignancy

A rare, secondary, malignant tumor, called lymphangiosarcoma, can be the result of chronic lymphedema of any origin and be associated with its development.[129] It is usually seen in patients with massive and protracted edema,[130] and has been classically described as occurring in the post-mastectomy patient (Stewart-Treves syndrome),[131–133] or with primary lymphedema and chronic filarial lymphedema.[134–136] The tumor originates in vascular endothelial cells of the affected arm with lymphedema, not the lymphatic vessels.[132] It may initially appear as blue-red or purple skin lesions with a macular or papular shape. Multiple lesions are common and subcutaneous nodules may appear. Such skin lesions should be carefully evaluated in patients with chronic lymphedema.

Late-onset malignancies are a potentially devastating, but rare, complication of long-standing lymphedema. In most cases, they develop in no more than 1% of patients with lymphedema. Most common malignancies are angiosarcomas[137] and lymphangiosarcomas,[138] which are thought to represent the neoplastic transformation of blood vessels and lymphatics, respectively.

Histologically and clinically, it is difficult to distinguish these two sarcomas from each other. The occurrence of angiosarcoma (or lymphangiosarcoma) in the setting of lymphedema is commonly called Stewart-Treves syndrome.[137] Sarcomas can develop in patients with long-standing lymphedema of any cause: primary lymphedema or lymphedema secondary to filariasis,[136] hysterectomy,[139] trauma,[140] or mastectomy.[140] Other malignancies, including Hodgkin and non-Hodgkin lymphoma,[141] Kaposi sarcoma,[142] squamous cell carcinoma,[143,144] and malignant melanoma,[145] have been associated with chronic lymphedema, but a causal link has not been established.

Psychological Impairment

Chronic lymphedema continues to be an incurable and disabling condition.[146] The intensity of symptoms may differ from one patient to another; however, overall, most patients will have psychological impairment[147] and/or decreased quality of life, including social, functional, and emotional components.[148,149] Psychological and functional impairments associated with lymphedema are significant.[28] The psychological impact of long-term disfigurement, especially in adolescents, needs to be considered. The disturbance of body image is the underlying cause for younger women to have psychological distress, and often for older women to have depression.[150] Kim et al. found that lymphedema secondary to pelvic lymph node dissection among gynecologic cancer survivors decreased their quality of life due to the related symptoms and financial difficulty.[151] Winch et al. found the potential to accentuate sexual issues caused by lymphedema secondary to breast cancer, and women were reluctant to discuss these issues with anyone other than their partner.[152] Park et al.[28] found that 12% of patients reported that they were limited to jobs working at a desk or that allowed frequent sitting. Effective management of lymphedema may improve patient quality of life and reduce interference in daily activity.[153]

INSURANCE ROLE

From our local lymphedema clinic, it was reported that most insurance coverage plans cover CDT, but managed healthcare systems often limit the number of visits or units (e.g., 15 minute increments of care). In some cases, more visits may be requested with the submission of documentation. Typically, successful CDT treatment requires five visits/week for the first 2 weeks and then three visits/week for an additional 2 weeks. Hopefully, following CDT treatment, the size and volume of interstitial fluid has reduced to the point where a good assessment can be made. After which, compression garments can be fit and patients are provided with instruction for donning, along with self-care instructions and home protocols are provided to achieve the best compliance and long-lasting results. As there is no cure for lymphedema, in most cases there are few problems with coverage based on severity, as lymphedema is always progressive, if not appropriately managed. Unmanaged lymphedema places patients at great risk of infections.[95] However, it has also been reported that some third-party payers have suggested that edema is a cosmetic problem; consequently, they deny reimbursement for both treatment and garments. Such policies or beliefs often require repeated communications between payers and physicians to gain approval for treatment.[154] As part of a reconsideration of coverage policy, the Centers for Medicare and Medicaid Services requested a systematic review of the evidence on the use of pneumatic compression devices in the home environment for treatment of chronic venous insufficiency (CVI) and venous ulcers.[155] "The Lymphedema Treatment Act is a federal bill that aims to improve insurance coverage for the medically necessary, doctor-prescribed compression supplies, which are the cornerstone of lymphedema treatment."[156]

Currently Medicare does not cover compression garments, yet the lymphedema population is the one that could benefit the most. There is a rather lengthy application and a corresponding $25 fee paid by the patient. If approved, then they are

eligible for one set of garments and may apply again each year. However, the time and effort is well rewarded as thigh- and knee-high garments per leg are approximately $480 and $280, (USD, 2016), respectively.

In one study, researchers found an association between significant reductions in episodes of cellulitis and outpatient care and costs following the use of advanced pneumatic compression devices in patients with both cancer-related and noncancer-related lymphedema. Since the publication of this study in the *Journal of the American Medical Association* (JAMA),[157] healthcare payers have been more willing to reimburse for such treatments. Hopefully, these results will encourage healthcare providers to purchase comparable equipment, such as the Flexitouch System by Tactile Medical, because trial and treatment adjunct is very expensive.

IDEAL OUTPATIENT LYMPHEDEMA CLINIC

First and foremost, assessments, consultations, and treatment for lymphedema should take a multidisciplinary and team approach. The multidisciplinary team could include—but would not be limited to—specialists in nursing, podiatry, dermatology, plastics, oncology, physiotherapy, vascular, and psychology. The clinic should be a participating member of the National Lymphedema Network (NLN) because it is a good resource for healthcare professionals as well as patients. The Marilyn Westbrook Garment Fund is administered by NLN and provides garments to member patients who are in financial need and are treated by NLN-affiliated therapists. The lymphedema clinic should have a minimum of three certified lymphedema therapists who are certified by the Lymphedema Association of North America (LANA). Preferably there should be two physical therapists: one occupational and one physical, and at least one therapist experienced and certified in wound care. There should be a certified fitter for custom garments available at least 1 day a week. In addition, the clinic should have a working relationship with garment and supply vendors who provide dependable and timely service.

The necessary supplies for providing CDT should be maintained on site. In addition, under-stockinets of various sizes, compression foam of varied density, and short-stretch bandages various sizes should be kept in stock. For example, one leg

could require three boxes of foam, two 8 cm short-stretch and four 10 cm short-stretch bandages. The clinic should work with patients to remove any financial barriers that may restrict treatment. It is beneficial for patients to receive arm and leg kits prior to starting therapy; starter kits can be expensive especially if treatment is necessary for both legs and arms. In addition, two sets are needed, one to wash and one to wear. Finally, the treatment room must have a sink, no carpeting, and be large enough to accommodate large patients. The treatment table needs to be safe for supporting up to 600 pounds and have the capability to be elevated.

The lymphatic system is the least understood part of the vascular system. Lymphatic malformations such as chylous disorders, cystic hygromas, and lymphocysts are rare; acquired disorders such as lymphoceles and chylous effusions are also uncommon. However, local interruption and obstruction of the lymphatic vessels occur frequently from either congenital or acquired causes (see Chapter 168). In developed countries, most acquired lymphatic obstructions are iatrogenic, caused by medical procedures. In developing countries, the most frequent cause of lymphatic obstruction resulting in chronic lymphedema is filariasis.

BASIS OF SURGICAL TREATMENT

The development of lymphedema can be described as an imbalance between the lymphatic load (the amount of lymph that has to be cleared from a body part within a given time) and the lymphatic transport capacity (the amount of lymph that can be transported out of a body part within a given time), which is dependent on the number and function of lymphatic vessels and nodes (see Chapter 10).[1] Reduced lymphatic flow due to obstruction leads to secondary tissue changes, a process that is not yet fully understood. Lymphatic outflow disorders

are manifested mainly with advanced secondary changes and chronic lymphedema, a condition that can be difficult to treat unless the underlying problem of reduced lymphatic outflow is resolved. Historically, secondary tissue changes leading to excess fibrous and adipose tissue were treated solely by excisional procedures, without correcting the underlying cause. However, modern surgical concepts have been developed to attempt to correct the underlying pathophysiologic mechanism to the extent possible.

Because conservative therapy consisting of limb elevation, compression garments, complex decongestive therapy, and compression pump therapy should be the first step (see Chapter 169), the question arises whether and at what time surgery is indicated. If the only purpose of surgery is resection, it is wise to reserve it as a last option. If, however, surgical reconstruction is possible, this procedure should be considered and offered to the patient early in the course of lymphedema.

HISTORICAL PERSPECTIVE

Excisional Operations

Surgical Excision

The most radical excisional approach is the classic operation first described by Charles in 1912.[2] It involves complete and circumferential resection of the skin, subcutaneous tissue, and deep fascia, followed by split-skin grafting. However, this procedure is associated with significant complications, and follow-up studies revealed hyperkeratosis, papillomatosis, and ulcerations in the grafted areas.[3,4] Modifications of this technique, using the resected skin for grafting and performing the surgery in two stages,[5-11] reduced the surgical trauma and the rate of complications.

Liposuction

A less invasive way to reduce the amount of subcutaneous tissue is liposuction. It was first described by Illouz as a method for treating lymphedema.[12] More recently, Brorson and Svensson demonstrated lasting volume reduction if elastic compression garments are worn after the surgical procedure; this can result in an extremity that is even slimmer than the healthy limb.[13]

Functional Procedures

Early Techniques

The first attempts to divert lymph from the subcutaneous to the muscular compartment through partial or complete resection of the fascia were described by Lanz and Kondoleon.[14-16] Redirection of lymph from the superficial to the deep compartment is also a component of the Thompson method. Thompson resected the fascia along with parts of the subcutaneous tissue, created a flap in two stages, and de-epithelialized the rim of the flap to allow the outflow of lymph. Subsequently, he buried the flap near the deep vessels to facilitate the creation of spontaneous lymphatic anastomoses.[17-24]

The use of veins for the reconstruction of an interrupted lymphatic system was investigated by Holle and Mandl experimentally and performed in two patients clinically.[25,26] Campisi and colleagues reported on a larger series using this technique.[27]

Modern Techniques

Currently, the most common way to drain lymph from edematous tissue is the construction of connections between the lymphatic (Fig. 170.1) and venous systems in the periphery. The first reports on lymphonodular and lymphovenous anastomoses were provided by Laine and Howard,[28] Nielubowicz and Olszewski,[29] Rivero and coworkers,[30] and Allen and Taylor.[31] Degni designed a special needle to facilitate the insertion of lymphatic vessels into veins.[32,33] Further improvements were described by O'Brien and colleagues using microsurgical techniques.[34,35] In some patients, excisional methods were combined with lymphovenous shunting. A large cohort of patients successfully treated with microsurgical lymphovenous anastomosis was reported by Campisi and associates.[36]

However, experimental studies revealed problems with thrombotic occlusion at the site of anastomosis, with a patency of 20% after 5 months of follow-up.[37-39] Specific preparations that ensured an undisturbed connection to the venous valve led to an improved patency rate of 44% after 6 months.[40,41] Gloviczki and colleagues reported on results of experimental microsurgical end-to-end anastomoses between normal femoral lymph vessels and a tributary of the femoral vein in dogs and noted a 50% patency rate up to 8 months after the operation.[42]

Direct reconstruction of the lymphatic system became a possibility only after the development of microsurgery. Before that time, it was commonly thought to be impossible to anastomose lymphatic vessels because of their extremely small diameters. Hence, Danese approximated lymphatic vessels as close to each other as possible and waited for spontaneous regeneration. He was able to demonstrate transport of contrast medium (through the lymphatics) with this technique.[43] In a patient with lymphedema of the arm, he mobilized two lymphatic channels proximally and distally, approximated them in the axilla, and achieved a reduction in edema.[44] Subsequent approaches included interpositioning veins between lymphatic vessels,[25-27] implanting microsurgical lymph node grafts,[45,46] and implanting free flaps with lymphatic vessels.[47,48]

The question of optimal reconstruction material has been the subject of two experimental studies. In a series of 14 rats, 100% of the autologous lymphatic grafts were patent (observations made between days 7 and 119 postoperatively), whereas allogeneic lymphatic grafts were patent only until day 21 after transplantation. When lymphatics were replaced by small veins ($n = 10$), a patency of 70% was observed. Expanded polytetrafluoroethylene implants ($n = 10$) used as lymphovascular conduits were already thrombosed by day 7.[49] In a comparison of lymphatic and venous interpositional autografts in 71 dogs, all 26 lymphatic autografts remained patent up to the end of the observation period at 24 weeks. Of 30 venous interpositional autografts, only 4 were patent after 1 week. None of the lympholymphatic anastomoses with silicone tubing showed patency at any time.[50]

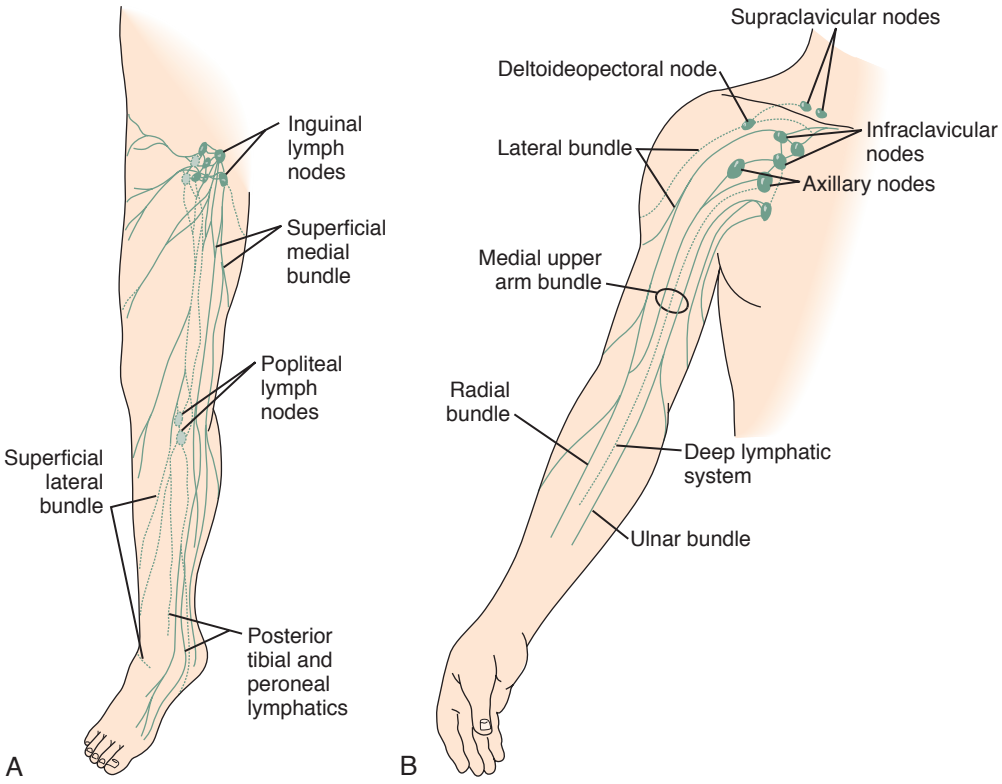

Figure 170.1 (A) Superficial lymphatic system of the lower extremity. (B) Lymphatic system of the upper extremity. (Courtesy Mayo Foundation.)

Acland and Smith were the first to attempt to anastomose lymphatic vessels.[51-53] The first successful therapeutic lympholymphatic graft was performed in 1980 by Baumeister in a patient with unilateral lymphedema of the lower extremity.[54-57] This followed extensive animal experiments on thoracic duct transplants in rats[58] and the treatment of experimental lymphedema in dogs using lymphatic autografts.[53]

PREOPERATIVE PLANNING

Visualizing Lymphatic Vessels

Lymphography

Direct contrast lymphography, using oily contrast medium and invasive administration through dissected lymphatic vessels, was introduced by Kinmonth and greatly advanced our knowledge of the lymphatic system.[59] However, owing to the invasiveness of the procedure (and injury to the lymphatic vessels and lymph nodes), it was found to worsen lymphedema and is rarely used today. Indirect contrast lymphography, using a water-soluble contrast medium injected subepidermally, cannot visualize lymphatic vessels as successfully as direct lymphography and gained only limited use.[60]

Magnetic Resonance Imaging

Attempts to visualize lymphatic vessels with magnetic resonance imaging (MRI) and subdermally administered contrast medium have been promising. This technique may be useful in the future for preprocedure planning and postoperative assessment of the patency of lymphatic reconstructions.[61] For the detection of vascular lymphatic malformations, MRI is extremely valuable both with and without contrast medium.

MR lymphangiography and lymphoscintigraphy show a clear concordance. Inguinal lymph nodes were better visualized using lymphoscintigraphy, whereas lymph vessels and their abnormalities were better depicted by MR lymphangiography.[62]

Lymphoscintigraphy

The most important test to evaluate chronic lymphedema and to plan surgical treatment is lymphoscintigraphy. It can be repeated and used for treatment planning and follow-up. It not only evaluates function but also visualizes routes of lymphatic transport. The *lymphatic transport index* summarizes the findings derived from lymphoscintigraphic studies and allows a semiquantitative evaluation of lymphatic flow without the need for standardized physical movements by the patient. The transport index ranges from 0 for an optimal lymphatic outflow to 45 for no visible transport; normal values are less than 10. It also provides a good basis for follow-up studies and can show lymphatic transport along the route of lymphatic grafts.[63,64] In measuring lymph transport at regions of interest, it is critical to standardize the dose of radiopharmaceutical and the physical activity of the patient during the procedure.[65]

Dye Injection

Another diagnostic tool that can be used to identify lymphatic channels is the subepidermal injection of a vital dye (patent blue dye in Europe; isosulfan blue [Lymphazurin] dye in the

United States). Normally, lymphatic transport is visualized in the superficial lymphatic collecting system. In pathologic situations, dermal backflow leads to the pooling of contrast medium within the skin, resulting in a cloudlike appearance. Because allergic reactions have been reported, staining of lymphatic vessels with patent blue or isosulfan blue dye is generally performed during surgery under general anesthesia.

Lymphatic Donor Site Assessment

For lymphatic grafting, it is critical to choose and carefully evaluate the proper harvest site for lymphatic vessels to avoid the development of edema secondary to the procedure. Thus, the donor lower extremity must be evaluated by lymphoscintigraphy before harvesting. During the harvest, the narrowing lymphatic system at the medial aspect of the knee and the groin must be left untouched, and all stained lymphatic vessels other than those used as grafts should be left in place. A study including 80 patients with arm edema showed that when this method was used, the harvest site and the untouched leg were not different in size.[57]

No pathologic values were detected after the harvest in a study of 19 consecutive patients, where the donor limb was examined pre- and postoperatively by lymphoscintigraphy. The scintigraphic follow-up was performed 48.6 months following harvest and transplantation. In all patients, the postoperative transport index was close to the preoperative baseline value and within the normal range.[66]

Patient Risk Assessment

Because this type of surgery is performed in the subcutaneous tissue, the surgical risk is generally low, and the procedure is well tolerated. Peripheral lymphovenous shunting is often performed under local anesthesia and is unproblematic as long as the patient tolerates local anesthetics. Because the application of patent blue or isosulfan blue dye can lead to allergic reactions, it should be used only under general anesthesia. Excisional methods typically involve more surgical trauma and the possibility of greater blood loss. Therefore, it is sometimes advisable to perform large excisional operations in two stages. For surgical intervention within the abdomen and thorax, the usual preoperative risk assessment must be done (see Chapter 32).

SURGERY

Autologous Lymphatic Grafting

Indications

Lymphatic vessel grafts can be attempted for the treatment of secondary lymphedema caused by localized obstruction or interruption of lymph vessels and lymph nodes, such as the lymphedema of the arm that develops after breast cancer surgery because of the excision of axillary lymph nodes and possible radiation treatment (see Fig. 170.1B). Patients with unilateral lower limb lymphedema due to the excision of inguinal or pelvic lymph nodes or pelvic irradiation for malignant disease are also potential candidates for such procedures. Transplantation of lymphatic vessels can be attempted in patients with primary lymphedema if it is caused by localized lymphatic obstruction or atresia, such as unilateral atresia of the pelvic or inguinal lymphatic system.

Surgical intervention should be considered only after a trial of conservative therapy. Conservative treatment should be continued for at least 6 months because spontaneous regression has been reported. However, if conservative therapy is unsuccessful during this time frame, reconstruction should be attempted soon to avoid secondary tissue changes. Unfortunately, treatment is often delayed. In my experience, the mean time between the onset of edema and the patient's presentation for surgery is more than 7 years.

Surgical Technique

The lymphatic grafts are harvested from the patient's thigh (Fig. 170.2). The ventromedial lymphatic bundle contains up to 16 lymphatic vessels.[67] About one to four lymphatic collectors are dissected in the medial area of the thigh, and great care is taken to spare the lymphatic system where it narrows at the level of the knee and groin. Additional peripheral branches often exist, and these can be dissected as well to create a greater number of peripheral anastomoses.

For free transfer of the graft, a ligature is placed on the lymphatic vessel selected as a graft beneath the inguinal lymph nodes with 6-0 polyglactin 910. One thread is left long to facilitate handling of the graft thereafter. Proximal to the ligature, the lymphatic vessel is transected. At the distal end of the proposed graft, the lymphatic vessel is transected proximal to

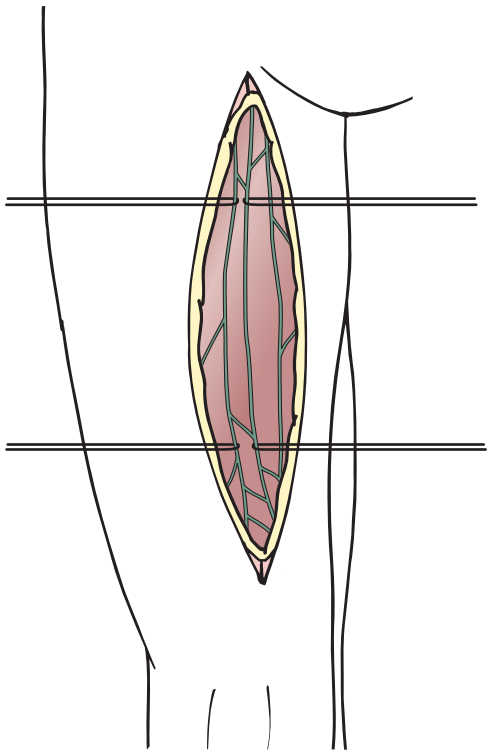

Figure 170.2 Harvesting of lymphatic grafts from the patient's thigh.

the level of the knee. The lymphatic vessel beneath the transection site is occluded by placing a suture or by using coagulation to avoid lymph leakage.

If a transposition procedure is performed, the grafts are transected distally after double ligation and tunneled subcutaneously superior to the pubic symphysis to the contralateral side, where end-to-end lympholymphatic anastomoses are performed. In free transfers and in transposition procedures, the graft has to be pulled from one incision to the other (e.g., from the upper arm to the neck or between inguinal regions). To avoid any friction during tunneling, tubes (suction catheters) are placed between the two incisions according to the proposed route of the grafts. Thereafter, the grafts themselves can be pulled through the tubes without tension. After removal of the tubes, the grafts remain undisturbed in place within the subcutaneous tissue.

Arm and Neck

For arm edema as a result of interventions in the axilla, the grafts are interposed between ascending lymphatic vessels in the upper arm and lymphatic vessels or lymph nodes in the neck (Fig. 170.3). In the upper arm, lymphatic vessels are usually epifascial (if not, they may be located subfascially in proximity to the vessels) and are best sought from an oblique incision made medially and superior to the route of the brachial vessels. The search is performed under the microscope with a medium (3× to 10×) magnification. In the early stages of lymphedema, the lymphatic vessels have a gray, shiny appearance, and the lumen can be seen clearly after transection. As the lymphatic vessels undergo fibrosis in later stages of lymphedema, it becomes more difficult to discriminate between small nerves and fibrous cords. In this case, the final decision about the potential use of grafting can be made only after transection of the structure.

The walls of lymphatic vessels are thinner in the neck than in the arms and legs. Injection of a vital dye in the hair-bearing parietal area above the ear facilitates the search for appropriate vessels. If the lymphatic vessels stain appropriately, recognition is easy. However, suturing in this area is often difficult because of the collapsing, thin-walled vessels. If this is the case, it is also possible to suture the grafts to lymph nodes. A superficial incision is made in the capsule of the node, and the graft is connected with approximately three single interrupted sutures.

To position the grafts between the sites of anastomosis, tubing from a drain is placed in the subcutaneous tissue between the incisions in the upper arm and neck. Subsequently, the grafts are pulled through the wet drain gently and without friction. After removal of the tube, the grafts remain in the subcutaneous tissue free of tension.

Leg

For unilateral edema of the lower extremity, the grafts remain attached to the inguinal lymph nodes, and the distal ends of the grafts are transposed to the opposite thigh with the help of tubing from a drain, which is temporarily interposed between the two incisions at the thigh (Figs. 170.4 to 170.6).

The tension-free technique is used to anastomose the lymphatic vessels under the operating microscope with maximal magnification (Fig. 170.7). The suture opposite the surgeon should be performed first. Because of the fragility of the vessels, the vessels are not turned over. Only the back wall is lifted as far as necessary to place a dorsal stitch. One or two additional single stitches complete the anastomosis. In my experimental studies of suture material, absorbable polyglactin was superior to nonabsorbable material. Currently, 10-0 absorbable suture (polyglactin 910) is the thinnest material available, used on a BV-75-4 needle.

Postoperative Treatment

After surgery, elastic bandages are applied, and an elastic compression garment is prescribed for 6 months, at which time discontinuation of the garment is considered. Antibiotics are given for about one week because of the reduced immunologic resistance in patients with lymphedema.

Results

Results were evaluated by volume estimation based on circumferential measurements along the limb in increments of 4 cm. Further, lymphatic outflow was measured semiquantitatively by the lymphatic transport index based on lymphoscintigraphic studies.[63] Direct visualization of the grafts is difficult because, with lymphangiography using water-soluble contrast medium, the lymphatic vessels can generally be visualized only over short distances. However, in several patients, patent grafts could be demonstrated more than 10 years after grafting with this technique.[68]

In a series of 127 patients with arm edema, a significant volume reduction was achieved, from a mean of 3368 cm^3 preoperatively to a mean of 2567 cm^3 after 8 to 10 days ($P < .001$). At a mean follow-up of 2.6 years, the mean volume was 2625 cm^3 ($P < .001$). In a group of 8 patients with long-term follow-up of more than 10 years, the mean volume was reduced to 2273 cm^3 from a mean preoperative volume of 3004 cm^3 ($P < .001$).

In 81 adult patients with unilateral edema of the lower extremities, the mean preoperative volume of 13,098 cm^3 was reduced to a mean of 10,578 cm^3 at the time of hospital discharge ($P < .001$). After a mean follow-up period of 1.7 years, the volume reduction was sustained, with a mean volume of 11,074 cm^3 ($P < .001$). In a group of 12 patients observed for more than 4 years, the volume was reduced to 10,692 cm^3 ($P < .001$).[57] The following complications were observed: two cases of erysipelas in the initial group of patients, one lymphocyst at the harvesting site, and swelling of the lower leg after thrombosis in one patient.

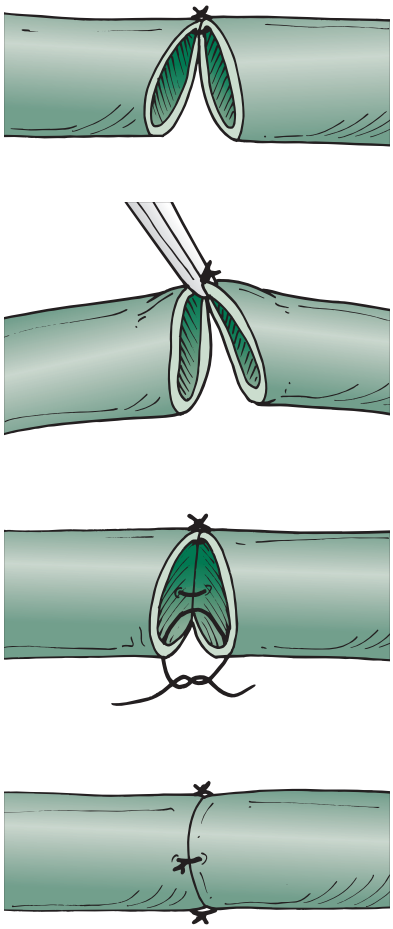

Figure 170.7 Tension-free technique for lympholymphatic anastomoses.

Lymphoscintigraphic studies were performed during a follow-up period of 8 years in 20 patients (12 upper extremities, 8 lower extremities). Of the 20 patients, 17 showed improved lymphatic outflow. In five patients, patent grafts could be demonstrated directly by visualizing the routes of activity.[69] Figs. 170.8 and 170.9 show lymphoscintigraphic studies along with the transport index for two patients with a follow-up period of 6 years. A quality-of-life study in 212 patients who underwent lymphatic grafting showed a significant improvement in the physiologic and the psychologic conditions as well.[70]

The functional outcome by dynamic imaging of lymph kinetics after autologous lymph vessel transplantation was studied recently in 177 patients suffering from upper limb lymphedemas. All patients underwent a preoperative scintigraphic baseline study and at least 1 scintigraphic follow-up. The patients were examined at four different time points after surgery: within 2 weeks (T1); between 6 and 12 months (T2); between 32 and 38 months (T3); and in 19 cases, at least 8 years (T4) after lymphatic grafting. Volume measurements were performed simultaneously.

At T1 the mean reduction in volume difference (RV) between the affected and normal extremity was 73%, and the mean improvement of the lymphatic transport index (ITI) was 28%.

At T2 the RV was 64% and the ITI was 23%, at T3 the RV was 63% and the ITI was 25%, and at T4 the RV was 68% and the ITI 25%. The mean overall correction was by a factor of 2.64.

The data confirmed the significantly improved lymph drainage after reconstruction by lymphatic autografts and showed a strong correlation between volumetric and scintigraphic findings.[71]

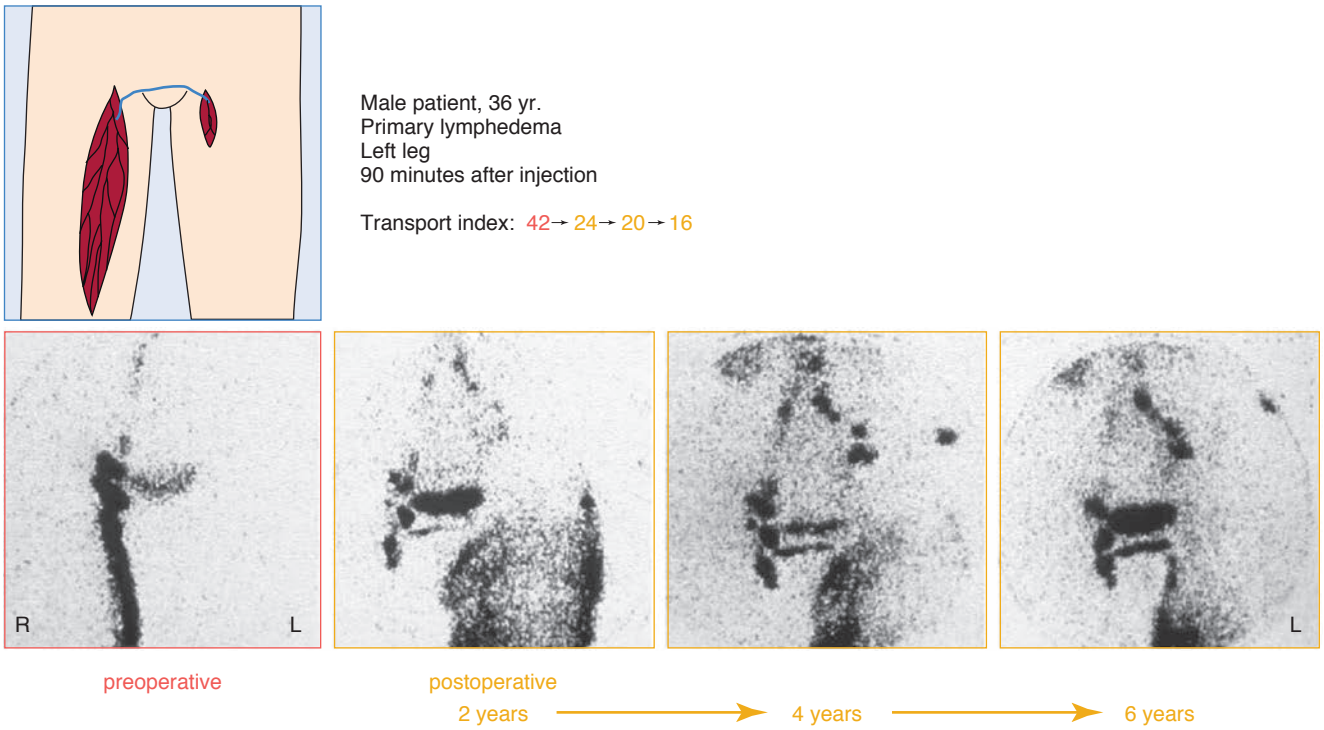

Figure 170.9 Lymphoscintigraphic long-term follow-up after lymphatic grafting in unilateral edema of the lower extremity.

Other Direct Reconstructive Methods

Trevidic and Cormier described a method of directly bridging a lymphatic defect with a free flap.[45] Li and colleagues isolated lymphatic vessels within the flap and created lympholymphatic anastomoses on both sides.[48] Ho and coworkers used the greater saphenous vein to invaginate the lymphatic vessels and also performed lympholymphatic anastomoses at the peripheral and central ends of the interposition tissue.[72] Another attempt to reconstruct a gap in the lymphatic system, described by Becker and associates, consists of free lymph node grafting with the goal of spreading lymphatic connections peripherally and centrally.[46]

Different areas of implantation of the transplanted lymph nodes were reported besides the area of the original defect, such as the wrist and the elbow at the upper limb and distal areas of the lower limb.[73]

However, reports of edema formation after the harvest have been published.[74,75]

Different aspects of the effect of vascularized lymph node transfer are postulated and under discussion: a pumping force of lymph nodes via intranodal connections between the lymphatic and venous systems, which transports along the microsurgical venous anastomoses and the enhanced presence of VEGF-C, stimulating the lymphatic network within the flaps around the lymph nodes.[76,77]

Another method of reconstructing an interrupted lymphatic system using veins was proposed by Mandl[78] and described in a series by Campisi and colleagues[27] (Fig. 170.10). The study

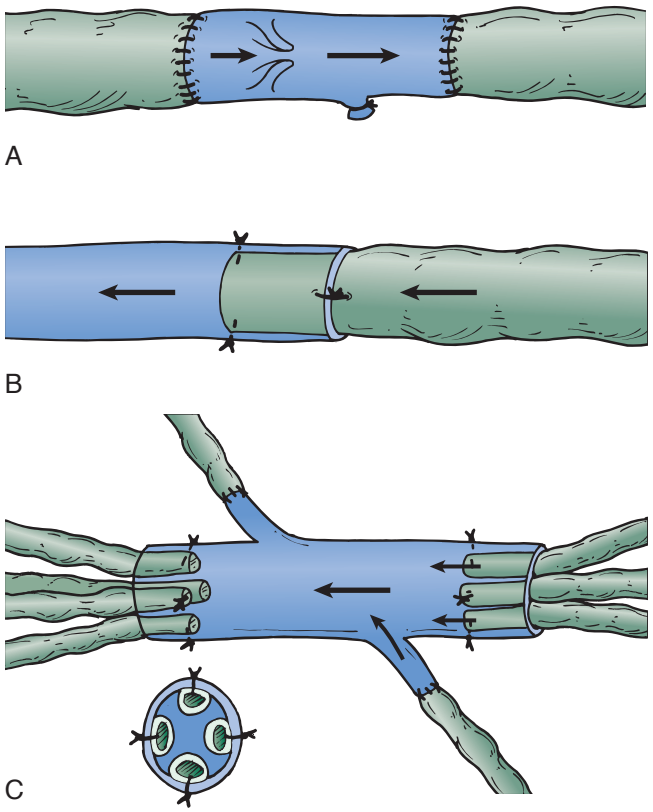

Figure 170.10 Techniques of lymphatic reconstruction with interposition vein graft (A) or lymphovenous anastomosis (B). Technique of invagination of multiple lymphatics into an interposition vein graft: lymphatic-venous-lymphatic anastomosis (C). (Courtesy Mayo Foundation.)

included 64 patients, 59 with leg lymphedema and 5 with postmastectomy edema. Marked reduction was reported in 40 patients, moderate reduction in 18 patients, and mild reduction in 6 patients.

Lymphovenous Anastomosis

Indications

Patients with secondary lymphedema of recent onset without previous episodes of cellulitis or lymphangitis are potential candidates for surgical treatment unless they can be managed easily with conservative measures. In the late stage of lymphedema, fibrosis and valvular incompetence of the main lymph vessels develop, the intrinsic contractility of the vessel wall is lost, and interstitial pressure decreases because of secondary changes in the subcutaneous tissue (see Chapter 10). The chance of successful lymphovenous anastomosis in such limbs is clearly diminished. Because venous hypertension impedes forward flow through the anastomosis, patients with chronic venous insufficiency are not candidates for this operation.

Preoperative Evaluation

Isotope lymphoscintigraphy is usually sufficient for preoperative imaging of the lymphatic system. In ideal candidates, it confirms the presence of dilated infrainguinal lymph vessels with proximal pelvic lymphatic obstruction. Although it does not differentiate between primary and secondary lymphedema, and even though it is primarily a functional study rather than an anatomic one, semiquantitative lymphoscintigraphy with technetium Tc 99m–antimony trisulfide colloid can reliably identify the pattern of lymphatic transport.[79] In selected patients, direct contrast lymphangiography can be performed to show the fine details of the lymphatic circulation.

Progress in visualizing superficial lymphatic vessels has been made with the use of indocyanine green fluorescence lymphography. Indocyanine green is injected intradermally. With the help of a near-infrared camera, the lymphatic vessels are detected as blurred linear images, whereas dermal backflow is seen as a spotty image. This facilitates the search for superficial lymphatic vessels appropriate for lymphovenous anastomoses.[80]

Other preoperative tests include noninvasive venous studies and duplex scanning of the deep veins. Computed tomography (CT) is used in most patients to exclude an underlying mass or malignant tumor. Once the decision to perform surgery is made, the patient is hospitalized for 24 to 48 hours to elevate the extremity in a lymphedema sling and to allow the use of intermittent compression with a pump to decrease the volume of the extremity.

Surgical Technique

Leg

For lower extremity lymphedema, a transverse incision at the midthigh or a longitudinal incision close to the saphenofemoral junction is performed to allow dissection of the lymphatic of the superficial medial bundle. The greater saphenous vein and any tributaries are also dissected. An attempt is made to visualize the lymph vessels by injecting 5 mL of isosulfan blue dye subcutaneously; half this amount is directed toward the first interdigital space and half toward the area 10 to 15 cm distal to the incision site. Because of lymphatic obstruction, even lymph flow in patent lymphatics may be minimal, and the dye usually is not visible during dissection. With experience, the whitish fluid-filled lymphatics, frequently with vascularized adventitia, can be distinguished from small subcutaneous nerves or fibrotic bands.

If contrast lymphangiography is performed within 24 hours of the operation, the contrast-filled lymphatics are easily identifiable and can be located during the operation with an image intensifier and a C-arm. In some patients, contrast lymphangiography helps avoid many hours of unsuccessful searching for patent lymphatics in the groin. Once the lymphatic vessels and the veins are isolated, a standard microsurgical technique is used to perform an end-to-end anastomosis with six to eight interrupted 11-0 monofilament sutures. The operation is performed with a Zeiss operating microscope with 4× to 40× magnification.

Arm

For arm lymphedema, the lymphatics are dissected through a transverse incision at the wrist or in the midcubital fossa or through a longitudinal incision at the medial aspect of the arm, a few centimeters proximal to the elbow. Lymphatics of the superficial medial lymphatic bundle are usually used for anastomoses, which are performed with the midcubital, basilic, or brachial veins or their tributaries in an end-to-side or end-to-end fashion.

Postoperative Treatment

Postoperatively, the limb is wrapped with an elastic bandage and elevated 30 degrees. For the arm, this can be accomplished with two pillows; for the lower extremity, the foot of the bed can be elevated.

Results

Objective evaluation of the long-term effectiveness of lymphovenous anastomosis has been difficult. Decrease in the circumference or volume of the extremity, patient satisfaction, decrease in episodes of cellulitis, and improvement in lymphatic clearance as measured by lymphoscintigraphy have been used as the criteria of success. In a review of 14 patients who underwent lymphovenous anastomosis at the Mayo Clinic, only 5 limbs remained improved at a mean follow-up of 46 months after surgery.[81] Improvement was observed in four of seven patients with secondary lymphedema but in only one of seven with primary lymphedema. Improvement in lymphatic clearance from the injection site was the only indirect sign of shunt patency. Therefore, the investigators were unable to provide objective evidence of late patency of the lymphovenous anastomoses in these patients.

A large experience with lymphovenous shunts was reported in Australia. O'Brien and colleagues published a well-documented report with long-term follow-up of 90 patients who underwent lymphovenous anastomoses for chronic lymphedema.[82] Although

a significant number of patients underwent additional excisional operations, improvement was documented even in those with only lymphovenous anastomoses. Of the latter, 73% had subjective improvement, and 42% had objective long-term improvement. Seventy-four percent of all patients discontinued the use of elastic stockings. However, objective imaging evidence that improvements were caused by patent and functioning lymphovenous anastomoses is still lacking.

The largest experience to date comes from Campisi and colleagues in Italy.[83,84] This group treated 665 patients with obstructive lymphedema using microsurgical lymphovenous anastomoses and achieved subjective improvement in 87% of their patients. In the 446 patients available for long-term follow-up, the authors observed volume reduction in 69% and discontinuation of conservative measures in 85%. This is a remarkable result that has not yet been duplicated elsewhere. The authors concluded that microsurgical reconstruction early in the course of lymphedema is more effective because the intrinsic contractility of the lymphatic vessel is maintained and the chance of normalizing the lymph circulation is better before significant chronic inflammatory changes develop in the subcutaneous tissue.

Koshima and coworkers from Japan reported significant improvement of lymphedema at a mean of 3.3 years after lymphovenous anastomoses in 8 of 13 patients.[85] However, Vignes and associates failed to confirm the therapeutic benefit of lymphovenous anastomoses in a group of 13 patients (10 with primary and 3 with secondary lymphedema).[86] Global assessment of clinical outcome was very good or good in five patients and intermediate in another five, but the operation failed to improve the volume of lower limbs or to reduce the frequency of erysipelas. A follow-up study of 237 lymphaticovenous side-to-end anastomoses, performed in 57 patients with lymphedema, showed at least one patent anastomosis in 34 patients by use of indocyanine green fluorescence lymphography after a mean follow-up period of 14 months. In 23 patients, no patent anastomosis was seen. There was no significant difference in limb volume reduction between the two groups.[87]

In one surgical technique, the so-called lymphaticovenous implantation, the lymph vessel is inserted into the lumen of a bigger vein together with the surrounding fat, including the lymphatic capillaries.[88] The same procedure is also used to improve lymphatic drainage of the dermal lymphatics.[80]

A large series of patients treated for secondary and primary lymphedema by supermicrosurgical lymphovenous anastomosis and lymphaticovenous implantation was published by Demirtas and colleagues.[89,90] In 40 patients with unilateral primary lymphedema, a mean reduction of 56% of the surplus volume was seen after a follow-up period of 13.3 months. Although only 17% of the patients had complex physical therapy before surgery, all stage 4 patients and most stage 3 patients (according to Campisi's classification) used custom-made pressure garments after surgery. In 20 patients with unilateral secondary lymphedema, a mean reduction of 60% was seen after a mean follow-up period of 12.8 months; 50% of the patients did not receive complex physical treatment before surgery, and continuous custom-made pressure garments were used in two of five stage 3 lymphedema patients and in all stage 4 lymphedema patients. There was no significant relationship between the number of microsurgical anastomoses or implantations and the mean reduction in volume.

Resection

Resection involves the removal of the lymphedematous, fibrotic, and frequently sclerotic subcutaneous tissue of the limb. Liposuction is a more recent technique used to accomplish resection. Other open excisions are usually performed during staged procedures. If the skin is diseased and requires resection, coverage with skin grafts may be necessary.

Liposuction

Surgical Technique

Brorson and Svensson advocate use of liposuction in patients with postmastectomy lymphedema to reduce the volume of the extremity.[13] The rationale behind this treatment is that chronic lymphedema causes hypertrophy of the subcutaneous fat. Removal of the hypertrophied and edematous adipose tissue is performed through 3-mm-long incisions (20 to 30 incisions) with vacuum aspiration. During the postoperative course, controlled compression therapy (CCT) is administered to decrease bleeding complications and to help reduce the volume of the limb.

Results

In a report by Brorson and Svensson, preoperative and postoperative arm edema volumes were measured by the water-displacement technique, and lymph transport was assessed by lymphoscintigraphy.[91] Twenty-eight patients were prospectively matched and divided into two groups. One group received liposuction combined with CCT, and one group received CCT alone. Liposuction combined with CCT was more effective than CCT alone; the edema reduction figures after 1 year were 104% for liposuction with CCT and 47% for CCT alone ($P < .0001$). Continued use of compression garments is important to maintain the primary surgical outcome. Liposuction can be useful in patients with no functioning lymphatics, but in others, the destruction of functioning lymphatics and worsening of the edema are possible.

Staged Subcutaneous Excision Beneath Flaps

Surgical Technique

The technique described by Miller and colleagues is most popular in the United States.[92-95] The excision is performed in two or sometimes three stages, starting medially during the first operation. A bloodless field is obtained with a pneumatic tourniquet. An incision is made along the ankle beginning 1 cm posterior to the medial malleolus and extending proximally into the midthigh. Flaps approximately 1.5-cm thick are elevated anteriorly and posteriorly to the midsagittal plane in the calf,

with less extensive dissection in the thigh and ankle. All subcutaneous tissue beneath the flaps is then removed, but the sural nerve is preserved. The deep fascia of the calf is incised over the tibia and resected, sparing the fascia at the knee and ankle to preserve joint integrity. Redundant skin, about 4 to 10 cm wide, is then resected; suction catheters are placed, and the wound is closed in a single layer with 4-0 nylon. In suturing around the ankle and knee, portions of the deep fascia are included in the suture to fix the skin flaps deeply and to ensure contour. The extremity is immobilized with a posterior splint and elevated. The patient is kept on bed rest for 9 days and mobilized afterward wearing tightly wrapped elastic bandages to prevent seroma formation and to promote optimal healing and contour. This regimen is continued for 3 weeks postoperatively.

The second stage, consisting of lateral excision, is performed 3 months later in a similar fashion. During lateral excision, the sensory branches of the peroneal nerve are identified and carefully preserved.

Results

Staged excision underneath skin flaps offers the most reliable improvement of all debulking operations while minimizing the likelihood of postoperative complications. Miller and colleagues reported the long-term results in 38 patients with chronic lymphedema after staged subcutaneous excisions performed beneath skin flaps.[95] Thirty patients had marked and durable reduction in extremity size with improved function. Episodes of cellulitis were reduced or eliminated. No difference in long-term results was seen in patients with primary versus secondary lymphedema. This series had a remarkably low rate of skin complications (four patients) and a low rate of late disease progression (six patients).

The clinical benefit of excisional operations is directly related to the amount of subcutaneous tissue removed. Patients are susceptible to recurrences and should continue to wear elastic compression stockings. Although good volume reduction is achievable with most of these procedures, prolonged hospitalization, poor wound healing, long surgical scars, sensory nerve loss, and residual edema of the foot and ankle can be significant problems. Because of these potential complications, these procedures are generally offered only to patients with significant, disabling lymphedema that is not responding to medical measures.

PRIMARY CHYLOUS DISORDERS

Chylous disorders are characterized by an accumulation of chyle in abnormal areas of the body. Chylous ascites, chylothorax, and chylocutaneous fistula may be caused by a malignant tumor (most frequently lymphoma) or by trauma to the mesenteric lymphatics or the thoracic duct, which may also occur during vascular surgical procedures. Primary chylous disorders are usually caused by congenital lymphangiectasia or megalymphatics, which in some patients are associated with obstruction of the thoracic duct. In patients with lymphangiectasia and lymphatic valvular incompetence, chyle may reflux into the lower extremities, perineum, or genitalia.[91-98] Depending on the site of the dilated lymphatics and the site of the chylous leak, these patients may also have protein-losing enteropathy, chylous ascites, chylothorax, chylopericardium, or reflux of chyle into the lungs and tracheobronchial tree.[91-108] In a series of primary chylous disorders at the Mayo Clinic, patients presented with lower limb edema (54%), dyspnea (49%), scrotal or labial edema (43%), and abdominal distention (37%).[100] The cause was primary lymphangiectasia in 66%, yellow nail syndrome in 11%, lymphangioleiomyomatosis in 9%, and other disorders in 18%.[100]

Medical treatment is aimed at decreasing the production of chyle by means of a medium-chain triglyceride diet or occasionally by parenteral nutrition. Repletion of proteins and calcium lost with chyle is as important as strengthening of the body's defense mechanism because lymphocytes and important immunoglobulins are also wasted in these patients. Only surgical treatment can provide long-term improvement and occasionally cure by ligation of the incompetent retroperitoneal lymph vessels and oversewing of the site of the lymph leak. Attempts to reconstruct the obstructed thoracic duct by the creation of thoracic duct–azygos vein or internal jugular vein anastomoses have been reported.[98,109-111]

Lower Extremity and Genitalia

Many patients with lymphangiectasia and reflux of chyle have unilateral lower extremity lymphedema. The main discomfort for these patients, however, is the intermittent or continuous discharge of chyle from cutaneous vesicles in the lower extremity or the genitalia. The first five patients known to have suffered from this rare condition were described in 1949 by Servelle and Deysson.[102]

The preoperative evaluation of patients with chylous reflux into the lower extremity or genitalia should include lymphoscintigraphy (Fig. 170.11A). However, contrast lymphangiography is the definitive test to confirm the diagnosis and to localize the dilated retroperitoneal lymphatics and, frequently, the site of lymph leak. MRI with contrast enhancement may provide more precise information in the future.

Surgical Treatment

The only effective technique to control the reflux of chyle and its drainage through skin vesicles in the perineum, labia, scrotum, or lower extremity is radical excision and ligation of the incompetent retroperitoneal lymph vessels. Gloviczki and coworkers used the technique of Servelle and performed the entire reflux operation in two stages through flank incisions by the retroperitoneal approach.[100] Four hours before the procedure, the patient ingested 60 g of butter and 8 oz of whipped cream. The fatty meal allowed ready visualization of the retroperitoneal lymphatics during exploration (see Fig. 170.11B to D). Ligation of the lymph vessels should be done with the utmost care to avoid tearing or avulsion of the lymphatics, resulting in residual leaks or rupture. In recent years, sclerotherapy of the dilated lymphatics has been added to ligation to increase the efficacy of the operation.

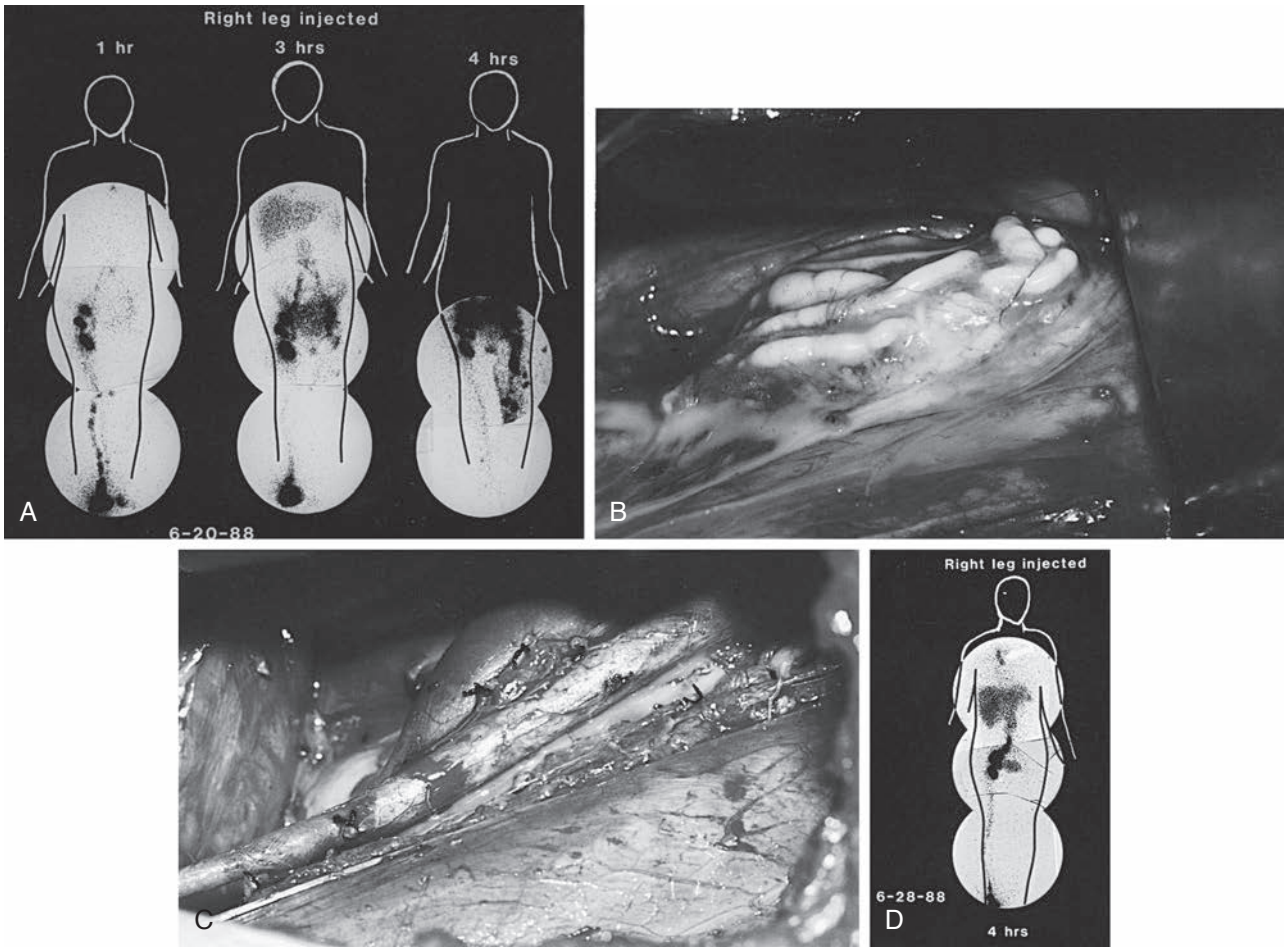

Figure 170.11 (A) Right lower extremity lymphoscintigram in a 16-year-old girl with lymphangiectasia and severe reflux of chyle into the genitalia and left lower extremity. Injection of the isotope into the right foot reveals reflux into the pelvis at 3 hours and into the left lower extremity at 4 hours. (B) Intraoperative photograph reveals dilated, incompetent retroperitoneal lymphatics in the left iliac fossa containing chyle. (C) Radical excision and ligation of the lymph vessels were performed. In addition, two lymphovenous anastomoses were created between two dilated lymphatics and two lumbar veins. (D) Postoperative lymphoscintigram reveals no evidence of reflux at 4 hours. The patient has no significant reflux 4 years after surgery. (From Gloviczki P, Calcagno D, Schirger A, et al. Noninvasive evaluation of the swollen extremity: experiences with 190 lymphoscintigraphic examinations. *J Vasc Surg*. 1989; 9:683.)

Tetracycline solution, 500 to 1000 mg diluted in 20 mL of normal saline, is injected directly into the dilated retroperitoneal lymph vessels to provoke obstructive lymphangitis.

As reported by Molitch and associates, percutaneous CT- or MRI-guided cannulation of these dilated lymphatics may be possible, and sclerotherapy to decrease reflux can be performed repeatedly if necessary.[104] Lymphovenous anastomoses with the dilated lymphatics can also be performed. Reflux of blood into the dilated and incompetent lymphatics can occur, however. A competent valve on the venous side completely avoids reflux and increases the chance of successful lymphatic drainage.[105,109]

Results

The largest group of patients studied was reported by Servelle, who operated on 55 patients with chylous reflux into the lower extremity or genitalia and reported a durable benefit in most patients.[97] In Kinmonth and Cox's series of 19 patients who underwent ligation of the retroperitoneal lymphatics for chylous reflux to the limbs and genitalia, permanent cure was achieved in 5 patients, and alleviation of symptoms—frequently after several operations—occurred in 12 patients.[98] No improvement or failure was noted in only two cases. Noel and coworkers reviewed the results of 35 patients with primary chylous disorders treated during a 24-year period.[105] Twenty-one patients (60%) underwent 27 surgical procedures. Nineteen procedures were performed for chylous ascites or reflux; 10 of these patients (53%) underwent resection of retroperitoneal lymphatics with or without sclerotherapy, 4 (21%) had lymphovenous anastomoses or saphenous vein interposition grafts, 4 (21%) had peritoneovenous shunts, and 1 (5%) had a hysterectomy for periuterine lymphangiectasia. All patients improved initially, but 29% had a recurrence of symptoms at a mean of 25 months (range, 1 to 43 months). Three patients with leg swelling had postoperative lymphoscintigraphy confirming improved lymphatic transport and diminished reflux.

Chylous Ascites

Chylous ascites usually results from intraperitoneal rupture of the mesenteric or retroperitoneal lymphatics or from exudation of chyle into the peritoneal cavity.[105] The evaluation of such patients should include CT or MRI to exclude abdominal malignant disease. The diagnosis of lymphangiectasia is confirmed by bipedal contrast lymphangiography. Paracentesis is both diagnostic and therapeutic.

Surgical Treatment

If conservative measures fail and ascites returns, abdominal exploration should be performed after a fatty meal, as described previously. If chylous ascites is due to primary lymphangiectasia, abdominal exploration may reveal ruptured lymphatics, which can be oversewn. Some patients develop large chylous cysts, which should be excised (see Fig. 170.11). If the condition is associated with protein-losing enteropathy and the disease is localized to a segment of the small bowel, the bowel segment should be resected. The outcome of the operation is usually good if a well-defined abdominal fistula is found. However, if the mesenteric lymphatic trunks are fibrosed, aplastic, or hypoplastic, and exudation of chyle is the main source of the ascites, the prognosis is poor and recurrence is frequent.

Results

Browse and coworkers treated 45 patients with chylous ascites.[99] The age at presentation ranged from 1 to 80 years (median, 12 years). Thirty-five patients had an abnormality of the lymphatics (primary chylous ascites); in the remaining 10, ascites was secondary to other conditions, principally non-Hodgkin lymphoma (6 patients). Surgery (fistula closure, bowel resection, or insertion of a peritoneovenous shunt) was performed in 30 patients. Closure of a retroperitoneal or mesenteric fistula, when present, was the most successful operation, curing 7 of 12 patients. In those patients who develop chylous ascites from iatrogenic trauma, frequently after aortic reconstructions, a short period of conservative management is justified. If chylous ascites reaccumulates, reoperation with ligation of the fistula is the most effective treatment. Campisi et al. reported on 12 patients with a mean follow-up of 5 years; there was 1 death after 1 year, 3 mild recurrences, and 1 major recurrence that was treated.[112]

Results with peritoneovenous shunts have been mixed; patency is usually judged by the recurrence of ascites. In Browse and coworkers' experience with nine peritoneovenous shunt placements, all occluded within 3 to 6 months after insertion.[99] Noel and colleagues used the LeVeen shunt with good results, although one of four patients developed symptomatic superior vena cava syndrome because of thrombosis around the shunt.[105]

Chylothorax

As with chylous ascites, the most frequent cause of chylothorax is trauma or malignant disease.[110] Primary lymphatic disorders that cause chylothorax include lymphangiectasia with or without thoracic duct obstruction. However, chylothorax may also result from chylous ascites passing through the diaphragm. In these patients, the chylothorax is cured when the chylous ascites is controlled. Preoperative lymphangiography should be performed in these patients because it may localize the site of the chylous fistula or document occlusion of the thoracic duct (Fig. 170.12).

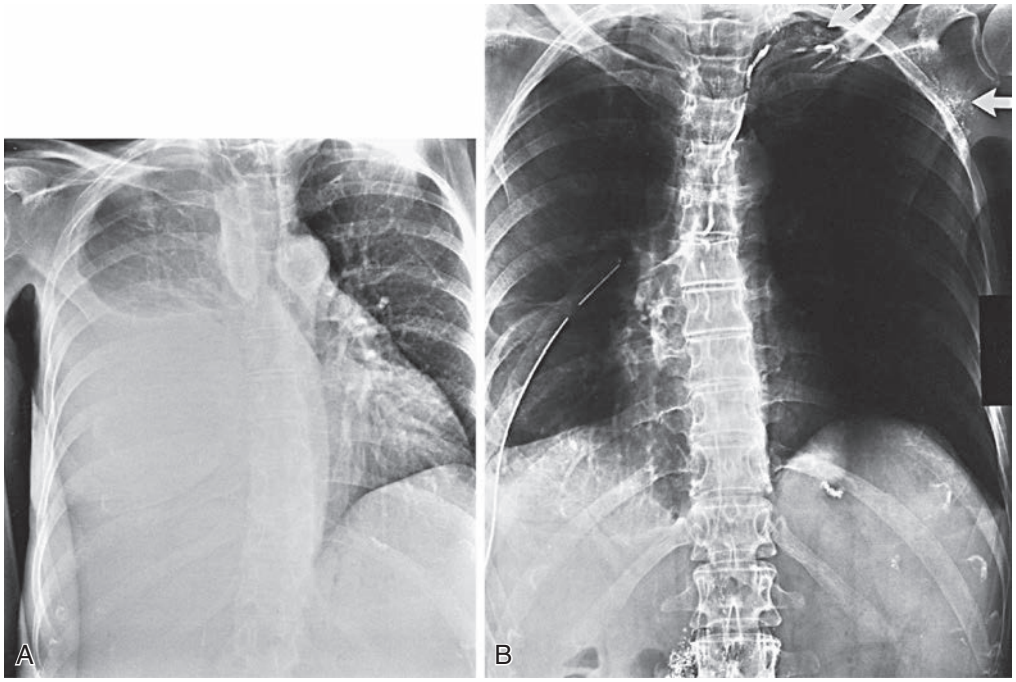

Figure 170.12 (A) Right chylothorax in a 63-year-old woman. (B) Bipedal lymphangiography confirms thoracic duct obstruction at the base of the neck. Note contrast medium in the supraclavicular and left axillary lymphatics *(arrows)*.

Thoracentesis usually is not effective in curing the disease, and chyle that leaks from the thoracic duct or one of the large intercostal, mediastinal, or diaphragmatic collaterals reaccumulates. Injection of tetracycline is frequently ineffective because it is diluted by the leaking chyle.

Surgical Treatment

The best treatment of chylothorax is surgical pleurodesis with excision of the parietal pleura and prolonged pleural suction.[106,110] After the patient has eaten a fatty meal, thoracotomy or video-assisted thoracoscopy is performed, and the leaking lymphatics are oversewn or clipped. This is followed by pleurodesis. In the Mayo Clinic series, eight procedures for chylothorax consisted of thoracotomy with decortication and pleurodesis (four patients), ligation of the thoracic duct (three patients), and resection of a thoracic duct cyst (one patient), with excellent early results in all patients.[105]

Thoracic Duct Reconstruction

If occlusion of the cervical or upper thoracic duct (Fig. 170.13) is the cause of lymphangiectasia and reflux of chyle into the pleural or peritoneal cavity, thoracic duct–azygos vein anastomosis can be attempted to reconstruct the duct and improve lymphatic transport. Preoperative imaging of the duct with contrast pedal lymphangiography is important because occlusion of the entire duct precludes anastomoses.

The operation is performed through a right posterolateral thoracotomy, and the anastomosis between the lower thoracic duct and the azygos vein is performed in an end-to-end fashion with 8-0 or 10-0 nonabsorbable interrupted sutures and magnification with loupes or an operating microscope. Only a few patients undergoing this operation have been described.[98,110] Both patients operated on by Gloviczki's group[113] had good immediate patency, and excellent flow of chyle was observed through the anastomosis intraoperatively (Fig. 170.14). Although neither had postoperative contrast lymphangiography, recurrent chylothorax (the main indication for the procedure) ultimately resolved in both. Browse et al. reported two successes in three patients who underwent thoracic duct reconstruction.[110] Kinmonth et al. performed this procedure in two patients and concluded that the anastomosis alone is not effective for decompressing the thoracic duct; ligation of the abnormal mediastinal lymphatics and oversewing of the sites of lymphatic leak are also necessary.[98]

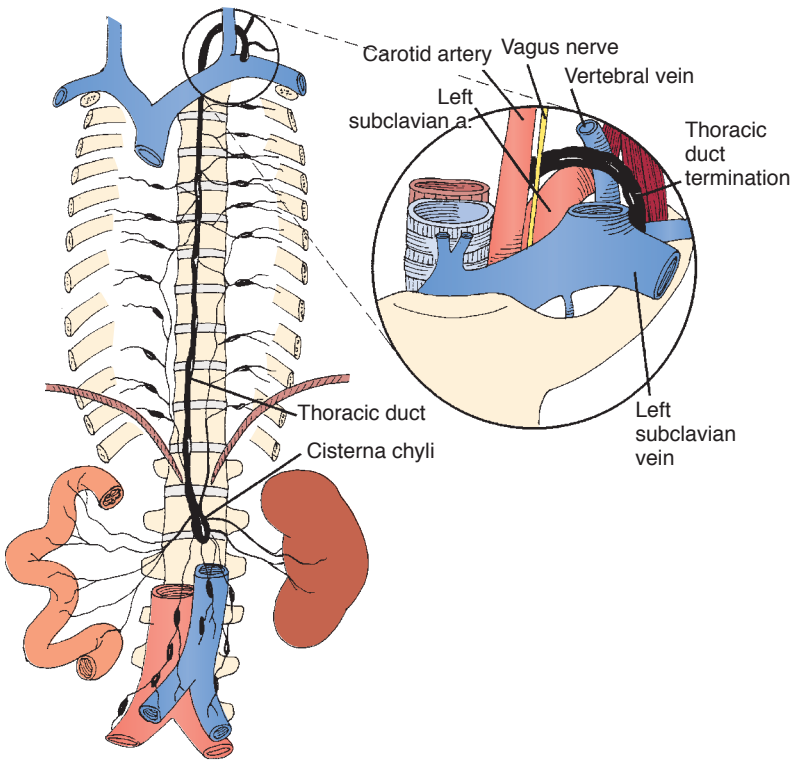

Figure 170.13 Cervical and thoracoabdominal anatomy of the thoracic duct.

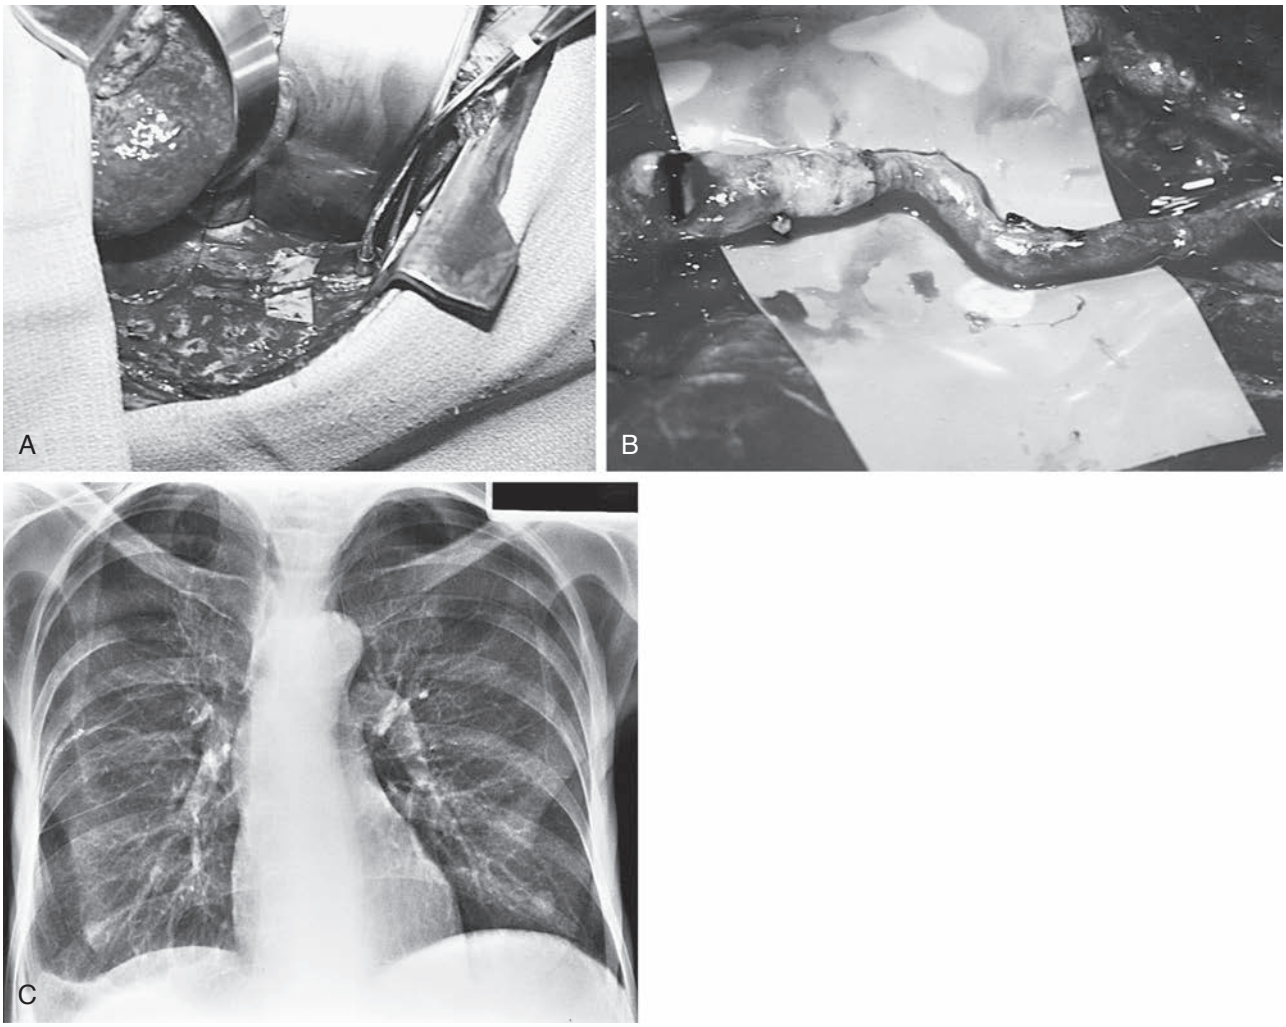

Figure 170.14 (A and B) Thoracic duct–azygos vein anastomosis performed through a right posterolateral thoracotomy in an end-to-end fashion with interrupted 8-0 polypropylene (Prolene) sutures. (C) Chest radiograph 2 years later confirms the absence of chylothorax.

LONG-TERM FOLLOW-UP ASSESSMENT 2250

Much progress has been made over the past 50 years in our understanding of why some children are born with imperfections, while the majority are born with normal anatomy.[1] The spectrum of congenital vascular malformations (CVMs) is very wide, and these often-disfiguring anomalies are commonly seen by both general practitioners and specialists. Successful treatment usually requires a wide range of specialists and multidisciplinary centers dedicated to their study.

DEFINITIONS

The term CVM is used to describe malformed vessels resulting from arrested development during various stages of embryogenesis.[2,3] It is present at birth, although not always immediately identifiable. CVMs may involve one or all three circulatory systems—arterial, venous, and lymphatic—either as a predominant form (e.g., venous malformation) or as a mixed condition

Abstract

This chapter aims to provide a general overview of congenital vascular malformations (CVMs); it clarifies the definition based on contemporary nomenclature and classification, more specifically the Hamburg Classification and the International Society for the Study of Vascular Anomalies (ISSVA) Classification. This should provide readers with a means to better understand its etiology, pathophysiology, diagnosis, and management.

Keywords

Congenital vascular malformation
Hamburg classification
ISSVA classification

extratruncular lesion
venous malformation
lymphatic malformation
arteriovenous malformation

(e.g., hemolymphatic malformation). They continue to grow regardless of type.

CVMs may be confused with a more common vascular anomaly, the infantile or neonatal hemangioma.[4,5] Although both CVMs and hemangiomas are vascular anomalies, they are fundamentally different not only in their anatomic, histologic, and pathophysiologic findings but also in their clinical course (Fig. 171.1).[6] A true hemangioma is a vascular tumor that originates from endothelial cells, appears in the early neonatal period, grows rapidly, and then involutes, usually by age 12 years. In contrast, CVMs are generally distinctive at birth as inborn errors, and they grow steadily in parallel with the child's systemic growth. CVMs never disappear or regress.

NOMENCLATURE AND CLASSIFICATION

The nomenclature and classification of CVMs originally contained numerous terms such as *angiodysplasia, cavernous hemangioma, cystic hygroma,* and *lymphangioma,* as well as numerous eponyms (Klippel-Trenaunay [KTS], Parkes-Weber [PWS] syndromes). A new classification was needed to accommodate the contemporary understanding of CVMs, and these old terms have largely been replaced by the Hamburg classification.[2,7-9] Eponyms are still used for the combined syndromes of vascular malformations, such as KTS and PWS. However, the vascular components of KTS are termed hemolymphatic malformations (HLMs—combination of venous, lymphatic, and capillary malformations), and the components of PWS consist of venous, lymphatic, capillary, and arteriovenous malformations (Fig. 171.2).[10-13]

The term *congenital vascular malformation* now replaces the term *angiodysplasia.* The term *capillary* or *cavernous hemangioma*[14] has erroneously been used to describe a venous malformation.[15,16] To prevent confusion, *hemangioma* should be used only to identify a genuine hemangioma (i.e., a vascular tumor), not a vascular malformation.[17]

Hamburg Classification

The Hamburg classification (Box 171.1) appropriately classifies CVMs according to the underlying anatomic, histologic, pathophysiologic, and hemodynamic status derived from different embryonic stages.[2,7,9] It is based on a consensus of CVM experts who met at the Seventh International Workshop on Vascular Malformations in Hamburg, Germany, in 1988. It has clinical applicability and has been well accepted.[18] It originally divided CVMs into five types based on the predominant vascular component: arterial malformation (AM),[19,20] venous malformation (VM),[21,22] arteriovenous malformation (AVM),[23,24] lymphatic malformation (LM),[25,26] and combined vascular malformation (hemolymphatic malformation-HLM).[27,28] The initial consensus did not include the capillary malformation (CM) because it was believed to lack the clinical significance of other CVMs. However, the addition of CMs was proposed and upheld at consensus meetings in Denver (1992)[29] and Seoul (1996).[30,31]

BOX 171.1 Hamburg Classification[a]

Congenital Vascular Malformations—Types

- Arterial defects
- Venous defects
- Arteriovenous shunting defects
- Lymphatic defects
- Combined vascular defects—hemolymphatic defects
- Capillary defects

Congenital Vascular Malformations—Embryologic Subtypes[b]

Extratruncular Forms

- Infiltrating, diffuse
- Limited, localized

Truncular Forms

- Stenosis or obstruction
  - Hypoplasia, aplasia, hyperplasia
  - Membrane; congenital spur
- Dilation
  - Localized (aneurysm)
  - Diffuse (ectasia)

[a]Modified from the original classification based on the consensus reached at the international workshop in Hamburg, Germany, 1988.
[b]Represents arrested development at different stages of embryonic life, with extratruncular being an earlier stage and truncular a later stage. Both forms may coexist.

Although the Hamburg classification has been accepted worldwide, it is far from perfect, and further improvements are necessary before it completely replaces the old terminology and classifications.

Each vascular malformation is classified into extratruncular and truncular forms, based on its embryologic stage of development (see Box 171.1).[32,33] The clinical behavior of every vascular malformation is dependent on its embryologic characteristics, particularly the stage of embryogenesis when arrested development occurred. The varied embryologic characteristics result in a wide range of clinical presentations, unpredictable clinical courses, and erratic responses to treatment, along with potentially high rates of recurrence. The embryologic subclassification of CVMs into truncular and extratruncular allows clinicians to predict the clinical course, response to treatment, and likelihood of recurrence.[34,34] Further information on their distinctive characteristics is included in subsequent sections.

ISSVA/Mulliken Classification

Another classification system, introduced by Mulliken et al., is based on the hemodynamic status of the CVM and provides an excellent guideline for clinical management.[4,5] In the International Society for the Study of Vascular Anomalies (ISSVA)/Mulliken classification, all CVMs are divided into two groups, depending on blood flow: fast-flow lesions and slow-flow lesions. This helps in understanding the hemodynamic status of a CVM. Currently, many specialists have adopted parts of this system and combined it with the Hamburg classification to monitor the treatments and outcomes.

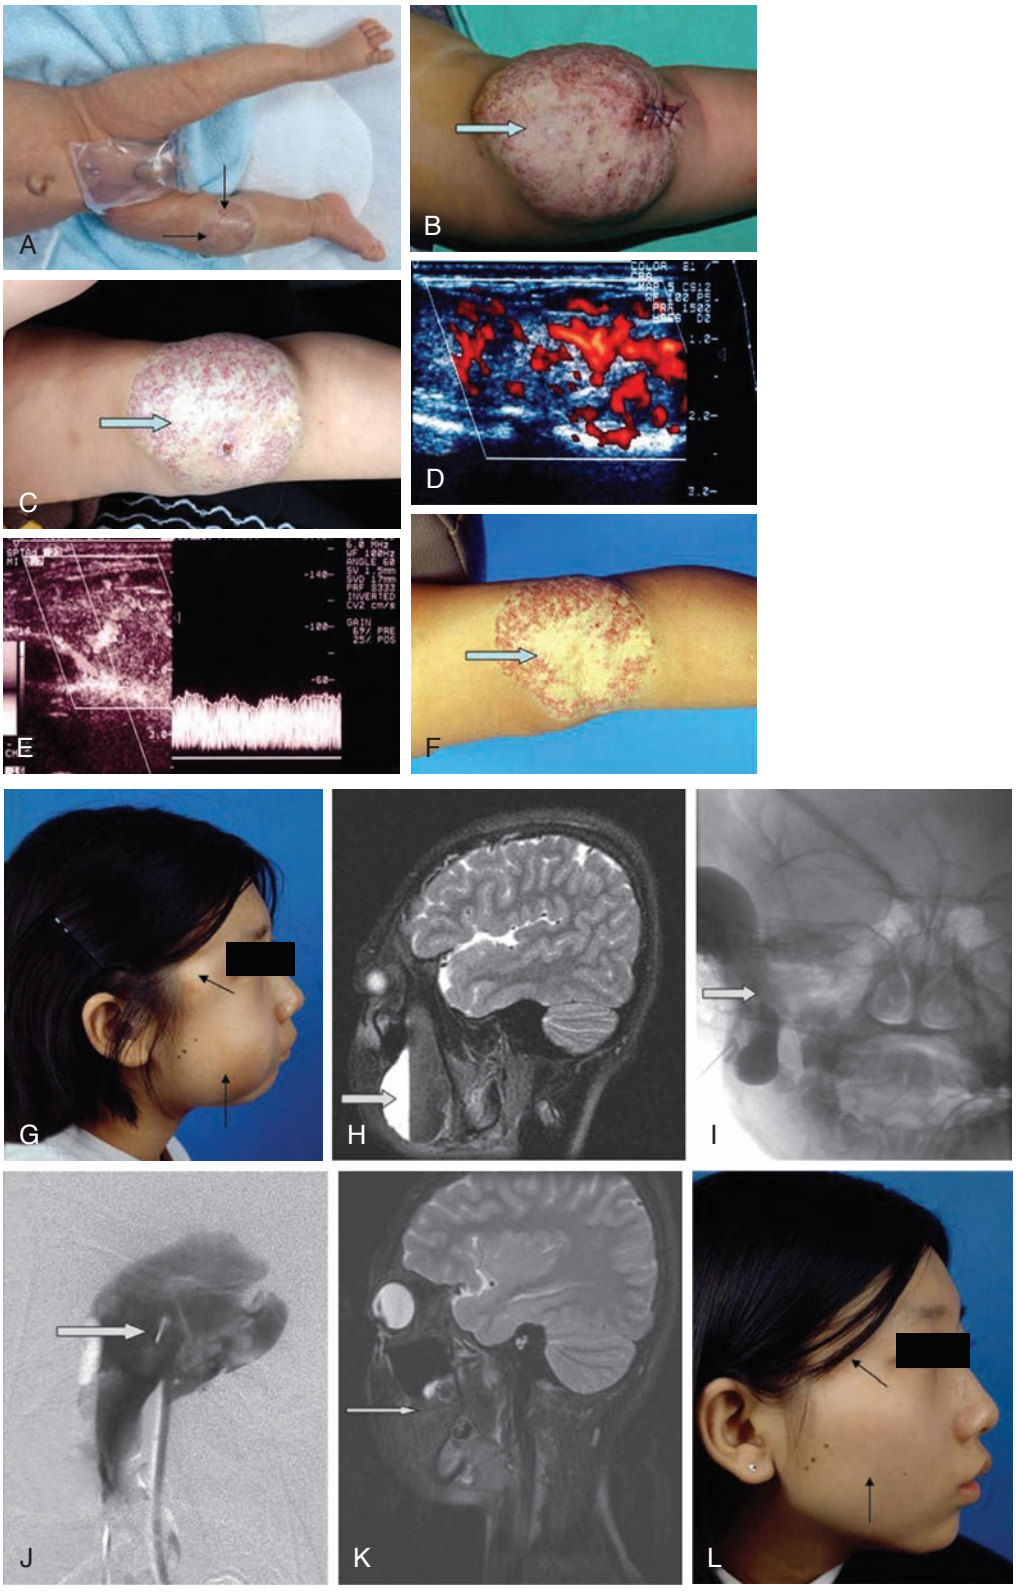

Figure 171.1 Hemangioma and Vascular Malformation. (A to F) Hemangioma. In this infant, a hemangioma appeared 1 month after birth in a normal-looking area of the right lower thigh (*arrows* in A). The swelling grew quickly, reaching its peak size within a year (*arrow* in B). This was followed by a significant reduction in size during the second year (*arrow* in C). Duplex ultrasonography during the proliferative stage shows typical vascular hyperactivity along the tumor, with distinctly large feeding arteries (D and E). The lesion regressed almost completely, leaving only an area of skin discoloration, before the child reached 4 years of age (*arrow* in F). (G to L) VM. This young girl was born with a swollen right cheek (*arrows* in G)—the site of a VM. The swelling was noticed at birth, but there was minimal change until menarche. Sagittal T2-weighted magnetic resonance imaging (MRI) depicts a large VM affecting the entire right cheek (*arrow* in H). Percutaneous direct-puncture angiography demonstrates a large cystic lesion (*arrow* in I). Percutaneous ethanol sclerotherapy resulted in complete control of the lesion (*arrow* in J), as shown by MRI (K) and a clinical photograph (L) taken at the 3-year follow-up visit.

Figure 171.2 Hemolymphatic Malformations. (A–I) Klippel-Trénaunay syndrome (KTS). In a patient with typical KTS of the left lower extremity, a port-wine stain covers most of the leg (*arrows* in A); there is limb swelling as well as leg-length discrepancy. Radionuclide lymphoscintigraphy demonstrates severe dermal backflow (*arrows* in B) due to primary lymphedema secondary to a truncular lymphatic malformation (LM). Percutaneous direct-puncture lymphangiography reveals a typical lace-pattern appearance (*arrows* in C) of an infiltrating extratruncular LM. Whole-body blood pool scintigraphy (WBBPS) shows abnormal blood pooling in the entire left lower extremity (*arrows* in D), suggesting an extratruncular venous malformation (VM) as the third component of the vascular malformation. Further evaluation with duplex ultrasonography (E) reveals a marginal vein as a truncular VM; this lateral embryonic vein is the fourth and last vascular malformation component of KTS. Transarterial lung perfusion scintigraphy (TLPS) results (F) rule out a hidden arteriovenous malformation (AVM). Coronal (G) and sagittal (H) T2-weighted MRI scans demonstrate soft tissue swelling typical of lymphedema (*arrows*). Ascending phlebography, performed to provide a roadmap for treatment, shows a marginal vein running along the lateral aspect of the left lower leg (*arrows* in I).

Continued

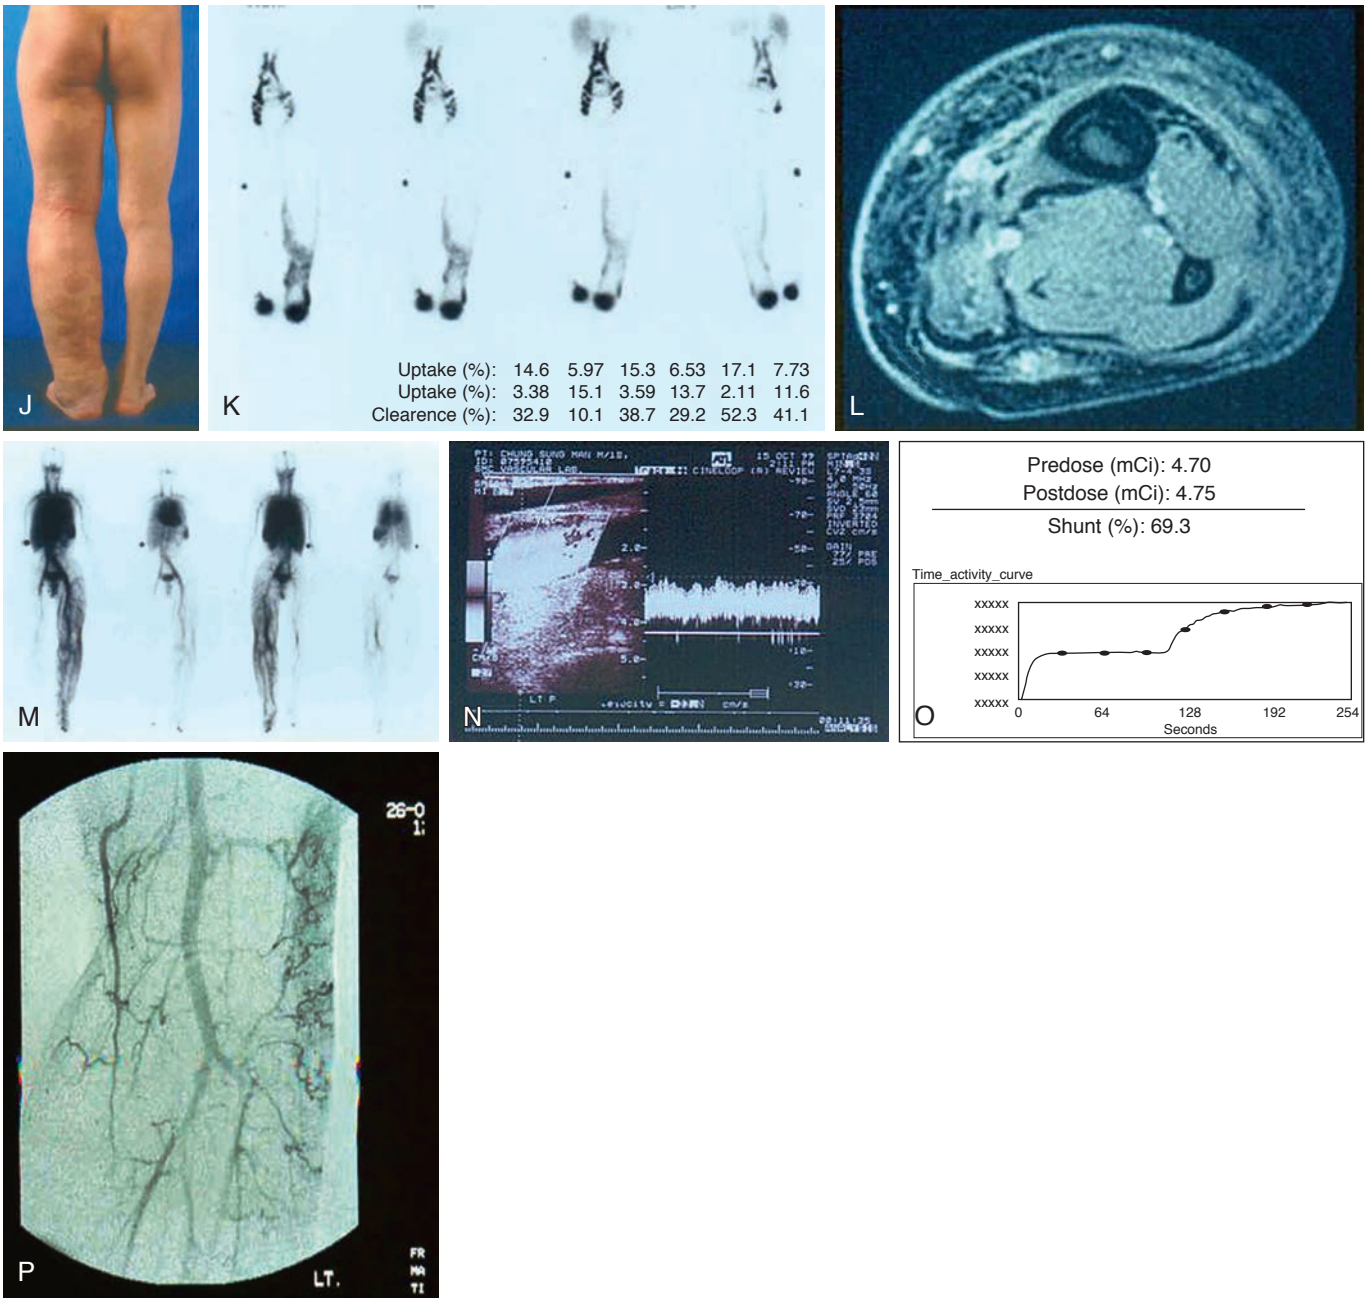

Figure 171.2, cont'd (J–P) Parkes Weber syndrome (PWS). The clinical features of PWS are localized to the left lower extremity (J), similar to the findings in KTS (see A). Radionuclide lymphoscintigraphy (K) and MRI (L) reveal primary lymphedema caused by a truncular LM. WBBPS (M) shows diffuse, abnormal blood pooling throughout the limb due to an extratruncular VM. Duplex ultrasonography (N) depicts a hyperdynamic arterial condition secondary to an AVM. TLPS (O) reveals the precise shunting percentage (69.3%) through the hidden AVM shunts. Arteriography (P) demonstrates multiple superficially located microshunting AVMs scattered throughout the lower extremity. The clinical diagnosis of PWS was confirmed (with LM, VM, AVM, and capillary malformation components).

INCIDENCE

Because of confusing nomenclature and definitions of CVMs in the past, epidemiologic data regarding CVMs are difficult to obtain.[36-38] In a comprehensive study of the incidence and geographic distribution of CVMs, Kennedy surveyed the world literature and published data based on 238 studies reporting more than 20 million births.[39] The overall incidence was 1.08%, ranging from 0.83% in data obtained from hospital records, birth certificates, and retrospective questionnaires to 4.5% in data from intensive examinations of children. In a large study sponsored by the World Health Organization, Stevenson and colleagues surveyed 426,932 live and stillborn births and reported an overall frequency of major and minor

malformations of 12.7% in single births and 4.6% in multiple births.[40] Tasnadi et al. reported an incidence of CVM of 1.2% among 3,573 3-year-old children studied. These included VM and/or AVM in 0.45%, CM (port-wine skin lesion) in 0.42%, LM/primary lymphedema in 0.14%, and mixed form CVM showing phlebectasia, nevus, and limb length discrepancy in 0.34%.[41]

CVMs have a male-to-female ratio of 1:1, and VMs are the most common type. Among VMs, the extratruncular type is the most frequent lesion and presents in either diffuse or localized forms.[37] Eifert et al. reported the prevalence of deep venous anomalies among 257 VMs; phlebectasia was the most frequent (36%), followed by aplasia or hypoplasia of the deep venous trunks (8%) and venous aneurysms (8%).[42] However, more than 70% of CVMs are mixed, and these complex forms can include arterial, capillary, venous, or lymphatic elements. When both extratruncular and truncular LMs are combined, their overall incidence is close to that of VM, if not higher.[37]

ETIOLOGY

A number of genetic and chromosomal abnormalities have been implicated in the development of CVMs. These have been associated with (1) exposure to damaging chemical compounds during the first trimester of pregnancy; (2) infections such as rubella, cytomegalic inclusion disease, herpesvirus, and toxoplasmosis; (3) thalidomide and other drugs such as aminopterin, cyclophosphamide, quinine, anticonvulsant drugs, cortisone, and corticotropin; and (4) alcohol, tobacco, and cocaine abuse. Maternal diseases and exposures including goiter, diabetes mellitus, thyroid disease, tuberculosis, hypoxia, and carbon monoxide and lead poisoning have also been identified as potential causes of CVMs.[39,40,43]

Although most CVMs are sporadic, autosomal dominant inheritance of mutated genes has been confirmed to cause some CVMs based on genetic studies of families.[37,38,44-49] These mutated genes encode for tyrosine kinase receptors and intracellular signaling molecules.[49] The endothelial-specific angiopoietin receptor TIE2/TEK, located on 9p21, was identified to cause familial mucocutaneous CVMs.[49] Further studies showed that somatic mutations in angiopoietin receptor gene TEK led to the loss of TIE2 receptor function.[50] This in turn upregulated expression of other vascular endothelial growth factors, such as βTGF and βFGF, resulting in the development of VMs.[51]

Vascular endothelial growth factor (VEGF) has been found to induce penetration of capillary vessels into the avascular epidermis.[52] A defective response of endothelial cells to VEGF as the consequence of abnormal signaling of VEGF receptors results in CVMs if the differentiation is abnormal and there is an arrest in the development of normal vascular tissue. The persistence of the embryonic vascular system also causes additional abnormal development.

Recently a high susceptibility loci within the HLA locus on chromosome 6p21.32 has been identified with development of truncular VMs. Due to deletion or duplication, the number of copy number variations is significantly associated with an increased chance to develop truncular VMs. The region contains 211 known genes.[53-57] In addition, the increased expression of matrix metalloproteinase-9 in intramuscular VM lesions suggests that VMs have the ability for angiogenesis to provoke invasive growth while expanding slowly due to the increase in hydrostatic pressure.[58] Progesterone receptors in VMs are also suspected to cause the progression of lesions when hormonal levels change.[59]

EMBRYOLOGY

When the embryo begins its exponential growth, an equivalent growth of the vascular system is required to deliver nutrition and oxygen necessary for the proper development of the fetus. If growth of vascular structures does not occur, there is a high risk for development of CVM.[60-63] The long complex process of angiogenesis increases the risk of developmental defects in comparison to other tissues from the same mesodermal origin, such as bone, muscle, and connective tissue. Embryonic blood vessels originate from the blood island of Pander, which represents the masses of vasoformative cells that undergo a complicated process of evolution.[33] Undifferentiated capillary plexus becomes the initial vasculature; subsequently, some capillaries undergo regression and coalescence with others to form a reticular structure. This reticular structure is efficient to meet the embryo's needs during the early, rapid-growth stage of embryogenesis. This extratruncular stage occurs before the final truncular stage, during which formation of the actual artery, vein, and lymphatic trunks occurs to complete the differentiation. The characteristics of the embryonic cells change drastically between the extratruncular and truncular stages.[2,7,9] The clinical behavior of the vascular defect depends on the stage at which arrested development occurs. Any defect occurring before the truncular stage maintains the embryonic characteristics of mesenchymal cells.

Extratruncular Lesions

Extratruncular CVMs represent arrested development during early embryonic life, while the vascular system is in the reticular stage.[33] These embryonic remnants of mesodermal origin retain the characteristics of mesenchymal cells (angioblasts) and have the potential to grow and proliferate when stimulated internally (e.g., by menarche, pregnancy, hormonal release) or externally (e.g., by trauma, surgery). Therefore all extratruncular lesions, regardless of type, carry a significant risk of recurrence after treatment and can grow rapidly.[64] By nature, an extratruncular lesion behaves like an infiltrating process, invading the surrounding structures. Because bones, muscles, soft tissues, and blood vessels all originate from the same mesoderm, there is no plane of partition between them. Therefore such a lesion, whether diffuse or circumscribed, produces a pressure effect on the surrounding tissues, in addition to the hemodynamic impact on the affected vascular system.

Truncular Lesions

Truncular CVMs arise when arrested development occurs later, during the vascular trunk formation stage of embryonic

development.[33] Truncular lesions have lost the embryonic characteristics of the mesenchymal cells, together with the potential to grow and proliferate. These lesions do not carry the same risk of recurrence as extratruncular lesions, but they are generally associated with more serious hemodynamic consequences.[65,66]

Based on pathology, truncular lesions are further divided into obstructive and dilated lesions.[1,7-9] All truncular lesions appear as formed vessels with various degrees of developmental defects, ranging from incomplete or immature lesions (aplasia or hypoplasia) to overdeveloped lesions (hyperplasia). A truncular VM may present as a persistent fetal vessel that does not involute normally (e.g., sciatic vein, marginal or embryonic vein) or as a defective vessel trunk (e.g., vein web, venous aneurysm/ectasia), resulting in stenosis, complete obstruction, or dilatation.[37,67,68]

PATHOPHYSIOLOGY

In terms of pathophysiologic significance, CVMs can be divided into two types: those with mechanical impacts on surrounding structures, producing compression and/or infiltration effects, and those with a hemodynamic impacts on the affected circulation. The relative significance of these variants depends on the type of CVM as well as its embryologic subtype.

Extratruncular Lesions

In general, all extratruncular lesions have both mechanical and hemodynamic impacts. The initial mechanical impact is generally of little significance; compression and infiltration become more significant as the lesion grows. With enlargement, a simple lesion can produce serious damage and become life-threatening, for example, by causing airway obstruction.

In general, the hemodynamic impact is usually far more serious than the mechanical impact.[69-71] High-flow CVMs (e.g., AVMs) have a greater hemodynamic impact than low-flow lesions (e.g., VMs), because the arteriovenous shunts do not have the resistance of the normal capillary system.[72,73]

Truncular Lesions

All truncular lesions, regardless of type, have mainly hemodynamic impacts, the significance of which depends on the type of CVM. For example, the impact of a truncular LM that manifests clinically as primary lymphedema remains limited to the lymphatic transportation system, seldom involving the accompanying venous system.[74-77] In contrast, a truncular VM affecting the lower extremity (e.g., femoral vein aplasia) can present with more serious hemodynamic impacts, resulting in chronic venous insufficiency.[78-81] When venous insufficiency is combined with lymphatic insufficiency in the case of a mixed CVM, the impact (e.g., phlebolymphedema) is even more serious.[82-85]

Among truncular VMs, a venous aneurysm situated between two segments of normal vein is a potential source of venous thrombosis and pulmonary embolism, especially when the deep system is involved. The most common symptoms are a painful mass and localized swelling. In some cases, a massive pulmonary embolism is the first symptom. The incidence of venous aneurysms is similar in men and women.[37] In our experience with 39 venous aneurysms in 30 patients, the majority were located in the deep system of the lower extremities, with 5 in the internal jugular vein and 4 in the superficial venous system.[86] Diagnosis was made by phlebography, color-flow duplex scanning, and/or magnetic resonance imaging (MRI). The size of the aneurysms ranged from 1.7 to 6 cm. Three patients had deep venous thrombosis, and three had pulmonary embolism.

In children, venous dilatation is most common in the internal jugular vein and is most noticeable during crying or other physical effort.

Truncular ("fistulous") AVMs, although rare, have the most powerful impact on the vascular system. The shunting of arterial blood to the venous system may result in a substantial degree of steal from distal arterial vessels, as well as extra-loading to the proximal and distal venous system.[87,88] These effects in turn may produce chronic venous hypertension distal to the lesion and high output cardiac failure.[38]

Secondary Organ Impact

CVM may also impact related tissues or organs. For example, an intraosseous CVM can stimulate the epiphyseal plate and induce abnormal long-bone growth, resulting in leg-length discrepancy.[89-91] Compensatory scoliosis with or without pelvic tilt can impact gait and/or the cardiopulmonary system. Other systems may also be affected.

CLINICAL PRESENTATION

The clinical presentations of all CVMs (both extratruncular and truncular) depend on the vascular system involved and whether the lesion is localized or diffuse. They may affect the arterial, venous, lymphatic, or capillary system as independent lesions or as mixed types (HLM). A complete examination is usually sufficient to establish a diagnosis, although imaging is sometimes required to determine lesion extent. In small children the diagnosis may be more difficult, as it may take some time for the lesion to become fully identifiable.[37,38,92-94]

Capillary Malformations

A CM appears as a port-wine stain on the skin with a distinctive color; it is different from the common vascular birthmark known as nevus flammeus neonatorum. Birthmarks are pinkish discolorations affecting the nuchal region ("stork bite") or the face along the eyelids, forehead, or lips ("angel's kiss"). In contrast, CMs can present anywhere on the body and can range from small localized lesions to extensive lesions covering the skin in multiple areas. CMs are often accompanied by other abnormal physical findings beneath the skin, heralding other CVMs. For example, a CM in the face is a warning sign for an intracranial CVM known as Sturge-Weber syndrome, with ipsilateral ocular and leptomeningeal vascular malformations.[95-98]

Venous Malformations

VMs present at birth as soft bluish swellings located near the skin surface, although some are not initially distinctive.[21,22] They are easily compressible and enlarge when the affected area is dependent or with a Valsalva maneuver. VMs in the extremity are easily collapsed when the leg is elevated to allow venous drainage. They usually present as slowly growing solitary lesions, but there may be multiple lesions, either localized or extensively infiltrative. VMs are associated with various degrees of pain and stiffness, especially in the morning but are generally not tender. The symptoms respond to compression therapy. However, when the lesions involve underlying muscle, bone, abdominal viscera, or the central nervous system, they may be complicated by secondary symptoms.[37,81]

VMs in the head and neck region are usually unilateral, with a mass effect that causes significant distortion of the features and facial asymmetry. VMs involving the tongue, palate, and oropharynx often result in significant deformity, including dental malocclusion, and represent a potential life-threatening condition if they encroach on the upper airway together with laryngopharyngeal lesions. VMs affecting the limb are often associated with leg-length discrepancy caused by long-bone growth disturbance when they extend into muscle and bone, resulting in compensatory pelvic tilt and scoliosis. Others can cause pathologic fractures, hemarthrosis, ankyloses, or degenerative arthritis. VMs can occur anywhere in the gastrointestinal (GI) tract, affect any or all layers of the bowel wall, and cause chronic bleeding.

Thrombosis and pulmonary embolism, sometimes fatal, can occur because of the presence of phlebectasias or aneurysms.[37,99]

Lymphatic Malformations

LMs present in the extremity as diffuse (primary lymphedema) or localized swelling (lymphangioma).[25,26] The swelling with lymphangioma ranges from a well-localized sponge-like condition to a diffuse infiltrating condition affecting large areas and having a varying consistency, depending on whether the lesion's components are macrocystic or microcystic. LMs are generally asymptomatic and neither tender nor painful until complications such as lymph leak or bleeding occur. However, LMs affecting the oral mucosa and tongue are often accompanied by pain, swelling, or bleeding, with mucosal vesicles.

Proptosis, amblyopia, strabismus, or even loss of vision can manifest with a periorbital LM. Difficulty chewing, talking, and breathing can occur because of overgrowth of the mandible, maxilla, or tongue as a result of an LM affecting the face or cervical region. Skeletal overgrowth or pathologic fracture of a long bone can also be caused by an LM affecting bone metabolism (e.g., Gorham syndrome).[100-102]

Arteriovenous Malformations

Small AVMs present at birth often remain obscure until they progress and become local swellings accompanied by symptoms and signs of arteriovenous shunting, including local hyperthermia, a thrill, bruit, and/or visibly dilated veins.[23,24] Ischemic changes and ulceration of the skin can develop distal to the shunt, often with intractable pain and intermittent bleeding. Distal gangrene is likely if the arterial insufficiency is severe, and high-output cardiac failure is unavoidable if a large AVM is not treated.[38,73]

Combined Vascular Malformations (Hemolymphatic Malformations)

Both the primary lesion and the secondary effects of HLM, including KTS[103-106] and PWS[107-109], are a mixture of each type of CVM involved (e.g., CM, LM, VM, and/or AVM).[27,37,110,111] Overgrowth of affected soft and skeletal tissue as a secondary phenomenon induced by the CVM is more distinctive; the port-wine stain's characteristic pattern over the lateral side of the involved extremity often extends to the buttock or thorax. Underlying LMs infrequently accompany various skin conditions and consist of vesicles, which often become symptomatic with leakage or infection.

Limb swelling caused by an HLM represents phlebolymphedema, a mixed condition with varying degrees of lymphatic and venous insufficiency.[83-85] Chronic lymphatic insufficiency usually manifests as primary lymphedema, while chronic venous insufficiency relates to insufficiency of the marginal vein (MV). The MV is an embryonic tissue remnant which fails to involute and is often visible or palpable as a large dilated vein along the lateral aspect of the lower extremity (see Fig. 171.2I). Its distal portion may be associated with sequelae of chronic venous insufficiency (stasis dermatitis, ulcer), secondary to venous reflux resulting from a lack of venous valves, known as avalvulosis.[37,112] Therefore all venous disorders, including varicose veins, thrombophlebitis, and pulmonary embolism, are major clinical signs of a VM involved with an HLM. In addition, the existence of the MV often heralds coexisting deep venous anomalies and warrants proper investigation.

Soft tissue and skeletal hypertrophy or hypotrophy ("vascular bone syndrome") are secondary effects of the primary lesion in the affected limb. They are often obvious at birth and can be progressive. HLMs affecting the extremity carry a higher risk of involvement of other intraperitoneal, retroperitoneal, intrathoracic, and mediastinal organs. Depending on the CVM, the clinical findings may include cardiopulmonary, musculoskeletal, GI, genitourinary, or gynecologic symptoms. Infrequently, the lesion presents with a distinctive condition such as hematuria, hematochezia, chyluria, chylorrhea, chylothorax, or pleural effusion. Occasionally, it presents with vague symptoms such as constipation, malabsorption syndrome, bladder outlet obstruction, or recurrent infection.

DIAGNOSIS

General Principles

The majority of CVMs can be detected in early childhood based on a heightened clinical suspicion when a child presents with abnormal swelling and disfigurement. A careful history and physical examination often provide enough clues to make a

BOX 171.2 Diagnostic Tests for Congenital Vascular Malformations

Noninvasive to Minimally Invasive Studies

- Duplex ultrasonography
- Magnetic resonance imaging—T2-weighted study
- Radioisotope lymphoscintigraphy
- Computed tomography with contrast and three-dimensional reconstruction
- Bone scanogram
- Whole-body blood pool scintigraphy (transvenous angioscan using radioisotope-tagged red blood cells)
- Transarterial lung perfusion scintigraphy (transarterial angioscan using radioisotope-tagged microsphere albumin)
- Air plethysmography
- Magnetic resonance venography or arteriography
- Magnetic resonance lymphangiography
- Indocyanine green lymphangiography
- Ultrasound lymphangiography

Selective Invasive Studies

- Standard, selective, or superselective arteriography
- Ascending, descending, or segmental phlebography
- Percutaneous direct-puncture angiography: arteriography, phlebography, or lymphography
- Contrast (classic) lymphangiography

presumptive clinical diagnosis. By nature, a CVM may appear anywhere in the body, either as a predominant lesion or as a mixed anomaly. To further confuse the clinician, these lesions may change due to internal or external stimulations. One CVM might suggest other hidden lesions scattered throughout the body, so any evaluation should include a full-body investigation.[113,94,114]

The initial diagnostic workup should start by ruling out infantile hemangioma and then identifying the type and subtype of CVM.[113] Following the history and physical examination, the appropriate combination of noninvasive or minimally invasive tests should be performed (Box 171.2). This often results in a diagnosis. Invasive tests can generally be deferred to a later time if the diagnosis needs refinement, if surgical or other invasive therapeutic measures are being considered, or if the symptoms merit further investigation.

Because AVMs are potentially limb- or life-threatening, their evaluation is different; a full assessment of their status is recommended as early as possible, regardless of the patient's age.[115,116]

Children younger than 2 years should have only those procedures necessary for diagnosis. However, when the child has a condition that warrants earlier intervention (abnormal long-bone growth with leg-length discrepancy), the lesion is located in a limb- or life-threatening area, or it compromises vital functions, invasive tests should be included to start early treatment.[113,117]

Physical Examination

Inspection and palpation of all skin surfaces, including the genitalia, should be performed in a well-lit environment. Although the majority of VMs and LMs present as single lesions, a physical evaluation for both conditions should be made to assess their relative significance. Auscultation (for bruit) and palpation (for thrills and pulse character) are helpful to assess the presence and extent of an AVM.

The examination should be done with the patient in the standing and supine positions, and posture and gait should be evaluated to assess the dynamic impact of the lesion. Involvement of the skin, soft tissue, and bone should be assessed so that positive findings will not be missed.[91] The limb elevation test should be performed in all extremity CVMs. With this test, VMs may demonstrate dramatic emptying of the venous lakes or veins during leg elevation.[113] In VMs, the findings of acute and chronic complications and their sequelae should be investigated.

The evaluation of an AVM should include not only its hemodynamic impact on the distal and proximal arterial and venous systems, but also its effects on the central cardiovascular system, in addition to involvement of the lymphatic system.[35,64]

Imaging

The imaging evaluation aims to identify the type and subtype (extratruncular or truncular) of CVM and to confirm or rule out the presence of other CVMs. In most cases, the diagnosis of CVM can be made with noninvasive or minimally invasive studies.[113] These studies distinguish CVM from infantile hemangioma. Invasive studies are reserved for therapeutic planning or for the diagnosis of aggressive AVMs.

Minimally Invasive Studies

Imaging for CVM assessment includes magnetic resonance imaging (MRI),[118,119] duplex ultrasonography,[37,81,92,120] and preferably whole-body blood pool scintigraphy (WBBPS) if feasible.[121] If LM is suspected, radioisotope lymphoscintigraphy is added.[122,123] For an AVM, contrast computed tomography with three-dimensional (3D) reconstruction is essential.[124] T2-weighted MRI is the "gold standard" for VMs, and when used together with duplex ultrasonography, most other CVMs can be distinguished. WBBPS (a transvenous angioscan using radioisotope-tagged red blood cells) can detect small amounts of abnormal blood pooling throughout the body, and is valuable not only to confirm the presence of a VM but also to exclude an LM. This test is also used in the follow-up of multisession treatments (Fig. 171.3).

Transarterial lung perfusion scintigraphy (TLPS) is a transarterial angioscan with radioisotope-tagged microsphere albumin. It measures the percentage of blood volume shunted by AVMs located in the extremities. TLPS is valuable in detecting microshunting AVMs common in PWS, as is conventional arteriography (Fig. 171.4).

Ultrasonographic lymphangiography, magnetic resonance lymphangiography, and indocyanine green lymphangiography may be useful in candidates for lymphovenous reconstruction.[113,37,92,125-130]

Invasive Studies

The role of invasive studies in CVM evaluation is limited because the majority can be diagnosed by noninvasive tests. Nonetheless,

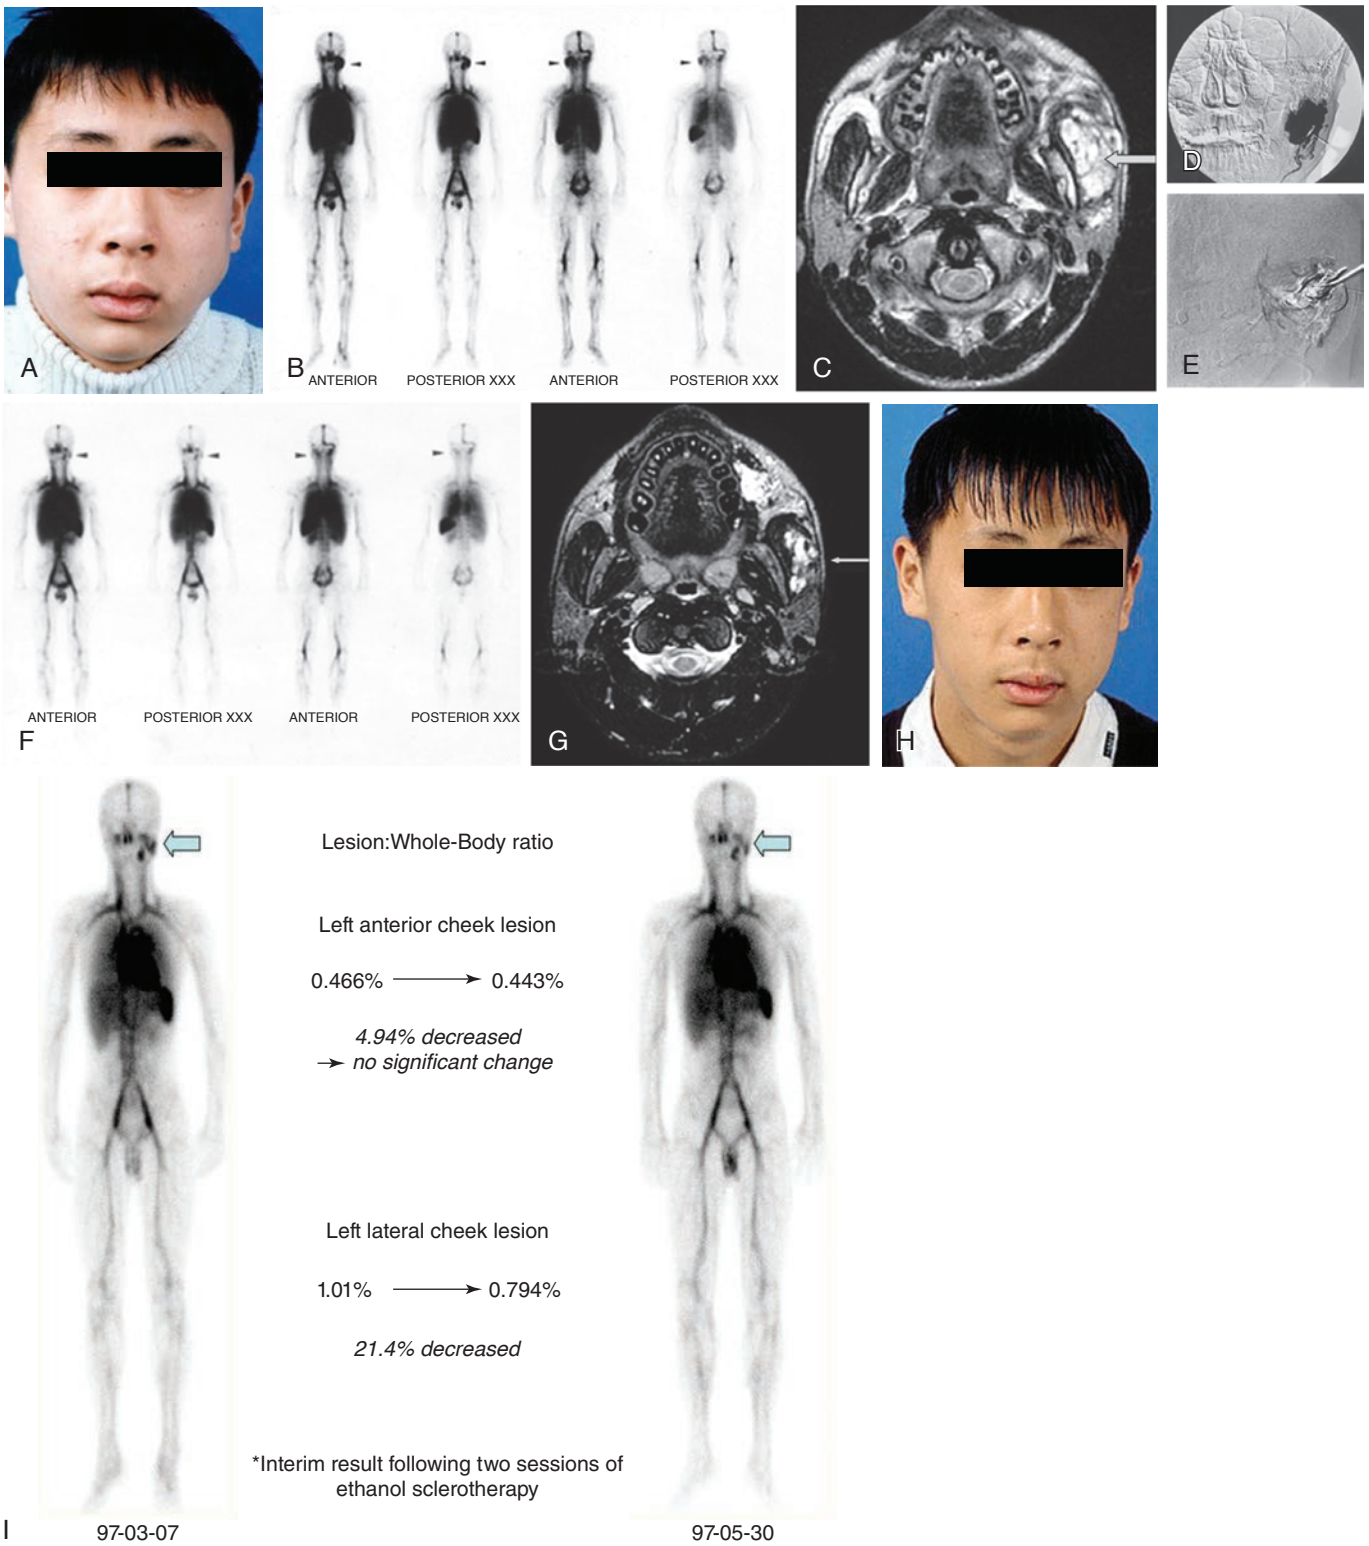

Figure 171.3 Role of Whole-Body Blood Pool Scintigraphy (WBBPS). (A–I) Qualitative and quantitative analysis of a venous malformation (VM). Photograph (A) demonstrates a VM affecting the left cheek and presenting as diffuse swelling. WBBPS (B) delineates abnormal blood pooling along the left cheek (*arrows*). T2-weighted MRI (C) reveals a large VM (*arrow*), compatible with other test findings. Based on the findings of percutaneous direct-puncture angiography (D), ethanol sclerotherapy (E) was carried out successfully. Both WBBPS (F) and MRI (G) findings demonstrate an excellent response (*arrows*) at interim follow-up. The swelling along the left cheek has completely disappeared (H). The quantitative measurement of the efficacy of therapy (I) is compatible with the qualitative findings (F).

Continued

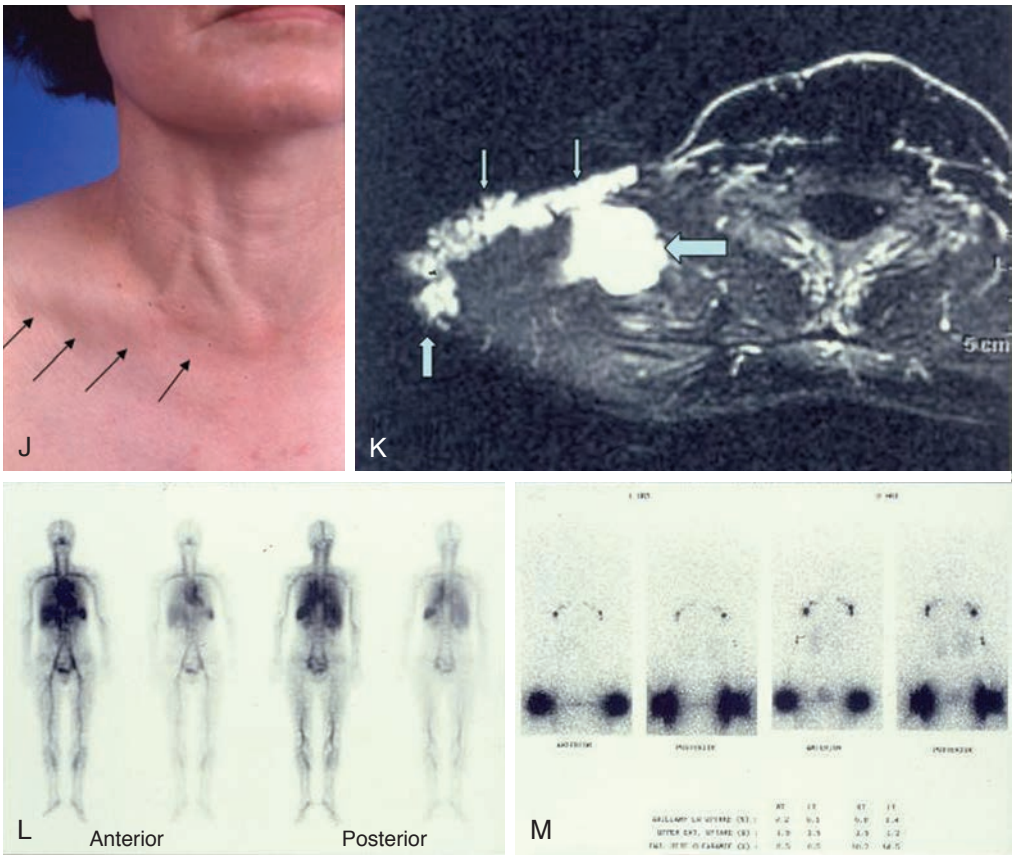

Figure 171.3, cont'd (J–M) Differential diagnosis of VM and lymphatic malformation (LM). Photograph depicts diffuse swelling over the right clavicular region (*arrows* in J), with vague but steady pain extending to the root of the neck and to the right shoulder. Clinically, this was considered a VM, based on an increase in size during the Valsalva maneuver. T2-weighted MRI shows findings typical of a VM (*arrows* in K). However, there was a strong clinical suspicion of an LM owing to its location in the common site of infiltrating, extratruncular LMs. WBBPS (L) does not show pooling in these areas, ruling out a VM. Radionuclide lymphoscintigraphy findings (M) illustrate a completely normal lymph transporting system.

they remain the gold standard, particularly for AVMs.[113] Selective arteriography is mandatory for the diagnosis of AVMs and as a roadmap for treatment. In the case of VMs, ascending, descending, or segmental phlebography serves as a guide for diagnosis and treatment. In patients with LMs, percutaneous lymphangiography is infrequently needed but occasionally performed to evaluate the extent of an extratruncular lesion.[28,122] In general, traditional lymphangiography is no longer used owing to its potential to damage lymphatic vessels secondary to inflammation produced by oil-based contrast, unless indicated specifically for reconstructive surgery.

Evaluation of Affected Systems

Leg-length discrepancy secondary to abnormal long-bone growth should be evaluated by bone scan, as described in the section entitled Congenital Vascular Bone Syndrome. Coagulation studies are not routinely included in the evaluation of CVMs, but may be required in cases of extensive extratruncular VMs and large marginal veins, especially when venous thrombosis is suspected. The use of coagulation studies is discussed more fully in the section entitled Coagulopathy: Thrombosis and Fibrinolysis.[17,37,99]

Differentiating Congenital Vascular Malformations From Infantile or Neonatal Hemangioma

Even though the overall incidence of CVM is much lower than that of hemangioma,[5,41,131] differentiating CVM from hemangioma should be the first step in the diagnosis of CVMs.[132,133] Hemangiomas are usually not present at birth, appear suddenly during the neonatal period as rapidly growing tumors, and ultimately involute. Hemangiomas are more common in females (3–5 : 1 female:male ratio). In contrast, a CVM is always present at birth, although it may not be apparent. Gender distribution is equal, and it grows commensurate with body growth. In most cases a history and physical examination will distinguish a CVM from a hemangioma; the distinction is confirmed by noninvasive studies. Tissue biopsy is rarely needed.

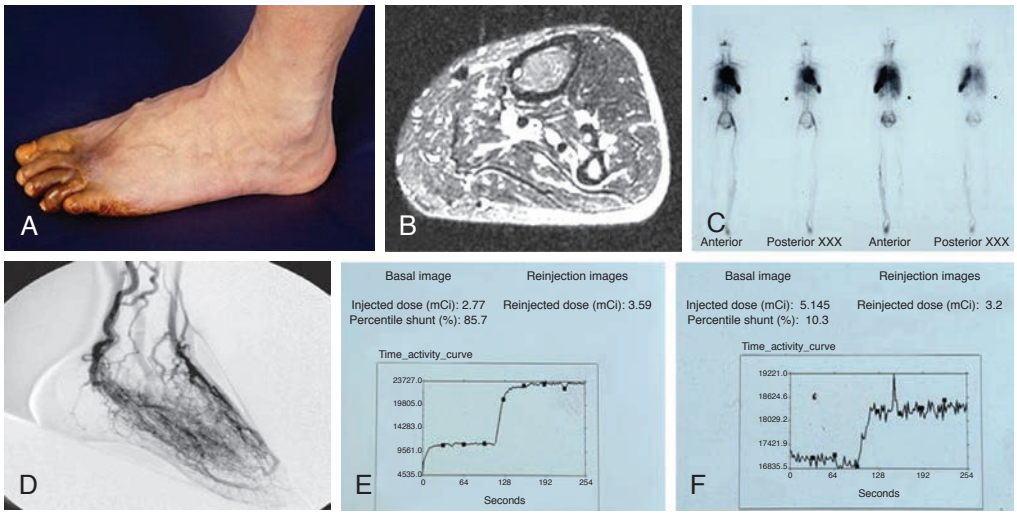

Figure 171.4 Role of Transarterial Lung Perfusion Scintigraphy (TLPS). (A) Ischemic left foot with impending necrosis of two toes. The local condition deteriorated rapidly after arteriovenous malformations (AVMs) affecting the pedal arterial arch were treated with coil embolization of the feeding artery. (B) MRI findings in the lower leg are compatible with an AVM affecting the foot only. (C) Whole-body blood pool scintigraphy shows the hyperdynamic status of the arterial system originating from the AVM in the foot. (D) Arteriography reveals massive shunting through the AVM. (E) Before treatment, the shunting percentage of blood measured with TLPS is 85.7%. (F) After multisession ethanol sclerotherapy, the shunting is effectively reduced to 10.3% on repeat TLPS. TLPS is a reliable test not only to assess the severity of AVMs, but also to follow the response to therapy. It is also useful to find hidden micro-AVMs, often exceeding the reliability of arteriography.

TREATMENT

General Principles

During the last century, limited knowledge about the natural history and biologic behavior of CVMs often contributed to poor outcomes following an overaggressive surgical approach—in particular surgery performed on extensive, unresectable lesions.[134,135] As a result of these poor outcomes, for many years surgery was limited to situations in which it was the only option (bleeding control, significant hemodynamic compromise, severe disturbances in bone growth, and disfiguring lesions). Eventually, new concepts and classification systems provided a better understanding of CVMs, and recognition of the fundamental differences between extratruncular and truncular lesions led to better management principles.

Extratruncular lesions grow and will recur unless the lesion nidus is completely destroyed. They should thus be treated aggressively. In contrast, truncular CVMs lack the potential for proliferation, and the same aggressive approach is not justified. Some can be handled conservatively until they become hemodynamically significant. Intervention should be performed only for symptoms and in situations such as thromboembolism, chronic venous insufficiency, and ulceration.[37,78,81,112] For best results, a multidisciplinary team of experts should review every CVM, and the treatment plan should be derived by team consensus following an appropriate diagnostic workup[115] (Boxes 171.3 and 171.4).[37,38,117]

The lateral embryonic or marginal vein deserves special attention.[90,91,136] Its treatment is discussed in the section entitled Klippel-Trenaunay Syndrome.

BOX 171.3 Indications for Treatment of Extratruncular Congenital Vascular Malformations

- Hemorrhage
- High-output heart failure (arteriovenous shunting malformation)
- Secondary ischemic complications (arteriovenous shunting malformation)
- Secondary complications of chronic venous hypertension (venous malformation)
- Lesions located in life-threatening (e.g., proximity to airway) or vital function–threatening (e.g., seeing, eating, hearing) region
- Disabling pain
- Functional impairment
- Cosmetically severe deformity
- Vascular-bone syndrome
- Lesions located in a region with a potentially high risk of complications (e.g., hemarthrosis, deep venous thrombosis, pulmonary embolism)
- Lymph leak with or without infection
- Recurrent sepsis (local or general)

Arteriovenous and Venous Malformations

All AVMs should be considered potentially life- or limb-threatening lesions necessitating an early, aggressive approach (Fig. 171.5).[23,24] A "controlled" approach minimizing damage to adjacent areas is preferable, but in certain situations, limb sacrifice may be necessary.[37,38]

VMs are less dangerous and may not require treatment.[31,81,137,117,37] When the risk-benefit ratio favors treatment, as in those which threaten vital functions or produce vascular bone syndrome, less aggressive options (e.g., foam/liquid

sclerotherapy) should be performed.[66,16] In pediatric patients, VM without bone involvement can usually be monitored until the child reaches age 6 years or is mature enough to tolerate diagnostic and treatment procedures.[113,117]

Order of Treatment

The treatment strategy should focus on the hemodynamic derangements associated with the primary malformation first, followed by treatment of secondary disorders. This can involve either reconstructive or ablative/excisional surgery. Corrective surgery for the sequelae of secondary hemodynamic consequences may follow. When severe CVMs result in a nonfunctional limb, early amputation should be considered.[37,38]

BOX 171.4 Components of a Multidisciplinary Team for the Management of Congenital Vascular Malformations

- Vascular surgery
- Pediatric surgery
- Plastic and reconstructive surgery
- Orthopedic surgery
- Anesthesiology
- Pathology
- Physical medicine and rehabilitation
- Otolaryngology
- Head and neck surgery
- Cardiovascular medicine
- Psychiatry
- General medicine
- Interventional radiology
- Diagnostic radiology
- Nuclear medicine
- Dermatology

Nonsurgical/Endovascular Therapy

Endovascular therapy, primarily embolization and sclerotherapy, is now accepted as the treatment of choice for surgically *inaccessible* extratruncular lesions, such as the diffuse, infiltrating type beyond the deep fascia with involvement of muscle, tendon, and bone.[37,38,117] In cases where surgery is anticipated, adjunctive endovascular therapy can be performed pre- and postoperatively to improve the safety and effectiveness of surgery.[117,138]

Sclerotherapy and Embolotherapy

Liquid sclerosants are now used as the major therapeutic tool for the treatment of CVMs. Frequently used sclerosants include ethanol, polidocanol, and sodium tetradecyl sulfate. Embolotherapy agents include coils, glue, and particles. *N*-Butyl cyanoacrylate (NBCA) and Onyx are useful as preoperative therapy to reduce morbidity prior to the surgical excision of AVM or VM.[139,140] Specific indications and techniques for the use of these agents can be found in Chapter 173.

Surgical Therapy

Excision is the only option for complete removal of a CVM, but generally requires extensive surgery with high morbidity.

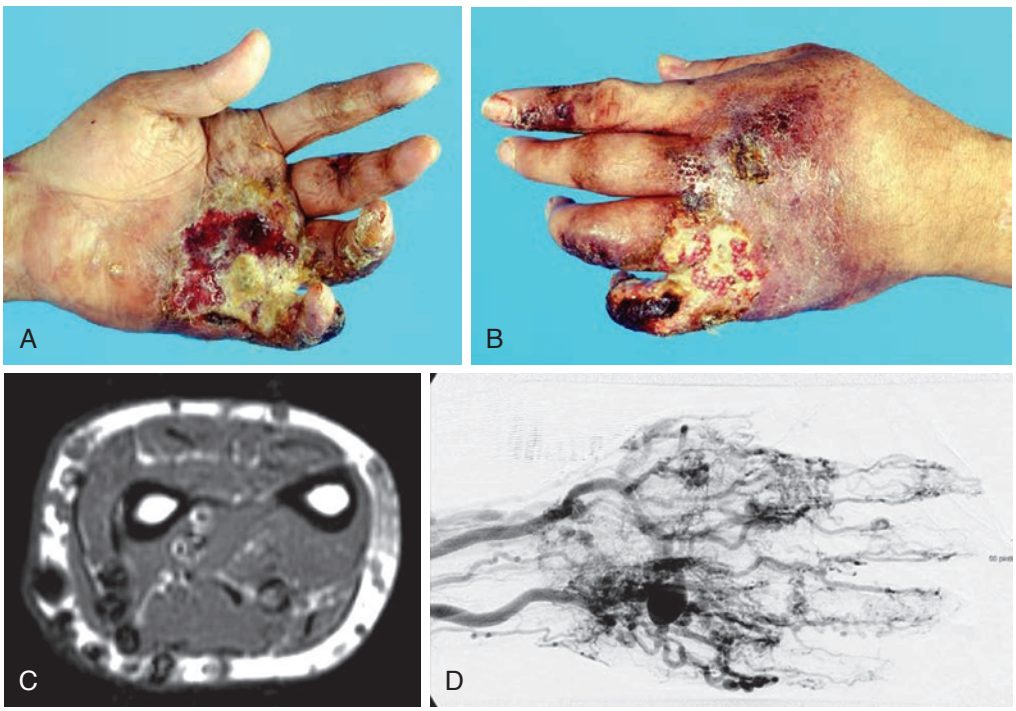

Figure 171.5 Natural Course of Arteriovenous Malformation (AVM), With Impending Limb Loss. (A and B) Ultimate outcome of a neglected AVM affecting the left hand and fingers. Stealing of arterial blood from the distal arterial trees by the AVM eventually leads to chronic arterial insufficiency and subsequent ischemia and gangrene. The hand and fingers are now in jeopardy, with great risk of major tissue loss. MRI (C) and arteriography (D) show evidence of massive shunting, making treatment more difficult.

Incomplete resection can result in recurrence. Therefore ideal candidates for surgical excision are limited to those with localized lesions.[37] Truncular VM lesions with involvement of the iliac veins or IVC can be managed surgically—for example, using segmental resection of the involved vein combined with various reconstruction techniques.[141-144] Venous aneurysms of veins such as the popliteal or femoral vein can be managed with resection and bypass/transposition using a new vein segment, or partial tangential resection and aneurysmorrhaphy. Valve function restoration is also technically feasible with vein valve transplant or transposition.[145-147] Indications and techniques for specific procedures can be found in Chapter 172.

SPECIFIC VASCULAR MALFORMATIONS AND CONDITIONS

Congenital Vascular Bone Syndrome: Angio-Osteodystrophy

CVBS is a group of syndromes associated with abnormal long bone growth caused by CVMs in childhood. Abnormal circulation around and/or inside the bone from CVMs results in angio-osteo-hypertrophy or angio-osteo hypotrophy.[89,91] Limb overgrowth is always due to hypervascularization, either by macroshunts or by microshunts.[148-150] Among VM, the presence of a marginal vein (MV) is known to cause angio-osteo-hypertrophy. Undergrowth with bone shortening may be induced by bone compression from abnormal vascular masses or reduction of arterial inflow from arterial hypoplasia. Tissue and bone growth factors may also be involved.[151] In one study of patients with VMs, the incidence of long-bone lengthening by CVBS was 19% and shortening was 7%. Among patients with AVMs, lengthening occurred in 49% and shortening in 4%.[89]

The diagnosis of limb length difference can be confirmed by plain x-rays and bone scans. Duplex ultrasonography together with MR or CT will confirm the intraosseous localization of the CVM.[152] Evaluation should be performed expeditiously so that treatment can be undertaken before the epiphyseal plate is closed between ages 16 and 18.[37,80] Alternatively, removal of the CVM in early childhood may retard bone growth and correct limb length discrepancy. In some cases, orthopedic procedures may also be required.[89-91,148,149]

Klippel-Trénaunay Syndrome

The typical patient with KTS has the following clinical features: (1) port-wine stain that may be localized to a relatively small area or involve the lateral aspect of one or more extremities; (2) limb hypertrophy or gigantism, manifested by an extremity that is longer and larger in circumference than the healthy extremity; (3) presence of large clusters of varicose veins extending throughout the entire extremity; and (4) a large lateral venous collector called the vena marginalis lateralis/marginal vein (MV), which usually drains into the pelvic veins. All patients with KTS have three CVM components, including VM, LM, and CM.[84,92,103-106]

The large majority of KTS patients can be managed with conservative measures such as compression (gradient elastic stockings with 35 to 45 mm pressure) and sclerotherapy. However, some patients have pain from large venous varicosities, as well as ulceration, thrombosis, and pulmonary embolism. In these cases, excision of large varicose clusters will relieve symptoms. Prior to excision, imaging should be performed to ensure that the deep system is present, as 8% of patients with KTS have either atresia or hypoplasia of this system. We recommend surgery in two or three stages, and the use of a tourniquet to eliminate or decrease bleeding. Beginning 2 months after surgery, sclerotherapy using either liquid or foam should be used to eliminate residual varicosities.[37,112]

A large marginal vein should be excised in its entirety when the deep system is patent, using segmental resection through several incisions. Large perforators, often 8 to 10 mm in diameter, connecting to the deep system, should be ligated to prevent profuse bleeding.[103-106]

Because patients with KTS may also have venous aneurysms or enlarged phlebectatic veins in the deep venous systems, imaging such as CTV and MRI should be performed to identify these and treat the sequelae as indicated.[92]

Growth discrepancies in the extremities can lead to disabling skeletal sequelae in early adolescence. For this reason, children with KTS should have orthopedic evaluations and the proper measures taken to prevent scoliosis.

In some patients, lymphangioma cause significant problems, including swelling leading to deformity, repeated episodes of lymphangitis, lymph leakage through the perineum, lymphatic blisters, and cosmetic concerns.

Parkes Weber Syndrome

PWS is a condition first described in 1907 with clinical features similar to those of KTS. As initially described, the syndrome consisted of varicose veins, limb hypertrophy, and port-wine stain, but with a clearly detectable pulsation and thrill. The difference between PWS and KTS is based mainly on the presence of AVM in PWS, and therefore a different clinical course with different prognosis.[107-109] However, using radioactive isotopes (transarterial lung perfusion scan), some investigators have detected arteriovenous (AV) shunting among the patients previously diagnosed as KTS, blurring the difference between the two syndromes. The presence of significant AV shunting in a symptomatic patient with PWS warrants treatment by embolization.[37,92]

Coagulopathy: Thrombosis and Fibrinolysis

Extratruncular VM are associated with coagulopathy because of stasis of blood within the abnormal structures, which leads to the activation of the coagulation cascade.[153,154] This condition is known as localized intravascular coagulopathy (LIC). It is followed by fibrinolysis, which is reflected in elevated levels of fibrin degradation products such as plasmin derived D-dimer

epitopes.[155,156] Microthrombi in LIC form stonelike structures called "phleboliths," which can be detected by palpation when the VM is located superficially or visualized on plain x-rays when located in deep VM.[155,157]

LIC can result in thromboembolic events, including deep vein thrombosis (DVT), pulmonary embolism (PE), and subsequent chronic pulmonary hypertension. Furthermore, this relatively benign local condition can progress to disseminated intravascular coagulation (DIC) with life-threatening hemorrhage and multiorgan system failure. Events known to trigger the conversion of the LIC to DIC include sclerotherapy, surgical resection, bone fracture, prolonged immobilization, and pregnancy or menstruation.[157-161] The presence of phleboliths may therefore represent an indication for anticoagulation, especially when the accompanying lesion is large and extensive.[162,163]

All patients with VMs should undergo testing for hypercoagulable state as part of their routine diagnostic evaluation. Large and/or multifocal VMs with significant elevations of D-dimer levels are strongly suggestive of coagulation disorders. Extensive VMs affecting an extremity with low fibrinogen levels are suggestive of an increased risk for bleeding, particularly if surgery or sclerotherapy is anticipated. We recommend management with low molecular weight heparin (LMWH).[164,165]

LONG-TERM FOLLOW-UP ASSESSMENT

The clinical behavior of every vascular malformation depends on the stage of embryogenesis at which developmental arrest occurs. Therefore as mentioned previously, the entire extratruncular lesion is destined to grow whenever there is adequate stimulation. All CVMs affecting the extremity should be closely observed during the child's growth until the epiphyseal plate has closed. Female patients have much higher risks of deterioration or revival of the lesion, owing to menarche, pregnancy, or hormonal therapy.[89] A dormant lesion (e.g., microshunting AVM) may become clinically active, changing its clinical characteristics in this setting. Trauma or surgery can also trigger activity in a previously quiet lesion, stimulating it to grow rapidly. Hence lifetime follow-up at regular intervals is necessary in all treated or untreated lesions, especially after pregnancy. Periodic follow-up evaluation, including radiographic studies and various noninvasive studies, is essential for proper long-term care.[37,38]

INTRODUCTION

The proper diagnosis and treatment of vascular anomalies has long been impeded by misused terminology. Advances in our understanding of these disorders led to the creation of a biological classification system, formally adopted by the International Society of the Study of Vascular Anomalies in 1996 and updated in 2014.[1-4] This classification scheme divides these anomalies into vascular tumors and vascular malformations based on physical characteristics, natural history, and cellular features. Vascular tumors are true neoplasms that arise from cellular hyperplasia, while vascular malformations are congenital lesions originating from errors of embryonic development of blood vessels. Vascular tumors include infantile hemangioma, kaposiform hemangioendothelioma, and tufted angioma. Vascular malformations can be further subdivided based on vascular channel type (capillary, lymphatic, venous, arterial, or combinations thereof) or by flow (slow vs. fast). Slow flow lesions include capillary malformations (CM), lymphatic malformations (LM), and venous malformations (VM). Examples of fast flow lesions include arteriovenous fistulas (AVF) and arteriovenous malformations (AVM). Combined malformations (such as Klippel-Trenaunay and CLOVES [congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal abnormalities] syndromes) consist of two or more types of vascular malformations and can be associated with other anomalies.[1,4]

Correct identification of the type of anomaly present in a vascular malformation is paramount to appropriate treatment selection. Consequently, lesions must be properly imaged prior to procedural planning. Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) are the most common modalities used to determine the extent of the malformation. Angiography can also be useful for delineation of AVM, demonstrating the nidus and its feeding vessels, along with flow characteristics.[5,6] For those with lymphatic anomalies, lymphoscintigraphy may be useful for demonstration of lymphedema, while digital subtraction lymphangiography and magnetic resonance lymphangiography can best delineate the alternate anatomy and dysfunction of the central conducting lymphatics.[7-9] Additional information regarding appropriate diagnostic evaluations for vascular malformations can be found in Chapter 171.

Vascular malformations are primarily treated with sclerotherapy or surgical excision. Conservative treatment such as compression garments can help control symptoms of bulky disease and lymphedema. Recently, rapamycin inhibitors have

Abstract

Vascular anomalies are classified into two groups: vascular tumors and vascular malformations. In addition, vascular malformations can be further subdivided based on vascular channel type (capillary, lymphatic, venous, arterial, or combinations thereof) or by flow (slow vs. fast). Correct identification of the type of vascular anomaly is paramount to appropriate treatment selection, and imaging should generally be obtained prior to planned procedures to define the extent of the malformation. These lesions are primarily treated with either sclerotherapy or surgical excision. Complete surgical resection may not be achievable, and lesions may require multiple or staged procedures, sometimes in combination with sclerotherapy.

Keywords

vascular malformation
lymphatic malformation
venous malformation
arteriovenous malformation

been used to successfully treat several types of vascular anomalies, including LM, venous lymphatic malformations (VLM), and capillary lymphatic/venous malformations (CLVM).[10]

Preoperative sclerotherapy or embolization may decrease intraoperative blood loss and increase the likelihood of achieving a safe and successful surgical procedure.[11-15] General principles for resection have been well described by Upton and Taghinia.[16] One should avoid the creation of a large scar that may be as unaesthetically pleasing as the original malformation. Tourniquets should be used for extremity lesions to limit blood loss. Vital structures should also be tagged and avoided to prevent functional loss. Limiting administration of paralytics allows for the use of intraoperative nerve monitoring. Incisions should be closed without tension and drains used to prevent accumulation of fluid postoperatively.

Complete surgical resection may not be achievable, and lesions may require multiple or staged procedures. Resection is generally performed to improve contour and mobility, decrease infectious risk, and for pain relief rather than purely for cosmetic purposes.

This chapter addresses the surgical treatment of vascular malformations. Endovascular treatments, including sclerotherapy, are addressed in Chapter 173.

SURGICAL TREATMENT OF LOW-FLOW MALFORMATIONS

Capillary Malformations

Capillary malformations are present at birth and typically appear as flat, pink-red cutaneous lesions. They can be associated with underlying soft tissue and skeletal overgrowth, other internal abnormalities, or as part of combined malformations. Resection is not usually necessary for isolated CM, and treatment consists primarily of flashlamp pulse-dye laser therapy for cosmetic purposes. They may, however, be partially resected during debulking procedures for underlying venous or lymphatic malformations.

Lymphatic Malformations

Lymphatic malformations are often classified as macrocystic (diameter >1 cm), microcystic (diameter <1 cm), or a combination of both. This description of the type of LM, along with its location and extent, is useful when determining treatment options.[17] Presentation can vary from a localized mass to a diffuse anomaly. LM are unique among vascular anomalies in that they not only can serve as a source of infection, causing cellulitis or bacteremia, but they also are affected by illness occurring elsewhere in the body, increasing in size in response to infection. Cervicofacial LM in the head and neck region are common and can present with breathing and swallowing difficulties. Congenital anomalies of the central lymphatics can present with chylothorax or chylous ascites, respiratory compromise, malnutrition and hypoproteinemia, lymphopenia, and bony erosion.[18] Intralesional bleeding may also occur secondary to trauma or an abnormal venous connection. Cutaneous involvement of LM manifests as reddish-purple to black vesicles, which can leak serosanguinous fluid.

In general, LM that are predominantly macrocystic are more amenable to sclerotherapy, while those that are microcystic in nature often require resection. Lesions with poor response to sclerotherapy can also be resected. Massive LM, even when predominantly macrocystic, are often best treated with resection since shrinkage after sclerotherapy may not be sufficiently satisfying. Asymptomatic lesions can be observed. Indications for treatment include deformity, dysfunction, leakage into body cavities or from the skin, and recurrent infections. Since these procedures may be lengthy, operative intervention should be delayed until 6 months of age unless the airway is threatened.

Operative Treatment

Subcutaneous LM can cause considerable tissue expansion, and thus for larger lesions, a lenticular excision should be made. As much involved skin as possible (i.e., with creases, dimpling, or vesicles) should be included in the excision to prevent rupture of lymphatic cutaneous vesicles at a later time. The remaining overlying skin and subcutaneous tissue is then dissected off the underlying LM as flaps. The appearance of an LM is similar to fat but has a distinguishable texture. In situations where there is no normal subcutaneous tissue and the LM extends into the dermis, a deep subdermal dissection plane can be created to ensure sufficient vascularity. An intraoperative nerve stimulator is helpful, particularly when the LM encompasses neurovascular structures. Since LM are not malignant lesions, the entirety of the lesion need not be removed, and care should be taken to preserve any vital structures. Subsequent operations may be necessary to remove residual LM or re-contour areas following the initial resection (Fig. 172.1A-C). However, re-operations can be much more difficult because of scar tissue and loss of planes, so every effort should be made to be as thorough as possible at the initial operation. Moreover, depending on how much LM is left behind, any residual lesion may re-expand in the months following surgery. Closed suction drains are placed in the wound to absorb lymphatic leakage, and excision of redundant skin may be required to close the skin in a cosmetic fashion. Complex flaps may be required to provide adequate tissue coverage and cosmetic reconstruction.[19]

Treatment of symptomatic abdominal and pelvic LM can be challenging, and sclerotherapy is effective for macrocystic lesions. Microcystic lesions can be observed or partially resected, avoiding removal of major associated viscera when possible. LM of the gastrointestinal (GI) tract can cause pain and obstruction, and bowel resection may be required for symptomatic relief. Splenic involvement is common; splenectomy should be limited to patients who develop massive or symptomatic splenomegaly or hypersplenism.

Management of leakage from lymphatic anomalies can be difficult. Chylous pleural effusions from thoracic LM can sometimes be treated with chemical or mechanical pleurodesis. LM of the pericardium causing pericardial fluid accumulation can be treated by pericardial window or repeated pericardiocentesis by needle or indwelling catheter. Nonoperative

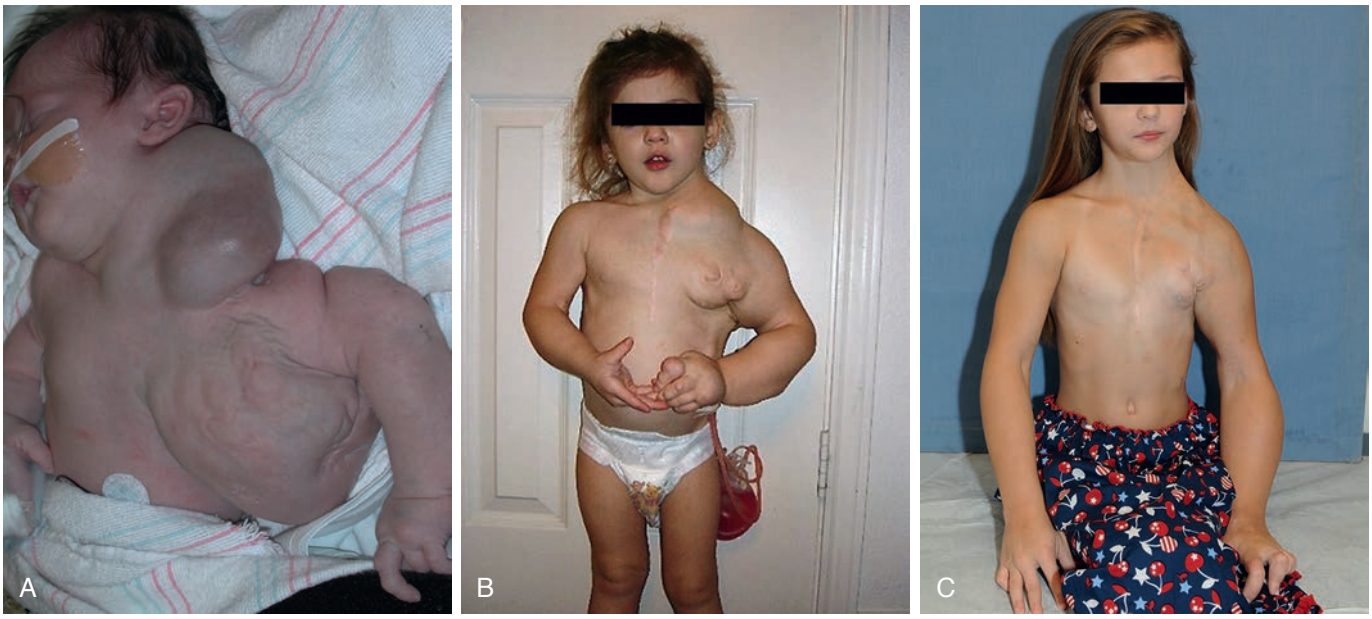

Figure 172.1 (A) Lymphatic malformation of left neck, axilla, mediastinum, and upper extremity in baby girl, shortly after birth. (B) Girl, age 3, following multiple sclerotherapy and debulking procedures. (C) Girl, now age 10, active in dance and other activities.

management aimed at decreasing the total volume of lymph fluid with octreotide, low-fat diets, or total parental nutrition may reduce thoracic duct flow. Ligation or embolization of the thoracic duct can be useful, but this should be done with caution in those with diffuse lymphatic anomalies, as outflow obstruction may exacerbate symptoms. In some rare cases, shunt procedures can provide palliation.

LM can occur in the subcutaneous tissue of the penis, and lymphedematous swelling of the penis not controlled by wrapping can be excised. The entire thickness of the subcutaneous tissue should be removed to minimize recurrent swelling.

Postoperative Management

Closed suction drains are left until output is minimal to prevent seromas and hematomas that may delay healing and induce wound disruption. These can remain in place for weeks to months, so patients should be warned preoperatively regarding the duration of drainage.

Cutaneous vesicles from unexcised lymphatic channels may occur within the surgical scar following resection, but they can be controlled by local intravesicular sclerotherapy or CO_2 laser treatment. They can be resected, but due to their extensive nature, recurrence is common. Consequently, to prevent development of vesicles, the uninvolved dermis should be advanced over the resection bed and any involved skin excised during the procedure.

Venous Malformations

Venous malformations may be present at birth and typically grow with the patient, although symptoms may not arise for some time. They may expand with dependent position and Valsalva maneuver. Stasis in VM can lead to phlebothrombosis, causing pain and swelling. In addition, VM of the bone and joints can lead to fractures and hemarthroses. VM involving the muscle can also present with pain and swelling, which are exacerbated by the dependent position and exertion, and can cause associated skeletal problems, including fracture, overgrowth, deformation, or undergrowth.[20]

Asymptomatic VM can be managed initially with compressive garments to minimize thrombotic episodes, and some patients feel improvement with daily low-dose aspirin. Surgery is reserved for symptomatic lesions, cosmesis, or functional impairment, but prior to any operation, coagulation studies should be obtained, as localized intravascular coagulation can occur.[21] Those VM that are well-localized are most amenable to surgical excision (Fig. 172.2A-D). Large lesions can be debulked if they are causing uncontrolled pain, significant limb length discrepancy, bleeding, severe cosmetic problems, impairment in function, or limitation of range of motion. Lesions that cannot be entirely resected may be treated with sclerotherapy, and preoperative sclerotherapy can also be performed to decrease blood loss and shrink the lesion.

VM of the GI tract can occur anywhere from mouth to anus. Blue rubber bleb nevus syndrome (BRBNS) is a rare disorder characterized by multifocal venous malformations, most commonly involving the skin and GI tract (Figs. 172.3A-C).[22] Skin lesions have the appearance of tiny "blue rubber nipples" and can be numerous. Lesions in the GI tract can cause intussusception, which is manifested by intermittent abdominal discomfort. Some lesions may never cause symptoms and require no intervention, and moderate fecal blood loss can often be managed conservatively with iron supplementation. Severity and frequency of bleeding can be decreased with stool softeners and avoidance of constipation. Exsanguinating hemorrhage is rare. However, those with significant anemia, particularly requiring

Figure 172.2 (A) Two-year old boy with large venous malformation of lower back. (B) Resection of venous malformation demonstrating creation of flaps. (C) Venous malformation following resection. (D) Child at 2-month follow-up.

blood transfusions, or an acute small bowel obstruction may warrant an operation.

Operative Treatment

For extremity VM, the use of a tourniquet can decrease intraoperative blood loss. VM have fragile, dysplastic vessels and permeate into surrounding tissues, which can result in significant blood loss with dissection.[23] Cutting through a VM produces a surface resembling a sponge, and bleeding is difficult to control with cautery, clamps, or sutures. Hemostatic devices such as bipolar sealers, electrocautery, and ultrasonic scalpels can be useful. Involved skin should be incorporated in the incision as much as possible. VM can also act as a tissue expander, leading to redundant skin once excised, and a large amount of involved skin can be removed with the specimen. Flaps are raised in all directions from the incision (see Fig. 172.2B). When lesions involve the dermis or are just below the dermis, flaps should be made as thinly as possible without devascularization of the skin. Care should be taken to preserve nerves, tendons, and joint cavities; and closed-suction drains are placed in the flap. Large resection areas can be covered by local or distant flaps, or by the use of skin grafts.

For those with blue rubber bleb nevus syndrome affecting the GI tract, VM can be removed with a combination of wedge

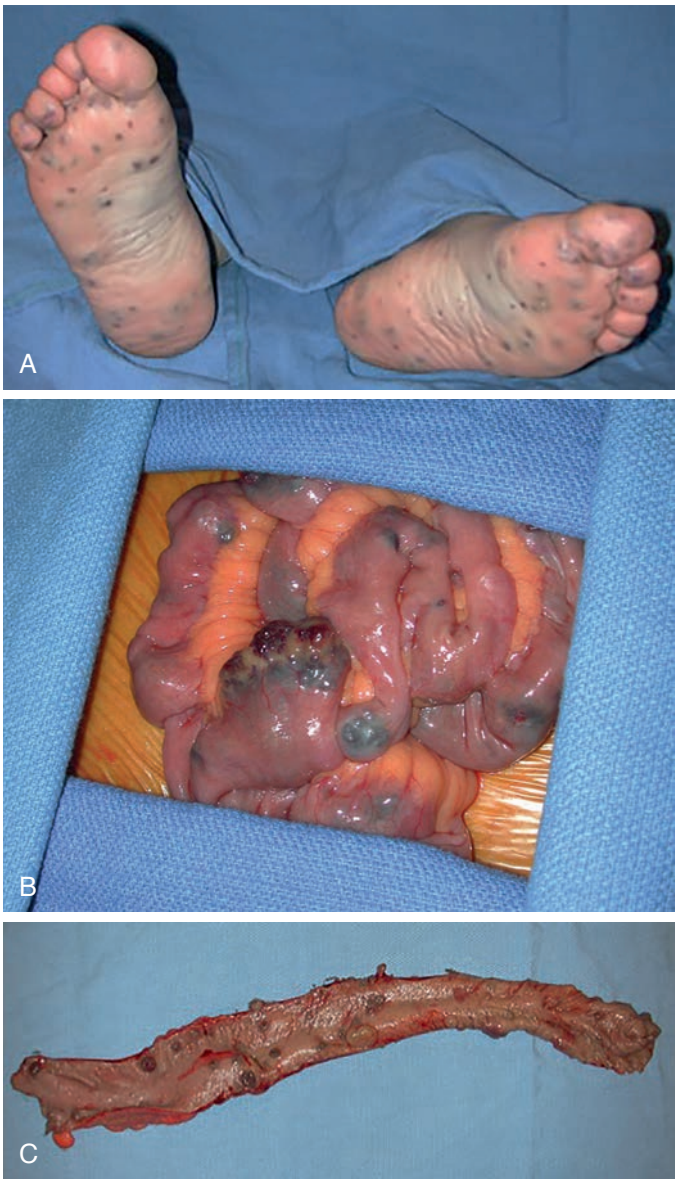

Figure 172.3 (A) Patient with blue rubber bleb nevus syndrome, with multiple venous malformations (VMs) of the foot. (B) Multiple VM in the intestine. (C) Densely populated VM in resected bowel.

bowel resection, band ligation, polypectomy, suture-ligation of narrow-based polypoid lesions, and segmental bowel resection (see Fig. 172.3B and C). It is preferable to remove individual lesions rather than sections of intestine, since lesions are distributed throughout the gut. Intraoperative endoscopy, from mouth-to-anus, identifies lesions that may not be seen externally or palpable. Serosal sutures or dye stain can be used to mark these lesions.

Diffuse and densely located VM, involving large continuous segments of bowel, require more than simple excision, and can be managed by colectomy, anorectal mucosectomy, and coloanal pull-through.[24]

Anorectal VM can be associated with an ectatic inferior mesenteric vein, which can siphon blood flow from the portal vein.[25] This causes stagnation of blood resulting in portomesenteric thrombosis and resultant portal hypertension. Patients with rectal VM should be screened for this anomaly, and if found, it can be ligated proximally to prevent thrombosis.

While bulky VM of the scrotum may be amenable to sclerotherapy, repeated sessions should be avoided to minimize radiation, and thus surgical resection is preferable. Sclerotherapy of labial VM can be performed as long as female gonads are shielded. Debulking is best undertaken after puberty, although massive lesions can be debulked earlier. Sclerotherapy of the clitoris should be avoided; clitoral VM can be resected, but care should be taken to avoid neurovascular injury.

Postoperative Management

Lesions not completely excised can re-canalize and enlarge, requiring additional procedures or sclerotherapy.[26] Postoperative complications include hematoma, partial skin necrosis, and persistent edema. Drains are left in place until fluid outflow is minimal.

SURGICAL TREATMENT OF HIGH-FLOW MALFORMATIONS

Arteriovenous Malformations

Arteriovenous malformations are characterized by abnormal connections between feeding arteries and draining veins. They may begin as only a pink stain, but they can expand during pregnancy or puberty or secondary to local trauma. Expansion can lead to skin ischemia and local steal phenomenon, resulting in pain, ulceration, functional impairment, nerve compression, soft tissue and bony destruction, and bleeding. These symptoms necessitate treatment.[13,27] Large AVM can also cause high output cardiac failure, which requires early intervention. Asymptomatic lesions can be observed, although it is preferable to treat before the AVM progresses.

Operative Treatment

Management of AVM includes embolization alone or in combination with surgical excision. Preoperative embolization of the nidus is followed by surgical resection in 2 to 3 days, since rapid expansion can occur during the period between embolization and resection (Fig. 172.4A and B).[13] Unless the surgeon is sure that the entire AVM has been removed, the proximal feeding arteries should not be embolized or ligated, as these provide the only avenue to reach the nidus of the AVM for subsequent embolization. Occlusion of the primary vessels will result in recruitment by the nidus of other nearby arteries, allowing the AVM to recur and progress. Embolization can also be used for palliation in persistent AVM.

The goal of the operation is complete excision to normal margins with removal of both the nidus of the AVM and involved skin. Focal AVM can be excised with good long-term control.[28] In addition, diffuse lesions have higher recurrence rates and are more difficult to treat, as residual tissue can form collaterals and re-expand.[29] Intraoperative Doppler examination and recognition of the bleeding pattern at the margin are also useful

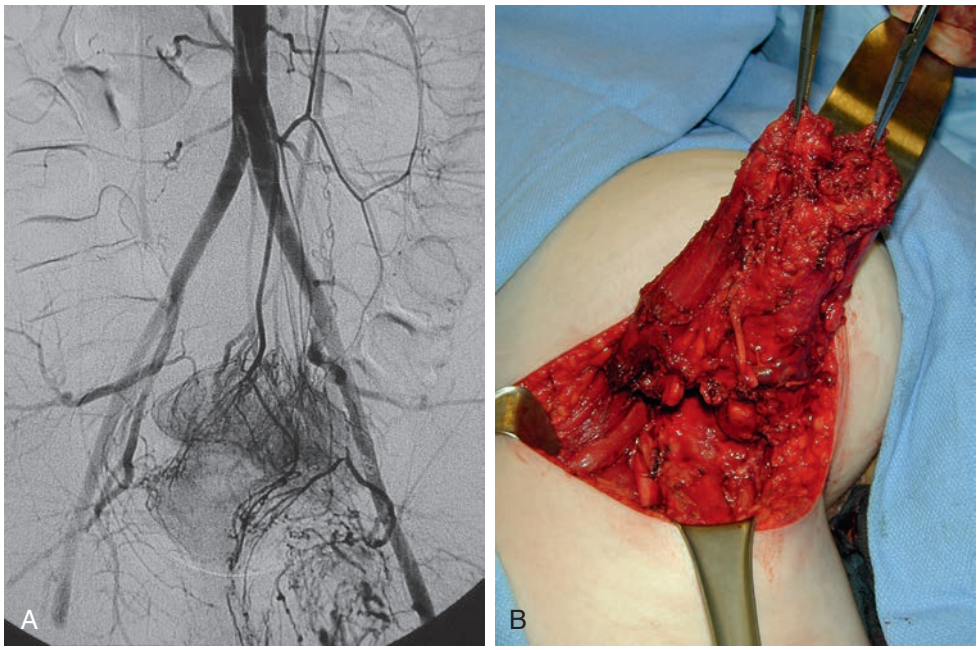

Figure 172.4 (A) Angiogram of diffuse arteriovenous malformation (AVM) of the gluteus maximus muscle, prior to preoperative embolization. (B) Excision of AVM.

guidelines for resection. Intraoperative frozen sections have not proven useful in determining the extent of resection.[13] Reconstruction immediately following resection may require skin grafts or local, regional, or microvascular free flaps.[13,28-30] Large excisions that do not allow for primary closure can be managed with vacuum-assisted closure devices or tissue transfer techniques. For difficult extremity AVM, particularly those with loss of function, amputation can be performed.

AVM of the thoracic and abdominal cavity are managed with a combination of sclerotherapy and open resection. Most AVM of the chest are intrapulmonary and can be associated with hereditary hemorrhagic telangiectasia. They can be managed with partial pulmonary resection. AVM of the GI tract are rare.[31,32] Most patients present with GI bleeding. Bleeding may be temporized with embolization, but recurrent or serious bleeding requires a formal resection. Splenic hilum or parenchymal lesions are uncommon, but they can be managed with splenectomy.[33,34] Pancreatic AVM can cause portal hypertension and eventual GI bleeding. Straightforward cases can be controlled with embolization, but permanent control may require complete resection, such as a pancreaticoduodenectomy.[35-39] More complex hepatic AVM may require hepatectomy or hepatic transplantation. Congenital arterioportal fistulae can cause ascites, abdominal pain, GI bleeding, or malabsorption.[40] Hepatectomy or surgical ligation of the fistula can be performed if transcatheter embolization fails.[41-43]

Urinary tract AVM can cause hematuria, hypertension, and flank pain.[44] Localized lesions can be resected.[45,46] AVM of the genitals can be managed with embolization and resection. AVM of the buttock often involves the gluteal muscles. These can be resected if embolization fails to control symptoms.

Postoperative Management

Patients should be followed long-term since lesions can recur. Reported rates of recurrence range from 8% to 93%.[29,30] Early signs of recurrence include erythema, superficial telangiectasias, swelling, pulsation, bleeding, or Suen sign (rapid soft tissue rebound upon palpation).

SURGICAL TREATMENT OF COMBINED VASCULAR MALFORMATIONS

Diseases with combined vascular malformations include Klippel-Trenaunay syndrome (KTS), Parkes Weber syndrome (PWS), and CLOVES syndrome and present within a wide-ranging spectrum. KTS is a slow flow combined capillary-lymphatico-venous malformation associated with prominent soft tissue and bony hypertrophy of one or more extremities.[47-49] Capillary malformations may be large, multiple, or develop lymphatic vesicles, which may weep or bleed. Lymphedema is a common complaint. The deep venous system can be absent or hypoplastic, and often anomalous superficial veins will develop in the extremity, including the primitive lateral embryonic vein of Servelle. These anomalous veins can cause cellulitis, pain, edema, and bleeding and are at risk for thrombophlebitis and as a source of pulmonary emboli.[50] These veins should be imaged prior to treatment.

Parkes Weber Syndrome is a fast-flow lesion characterized as a capillary-arteriovenous malformation (CAVM) or capillary arteriovenous fistulae (CAVF) and involves the upper and lower

extremities.[51] Congestive heart failure can develop secondary to the AVM and fistulae and may necessitate embolization of these.

CLOVES syndrome is characterized by congenital lipomatous overgrowth, vascular malformations, epidermal nevi, seizures, scoliosis, and skeletal/spinal anomalies.[52,53] Lipomatous masses on the trunk and flank can be present at birth, and extend into the mediastinum, pleural cavity, retroperitoneum, and paraspinal-intraspinal space. These can cause physical deformity and functional impairment (Fig. 172.5A). For example, large hands, macrodactyly, widened triangular feet, and "sandal gap" toes are extremity abnormalities found in these patients. Anomalous veins are also present in the extremities and along the thoracic wall and have been shown to cause pulmonary embolism.[54]

Nonoperative management with compression therapy can improve symptoms of pain, swelling, and heaviness from chronic venous insufficiency and lymphedema. Routine use of compression garments is started around age 4 to 5 years. Pneumatic compression devices can be used while sleeping or recumbent, but they are expensive. Anomalous veins were historically managed with resection, but endovenous laser ablation is now the more common therapeutic modality.

Operative Management

Soft tissue overgrowth can be managed by debulking and contour resections, which are typically done as staged procedures (see Fig. 172.5B-D).[55,56] The most common areas of debulking are the trunk, genitalia, perineum, buttock, and lower extremity. Asymptomatic lesions extending into the mediastinum or thoracic cavity are managed conservatively. Because of the risk of thromboembolism, patients should be considered for preoperative

Figure 172.5 (A) Patient with congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal abnormalities (CLOVES) syndrome, with mixed malformation of right upper extremity and chest wall, limiting range of motion. (B) Lenticular incision was created and malformation removed off muscle fascia. Note that the incision does not cross the axilla or elbow joint. (C) Closure of incision by adjacent tissue advancement technique. (D) At 14 months follow-up, patient now has improved mobility in upper extremity.

and postoperative anticoagulation and temporary inferior vena cava filter placement. Preoperative imaging is critical to determine if overgrowth is extrafascial or intrafascial, because injury to major neurovascular structures and immobility can occur with debulking of intrafascial overgrowth. Hypertrophy of the extremity can result in limb-length discrepancy that may require epiphysiodesis.

Debulking should be tailored to address the specific problematic areas of each patient and to remove as much excess bulk and weight as possible. The most extensive areas are usually addressed first. Blood loss and transfusions can be minimized by using tourniquets and intraoperative cell saver machines. A lenticular excision is used when excess tissue is present and should incorporate cutaneous lesions as anatomic options allow. The skin is incised down to the subcutaneous tissue and then skin flaps are raised. Areas with malformation that involves or is adjacent to the dermis require cautious dissection of flaps to avoid devascularization. The flap dissection should be limited to a maximum circumference of 180° to enhance flap viability and minimize postoperative wound complications. Once flaps are raised, the abnormal tissue between the muscle fascia and skin is removed. Drains are then placed in the wound bed, and skin flaps are reapproximated. The overgrowth acts as a tissue expander and often allows a large amount of excess skin to be removed. Amputation of an extremity may be necessary for palliation for unrelenting symptoms or destroyed fixed joints.

Postoperative Management

Patients should be counseled prior to resection regarding delayed postoperative healing and the protracted use of closed-suction drains. Because of altered circulation and poor lymphatic drainage, tissue in these patients makes for poor flaps, and wound healing can take several weeks to months. Drains are removed once output decreases to approximately 10 to 15 mL/day. Lymphatic vesicles may appear in and around the scar postoperatively and can be treated by laser therapy.

INTRODUCTION

Vascular anomalies comprise a collection of disorders characterized by abnormal blood vessel growth. The need for accurate characterization of these lesions has led to the development of a classification system based on biologic behavior that has been approved by the International Society for the Study of Vascular Anomalies (ISSVA) and is widely accepted in the medical community.[1,2] It broadly divides vascular anomalies into nonneoplastic lesions (i.e., vascular malformations) and neoplastic lesions (i.e., vascular tumors) (Table 173.1).

Vascular malformations are the more common anomaly, comprising approximately two-thirds of all vascular anomalies; they are congenital, nonneoplastic lesions that develop secondary to defects in vasculogenesis.[3,4] Vascular malformations are further subdivided into low- and high-flow lesions based on their hemodynamic characteristics. Low-flow vascular malformations are composed of capillaries (capillary malformation), veins (venous malformation), lymphatics (lymphatic malformation [LM]), or a combination (venolymphatic malformation). High-flow vascular malformations are characterized by a direct communication between arterial and venous vessels without an intervening capillary bed (arteriovenous malformations [AVMs] and arteriovenous fistulas [AVFs]).

Vascular tumors are neoplastic vascular anomalies defined by the presence of abnormal endothelial proliferation. Overall, the most common vascular tumor is the infantile hemangioma, which is benign and characteristically involutes over time.[5] Angiosarcoma and epithelioid hemangioendothelioma are examples of malignant vascular tumors and require oncologic evaluation and treatment.[5]

This chapter focuses on the diagnosis and treatment of vascular malformations, the vascular anomalies most commonly treated by endovascular specialists.

Abstract:

Congenital vascular malformations comprise a diverse group of anomalies that are defined by abnormal non-neoplastic growth of blood vessels. Vascular malformations are broadly divided into low-flow and high-flow lesions based on their hemodynamic characteristics. Minimally invasive endovascular therapies have been developed for many of the vascular malformations. Sclerotherapy is currently the first-line therapy for low-flow lesions, and arterial, venous, and/or percutaneous embolization serves as neoadjuvant (pre-surgical) or primary treatment for high-flow lesions.

DIAGNOSIS OF VASCULAR MALFORMATIONS

The diagnosis of vascular malformations can be confusing due to their relative rarity and overlapping clinical and imaging features. Because of this confusion, suspected vascular malformations are often referred to centers with a dedicated multidisciplinary vascular anomaly team for diagnostic workup and treatment.[6] It is common to seek consultation from experts in the fields of dermatology, plastic surgery, neurosurgery, vascular surgery, and diagnostic and interventional radiology. At our institution, the vascular anomaly team classifies vascular malformations according to an established visual pathway, known as the S.E. Mitchell vascular anomalies flowchart (SEMVAFC) (Fig. 173.1),[6] which combines clinical and imaging findings to accurately identify lesions. In some cases, syndromes associated with vascular malformations, such as Parkes-Weber syndrome and Klippel-Trénaunay syndrome (KTS), can be identified with SEMVAFC.

Vascular malformations can be imaged with duplex ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and conventional angiography. Patients are often first evaluated with US, which has the advantages of wide availability, lack of ionizing radiation, patient comfort, and real-time hemodynamic characterization. However, US is limited by a small field of view that may exclude portions of a larger vascular malformation. MRI is the preferred examination for most lesions, given its wide field of view, excellent soft tissue resolution, and ability to assess enhancement characteristics (Fig. 173.2).[7] Accurate classification is assisted by the addition of dynamic contrast-enhanced magnetic resonance angiography (DCE-MRA), which produces imaging of the lesion in the arterial, capillary, venous, and delayed venous phases.[8] MRI is also useful after treatment to judge changes in size and flow characteristics.

Our MRI protocol for vascular anomalies includes multiplanar fat-saturated T2-weighted, T1-weighted, and fat-saturated precontrast and postcontrast T1-weighted sequences (Fig. 173.3). MRA is an integral component of the postcontrast portion of the examination and is typically performed with contrast-enhanced time-resolved angiography with interleaved stochastic trajectories (TWIST) sequence.[8] The typical MRI appearance of common vascular anomalies is reviewed in Table 173.2 and discussed in detail in the following sections.

TREATMENT OF LOW-FLOW VASCULAR MALFORMATIONS

Introduction

The two most common low-flow vascular malformations encountered in clinical practice are venous malformations (VMs) and LMs.

Figure 173.1 S. E. VMs are uni- or multilocular lesions composed of postcapillary, endothelium-lined venous channels with abnormal mural smooth muscle. Most VMs occur sporadically; however, 1% to 2% may be inherited as an autosomal dominant trait.[9] Glomuvenous malformation (GVM), cutaneomucosal venous malformation (CMVM), cerebral cavernous VM, and blue rubber bleb nevus syndrome (BRBNS) are examples of hereditary diseases that can result in multiple lesions.[10,11] VMs range from small solitary lesions localized to the skin and subcutaneous tissues to diffuse masses that extend across multiple tissue planes and encase vascular, nervous, and visceral structures. VMs most commonly arise in the head and neck but can also affect the trunk and extremities. On physical examination, superficial VMs appear as compressible, bluish, nonpulsatile masses (Figs. 173.4 and 173.5). Lesions can expand with increased local venous pressure, as may result from dependency or with a Valsalva maneuver. Calcified phleboliths are characteristic and may be found via palpation or imaging. Common complications of VMs include pain and swelling related to phlebothromboses, infection, and psychosocial issues related to disfigurement. Additional morbidities are related to the specific location of the VM. For example, lesions in the head and neck may compromise respiration, speech, deglutition, and vision. VMs in the extremities can cause gait instability and limit mobility. Lesions within the gastrointestinal and genitourinary tracts can cause intraluminal hemorrhage resulting in acute and chronic anemia.

LMs are benign unilocular or multilocular cystic lesions composed of dysplastic endothelium-lined lymphatic channels. Cysts vary in size and may be classified as macrocystic (individual cysts >1-2 cm), microcystic, or mixed. The majority of lesions are sporadic, although some lesions are associated with Turner and Noonan syndromes.[12,13] Similar to other vascular malformations, LMs are usually diagnosed at birth or during the first

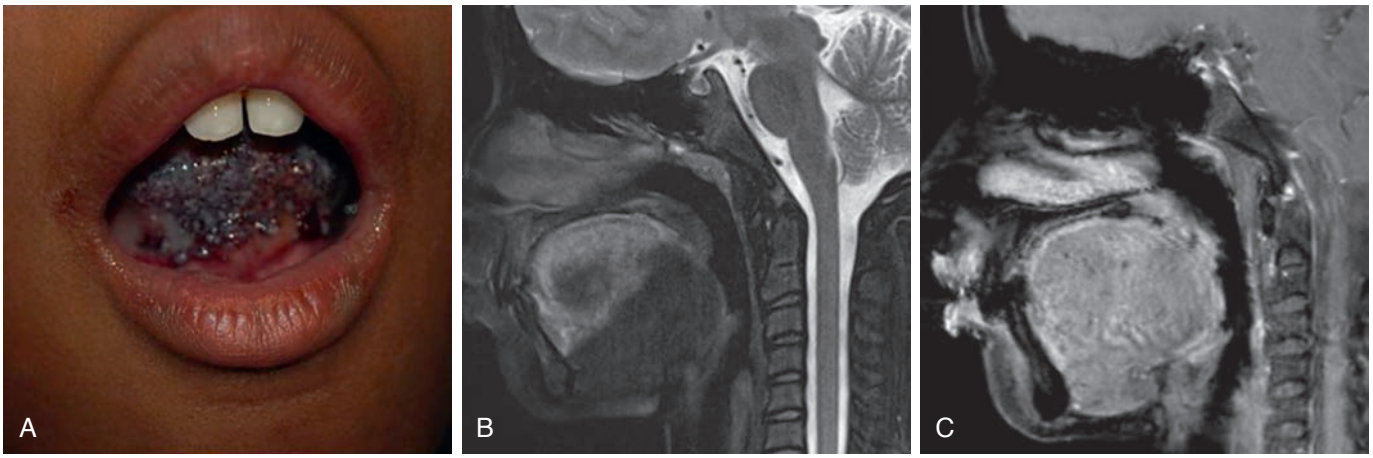

Figure 173.2 (A) An 11-year-old female with LVM of the tongue, status post–tongue reduction surgery and prior laser treatment. Recurrence of numerous small blue-black cystic lesions on her tongue. They weep clear lymphatic and bloody fluid. (B, C) Sagittal T2-weighted image of the tongue shows increased T2 signal in the intrinsic tongue muscles, which are mildly enhanced in the contrast-enhanced T1-weighted sagittal image (C). Magnetic resonance imaging (MRI) is helpful for identifying the depth of infiltration in this superficial lesion. (Reproduced from Tekes A, Koshy J, Kalayci TO, et al. S.E. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol*. 2014;69(5):443-457, Fig. 11.)

few years of life, but they may occasionally present later, in childhood, adolescence, or adulthood. The majority of LMs occur in the head and neck, but lesions are also found in the chest, axillae, and perineum. On physical examination, macrocystic LMs in the superficial soft tissues are palpable as cystic, rubbery, or ballotable masses (Fig. 173.6). Cutaneous LMs appear as small vesicles that discharge clear or milky lymphatic fluid when ruptured. A microcystic LM may simply appear as an area of soft tissue overgrowth. Intralesional hemorrhage is a common complication and typically results in pain and swelling. LMs may also enlarge and become painful in the presence of systemic infections. Like other vascular malformations, LMs in the head and neck can cause airway compromise.[14] Lesions deep in the chest and abdomen can cause pleural, pericardial, and peritoneal chylous effusions.[15]

Imaging

In general both VMs and LMs appear isointense to skeletal muscle on T1-weighted imaging and hyperintense on T2-weighted imaging, although intralesional hemorrhage will result in variable T1 and T2 signals depending on the age of blood products (Figs. 173.4–173.6). VMs and macrocystic LMs are cystic in appearance, whereas microcystic LMs appear as solid masses. VMs will characteristically demonstrate foci of signal void, corresponding to phleboliths, and will enhance during the venous phase of dynamic MRA. The cystic channels of LMs do not contain phleboliths or enhance internally during MRA, but the channels may contain fluid levels related to prior hemorrhage, and the peripheries of the cysts can enhance.[7] Duplex ultrasound is useful to diagnose vascular malformations in the prenatal setting, to differentiate high- and low-flow lesions, and to monitor for complications such as thrombosis and hemorrhage. Sonographically, vascular malformations appear as hypoechoic or anechoic fluid- or debris-filled cystic lesions. Phleboliths in VMs will appear as hyperechoic foci with posterior acoustic shadowing. Low-flow lesions typically exhibit essentially no flow on Doppler analysis.

Therapy Overview

Typically low-flow vascular malformations will grow and become more symptomatic over time. Treatment is often indicated to ameliorate pain, functional impairment, or disfigurement. Therapeutic options range from palliative to surgical measures. Compression garments can be used to decrease blood stagnation and swelling associated with vascular malformations in the extremities. Pharmacotherapy with aspirin and low-molecular-weight heparin (LMWH) may decrease the risk of thrombotic complications.[16] However, these measures do not decrease the overall disease burden, and more invasive therapies are usually indicated. Among the various minimally invasive and surgical options, percutaneous sclerotherapy has emerged as the first-line treatment.[10,11,17]

Sclerotherapy

Sclerotherapy involves percutaneously placing needles into the cystic spaces of a vascular malformation; they are then filled with an endothelium-damaging agent, or sclerosant. The goal of this therapy is to cause fibrosis and eventual contraction of the vascular malformation. This technique has been shown to be safe and effective for treating low-flow vascular malformations throughout the body.[18,19]

Preintervention Assessment

Patients who are being considered for sclerotherapy should ideally first be assessed in the clinic setting. A careful history

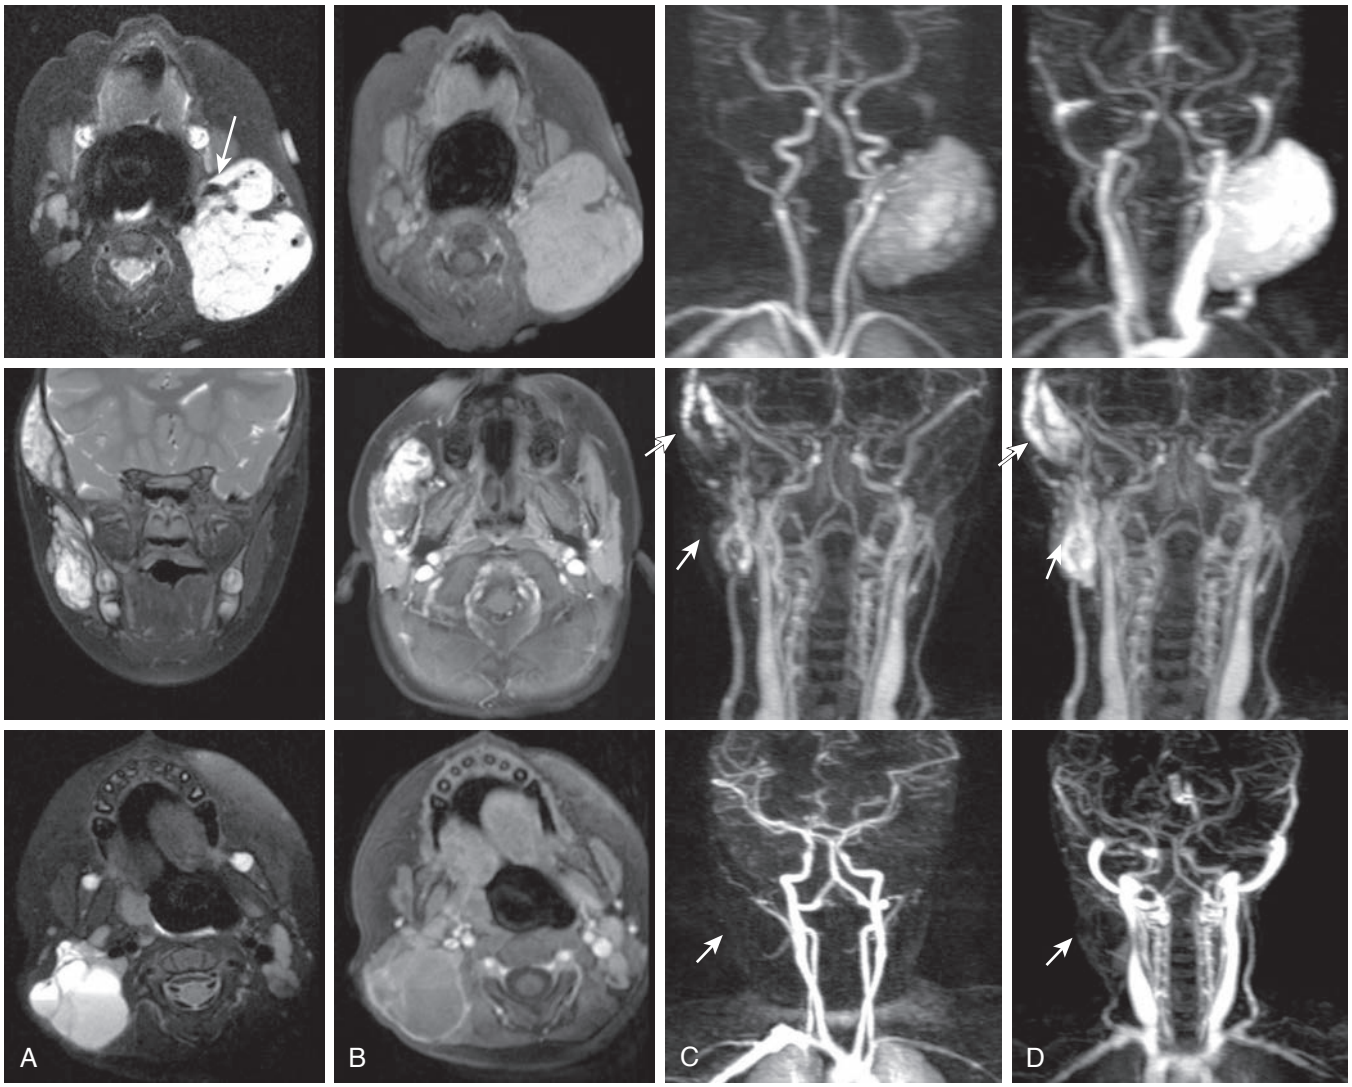

Figure 173.3 Top row: Infantile hemangioma (IH). (A) Axial T2-weighted fat-saturated image (B) and axial T1-weighted postcontrast fat-saturated image demonstrating a well-demarcated T2 hyperintense mass with clean borders and homogeneous internal enhancement. Note the serpiginous internal flow void *(arrow)* (A) from an arterial feeder. Coronal TWIST demonstrates avid enhancement in the arterial phase (C) with a feeder from the external carotid artery and lack of washout during the venous phase (D). Note the venous drainage to the left subclavian vein. *Middle row:* Venous malformation (VM). (A) coronal T2-weighted fat-saturated image demonstrates a predominantly T2 hyperintense mass infiltrating the right masticator and temporalis muscle. Note multiple small round T2 dark foci, representing phleboliths. (B) Axial T1-weighted postcontrast fat-saturated image demonstrates strong but somewhat heterogeneous internal enhancement. (C, D) Coronal TWIST demonstrates progressively increasing enhancement during the venous phase *(arrows)*. There was no enhancement in the arterial phase (not shown). *Bottom row:* Lymphatic malformations (LMs). (A) Axial T2-weighted fat-saturated image demonstrates a lobular multicystic mass with a fluid–fluid level in the soft tissues of the right lower neck. Axial T1-weighted postcontrast fat-saturated image (B) demonstrates enhancement of the cyst wall only without any internal enhancement. Lack of internal enhancement distinguishes LMs from VMs. The layering bright T1 signal is likely due to internal hemorrhage. Coronal TWIST did not demonstrate enhancement in the arterial or in the venous phase *(arrows)* (C, D). (Reproduced from Higgins LJ, Koshy J, Mitchell SE, et al. Time-resolved contrast-enhanced MRA (TWIST) with gadofosveset trisodium in the classification of soft-tissue vascular anomalies in the head and neck in children following updated 2014 ISSVA classification: first report on systematic evaluation of MRI and TWIST in a cohort of 47 children. *Clin Radiol.* 2016;71(1):32-39, Fig. 1.)

and physical examination should be performed. A preintervention MRI should be obtained and reviewed with the primary goals of defining the extent of treatable (nonthrombosed) disease and identifying critical nearby structures that could be damaged during sclerotherapy. Details of the treatment approach, risks, benefits, postoperative expectations, and length of treatment should be clearly discussed with the patient.

VMs continuously undergo cycles of spontaneous thrombosis and thrombolysis in a phenomenon called localized intravascular coagulopathy (LIC).[16] Although anticoagulants and platelet

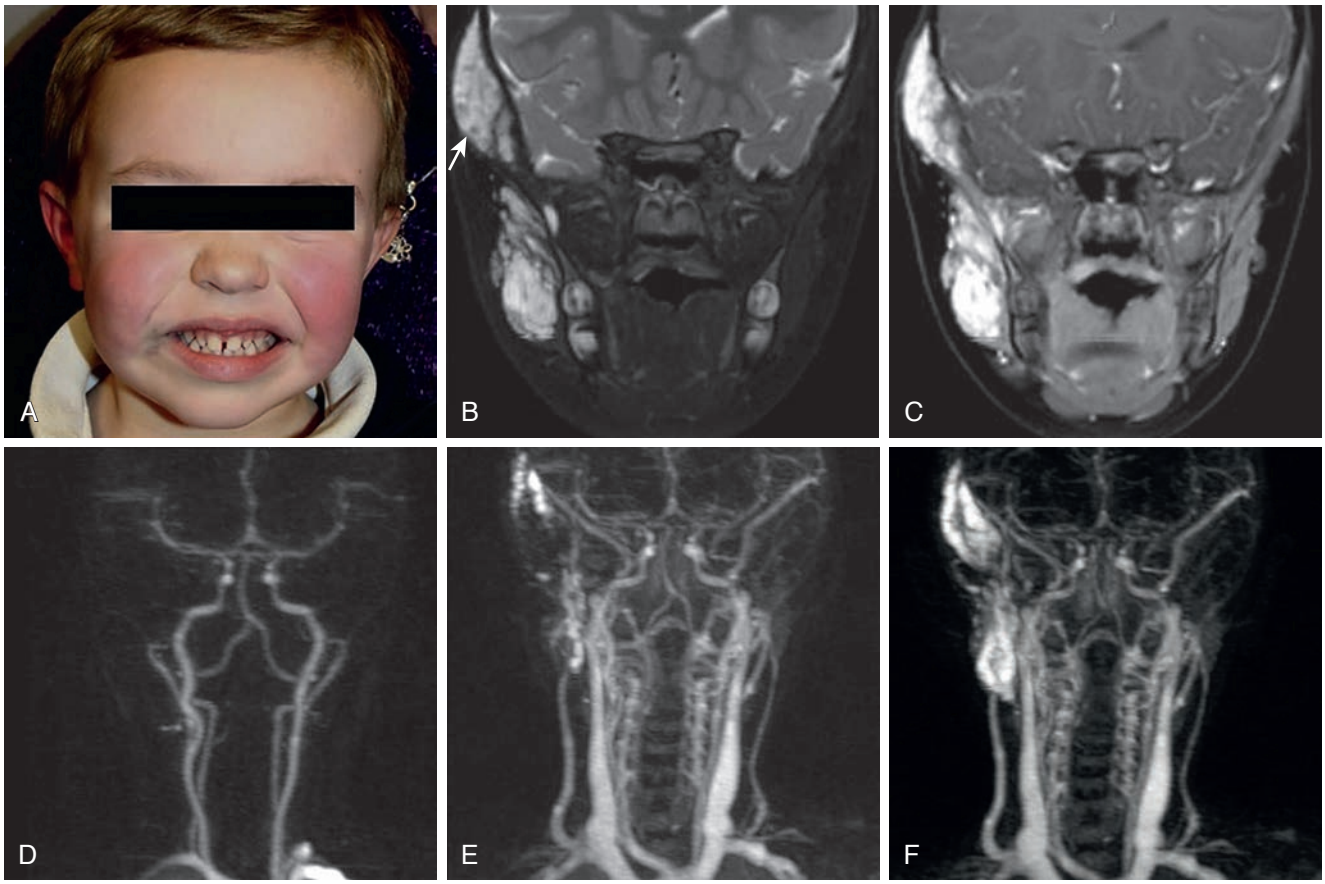

Figure 173.4 Venous malformation (VM). (A) A 4-year-old male with blue discoloration of his right cheek and the corner of right lip; it was noted to have been present since birth and was stable. Note that the right cheek is fuller than the left. The lesions are soft and compressible. (B, C) Coronal images show infiltration of the right temporalis muscle and right masticator space by a T2 bright (B) and enhancing mass (C). Note the T2 dark round foci in (B), representing phleboliths *(arrow)*. (D–F) Dynamic contrast-enhanced magnetic resonance angiography (DCE-MRA) demonstrates no enhancement in the arterial phase (D). Enhancement starts in the venous phase (E) and progressively increases in the delayed venous phase (F), which is typical for VMs. (Reproduced from Tekes A, Koshy J, Kalayci TO, et al. S.E. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol*. 2014;69(5):443-457, Fig. 6.)

inhibitory medications are not typically withheld prior to the procedure, LIC is common with large VMs, causing elevation of D-dimer, hypofibrinogenemia, and thrombocytopenia.[20] Immediately after sclerotherapy, LIC can progress to disseminated intravascular coagulopathy (DIC), and basic coagulation parameters (complete blood count, prothrombin time/international normalized ratio, partial thromboplastin time, fibrinogen, and D-dimer measurements) should therefore be obtained prior to interventions for large VMs. Patients with signs of LIC are prescribed LMWH for 10 days before and 10 days after the procedure. This therapy corrects the coagulopathy by halting the abnormal consumption of fibrinogen.

Patient comfort and immobility are important considerations during sclerotherapy; treatments are therefore generally performed in conjunction with general anesthesia. Patients who have cardiac, pulmonary, or other diseases that increase their risk for perioperative morbidity or mortality due to anesthesia should be identified and thoroughly evaluated by an anesthesiologist prior to undergoing sclerotherapy.

Technical Details

Sclerotherapy is best performed in an angiography suite. The patient should be positioned on the angiography table such that the area of interest can be safely and easily accessed by the operator. A preliminary US can be performed to identify the optimal skin entry sites, which are then prepped in sterile fashion. The procedure is considered "clean," and antibiotic prophylaxis is recommended.[21] Typical agents include intravenous cefazolin, and, for the penicillin-allergic patient, vancomycin or clindamycin.

Once preparations are complete and the patient is adequately sedated, US is used to guide a 21- or 22-gauge needle into the vascular malformation (Fig. 173.6). Several needles can be placed during a single procedure to treat multiple noncommunicating components of a lesion concurrently. In the case of a VM, intralesional placement of a needle is confirmed with blood return upon aspiration and digital subtraction angiography (DSA). DSA is used both to estimate the capacity of the lesion

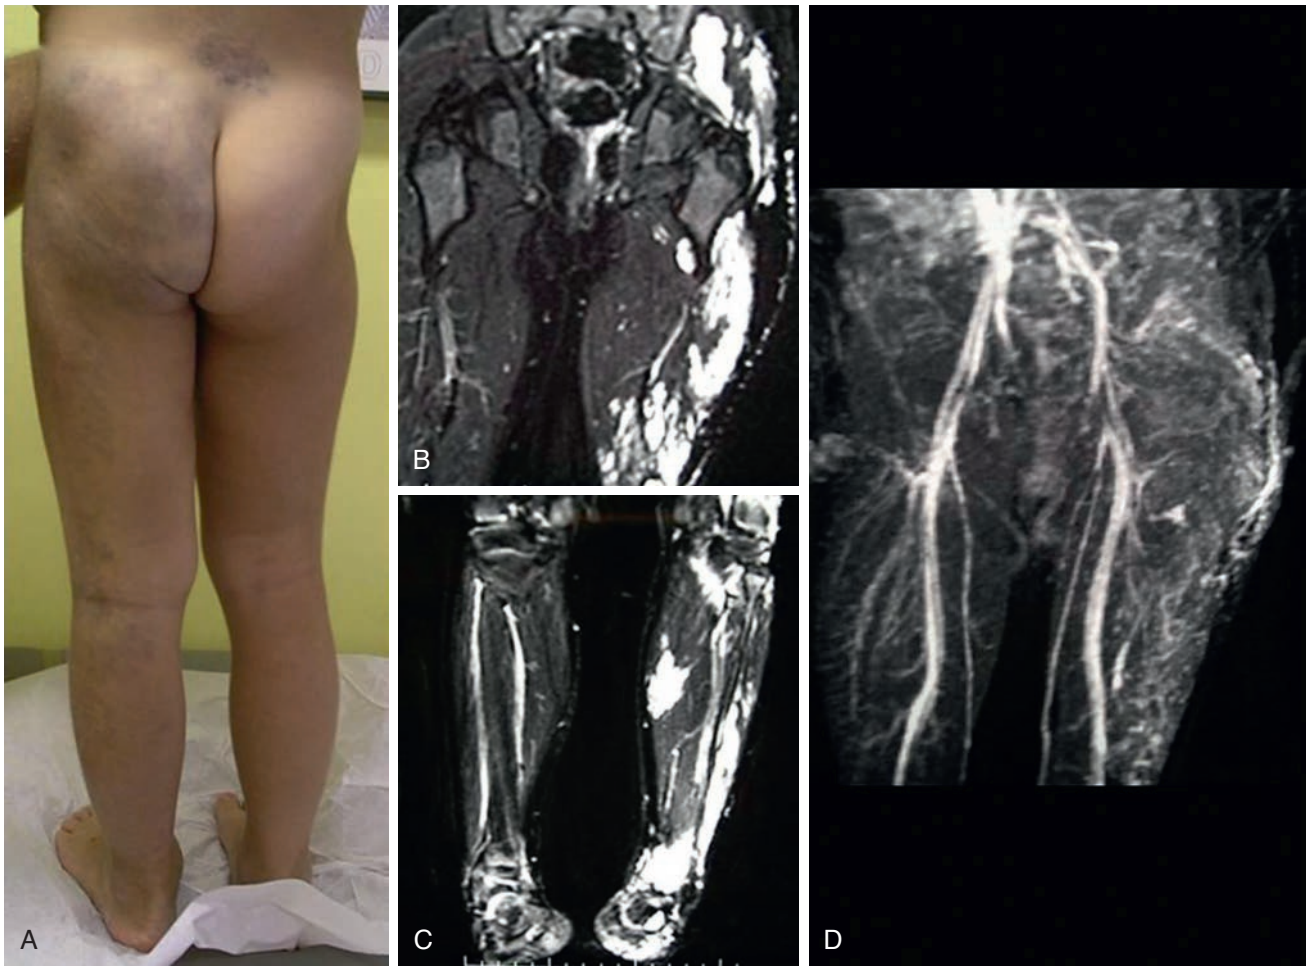

Figure 173.5 Venous malformation (VM). (A) A 4-year-old female with extensive blueness in her left leg and buttock region. She had no leg-length discrepancy on measurement. (B, C) Coronal T2-weighted image shows an extensive VM infiltrating the muscle groups in the left lower extremity and buttock. Note infiltration in the skin. (D) Dynamic contrast-enhanced magnetic resonance angiography (DCE-MRA) shows enhancement of the VM in the venous phase. (Reproduced from Tekes A, Koshy J, Kalayci TO, et al. S.E. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol.* 2014;69(5):443-457, Fig. 13.)

and to determine the presence of rapidly draining veins, which, if present, must be closed via manual pressure or coil or glue embolization to allow adequate sclerosant dwell time. A negative-contrast-technique sclerosant is hand-injected into the vascular spaces under fluoroscopic guidance. Commonly used sclerosants for the treatment of VMs include ethanol, sodium tetradecyl sulfate (often foamed), ethanolamine oleate, and more recently bleomycin.[22-24] The sclerosant is allowed to dwell within the lesion for a period of time, typically 15 to 20 minutes. Once the target dwell time is reached, the syringe is disconnected and the lesion assessed for venous return. If venous return is present, DSA is repeated to assess for residual disease and additional sclerosant is injected as needed. Once the treated area is closed and no venous return is noted, the needle is removed and the skin site is cleaned and dressed.

Sclerotherapy is also used for the treatment of macrocystic LMs. Needles are placed into the cystic spaces of the lesion, and lymphatic fluid is then completely aspirated and partially replaced with a sclerosant. In the case of larger macrocysts, placement of a drainage catheter and repeated infusions of sclerosant over several consecutive days may be necessary to close the cyst. Commonly used sclerosants for the treatment of LMs include doxycycline and bleomycin, although there are reports of using other agents such as ethanol, sodium tetradecyl sulfate, and OK-432 (Picibanil).[22,25] For microcystic LMs, bleomycin has been used with some success.[26] Microcystic LMs refractory to sclerotherapy can be considered for surgical resection.

Postintervention Care and Complications

Patients should be monitored in a postprocedure care unit as they recover from anesthesia. Procedure-related inflammatory pain and swelling are expected, and pain management, icing, and elevation of the treated area are routinely implemented during the recovery period. Steroids are often given to control swelling, particularly when the treated lesion is in the head

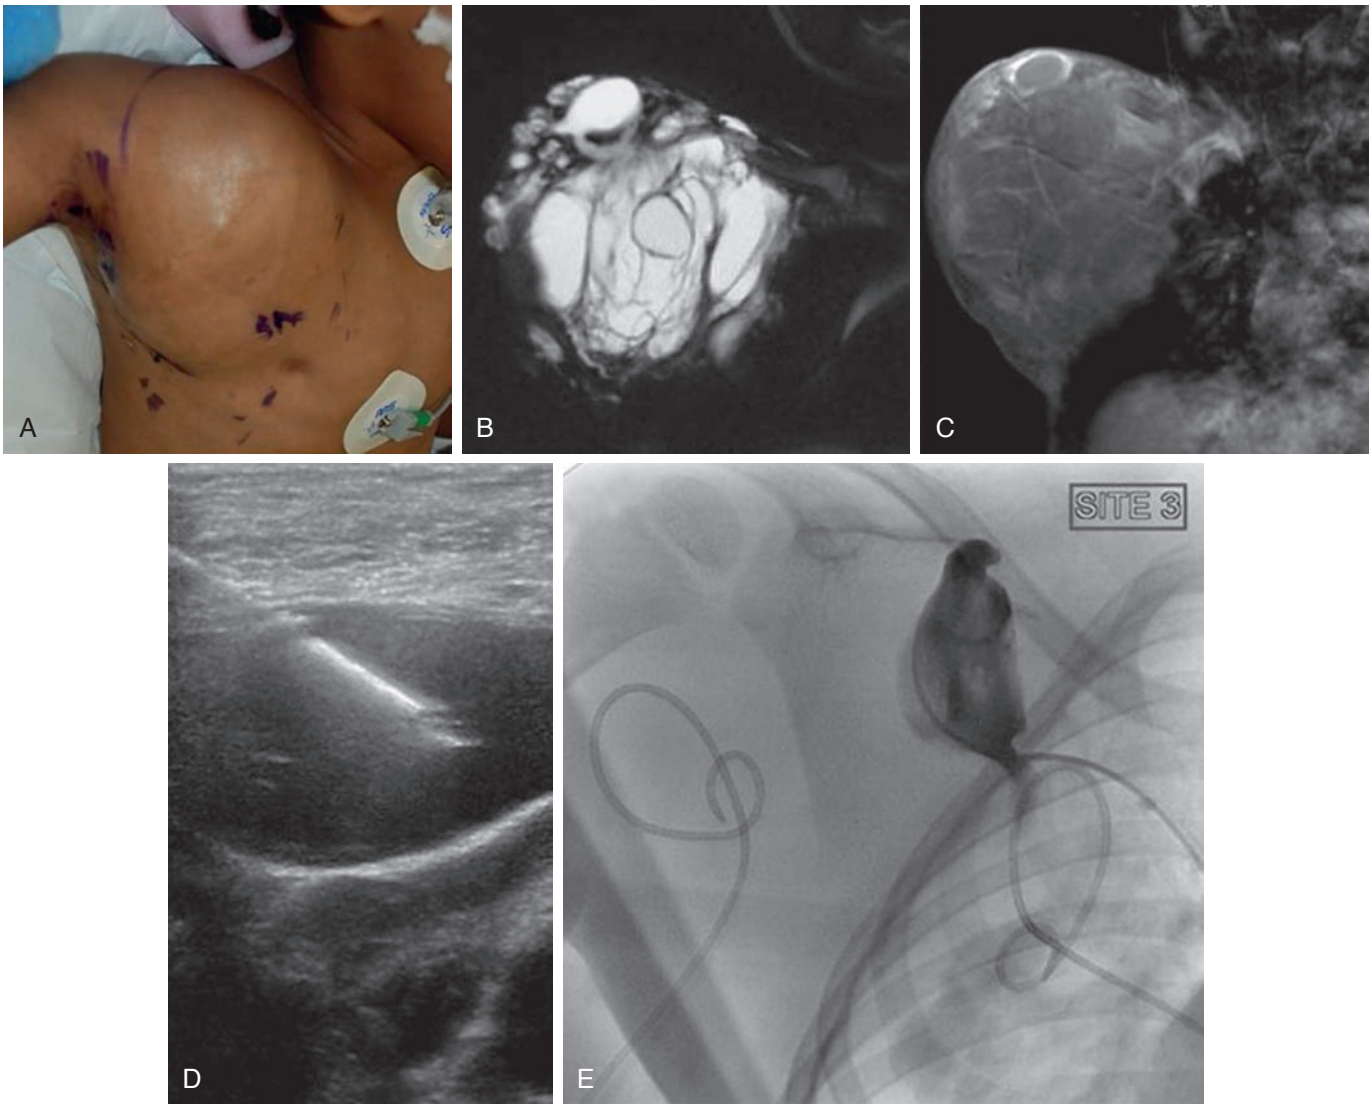

Figure 173.6 Lymphatic malformation (LM). (A) A 4-year-old male with a large mass on his right shoulder/chest wall. It was first noted soon after birth, and he underwent surgical debulking at that time. (B, C) A known LM that had recently grown larger. (C) Coronal T2-weighted image with fat saturation shows a T2 bright multicystic/septate large mass that shows enhancement of only the cyst walls and septa, typical for LMs. The relatively large size of each cyst qualifies for a macrocystic LM. (D) Ultrasound during percutaneous access demonstrates a macrocystic LM. (E) Injection of contrast medium into one of three macrocysts being treated with doxycycline sclerotherapy. (Reproduced from Tekes A, Koshy J, Kalayci TO, et al. S.E. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol*. 2014;69(5):443-457, Fig. 7.)

or neck or in an area susceptible to compartment syndrome, such as the forearm or leg. Most patients who undergo sclerotherapy are admitted for overnight observation and pain management.

Patients should be evaluated in the clinic 1 week following the procedure to assess for complications and again in 1 to 2 months after MRI has been performed to assess for reductions in symptoms and lesion size. Decreased T2 signal and enhancement are additional radiographic findings that are expected following sclerotherapy.[27] Successful treatment is often incremental, and large multifocal lesions will likely require additional procedures. In many cases clinical results are seen long before imaging results appear significant. As the goal of therapy is to treat the patient's symptoms, treatment can often be stopped despite little change on MRI.

The majority of complications are related to unintentional extravasation of sclerosant outside the lesion.[22] Extravasation is of particular concern during the treatment of superficial VMs because it may result in irritation, blistering, and necrosis of the adjacent skin or mucosal surface. It is paramount that the fluoroscopic images and skin site be carefully examined during the injection phase of treatment in order to detect and minimize extravasation. Extravasation appears as a blush of contrast material outside the lumen of the lesion on fluoroscopy. Any

instance of extravasation necessitates the immediate cessation of sclerosant injection. Skin necrosis is usually heralded by blanching, erythema, or other discoloration of the skin at the end of the procedure. Patients with suspected cutaneous complications should be examined frequently in the clinic and standard wound care, including topical antibiotics and clean dressings, should be practiced. Patients with areas of large or deep ulceration should be referred to a wound care specialist.

Hematuria, a consequence of sclerosant-induced hemolysis, is another common complication, particularly when large doses of sclerosant and intravenous contrast material are used. Placement of a urinary catheter is helpful to detect and monitor this complication, which tends to be a minor transient finding that resolves with oral and intravenous hydration.[28]

Acute compartment syndrome is an uncommon complication that can arise when the treated lesion is located in a fascia-bound compartment, such as a muscular compartment in an extremity. Inflammatory swelling causes high intracompartmental pressures and insufficient blood supply to the muscles and nerves. Recognition of the intracompartmental location of a lesion is important for proper treatment planning, as the inflammatory response can be mitigated by the avoidance of excessive treatment. Postprocedurally, ice packs should be applied and tight circumferential dressings avoided. Steroid therapy (e.g., intravenous dexamethasone) can be considered for patients who do not respond to more conservative measures.

Additional Endovascular Techniques and Other Therapies

Magnetic Resonance Imaging–Guided Sclerotherapy

The majority of sclerotherapy procedures can be performed with ultrasound and fluoroscopy for image guidance. Both of these modalities are easy to use and widely available. However, some vascular malformations, such as those deep in the abdomen or beneath scar or bone, are not adequately visualized or targeted with US. If these lesions require treatment, interventional MRI should be considered. The technique commonly relies on steady-state free precession imaging, which is a gradient echo–based MRI technique that provides real-time sequences for needle targeting and the monitoring of sclerosant delivery.[29-31] Large initial investments in equipment and MR-specific training are necessary prerequisites that currently hinder widespread usage of this useful technique.

Coil and Glue Embolization

Permanent embolic agents, such as coils and glue (e.g., N-butyl cyanoacrylate), can be used for percutaneous closure of draining veins and capacious venous spaces that are not responding to sclerotherapy.[32,33] Glue can be injected into vascular malformations through a percutaneous needle, whereas coils require placement of an endovascular catheter. Preoperative coil and glue embolization of VMs can be performed to reduce surgical morbidity and promote complete surgical excision by reducing disease volume and intraoperative blood loss.

Laser Therapy

Laser photocoagulation is an option to treat facial VMs.[34] Electro-optical synergy, a technique that combines laser light and radiofrequency energy, has also been effective.[35] Laser treatments can be combined with sclerotherapy to treat lesions with superficial and deep components.

Sirolimus

Ideally vascular malformations could be treated noninvasively by medical therapies that target the cellular pathways promoting abnormal vascular growth. In particular, inappropriate activation of the mammalian target of rapamycin (mTOR) intracellular signaling pathway is associated with some vascular anomalies, and the mTOR pathway has been proposed as a target for therapy.[36,37] Sirolimus, a compound that inhibits the mTOR pathway, has been approved by the US Food and Drug Administration for the treatment of lymphangioleiomyomatosis, which is also associated with abnormal activation of mTOR. More recently, a prospective phase II clinical trial has demonstrated sirolimus to be efficacious and safe in treating complicated vascular anomalies that were refractory to other therapies, including medication, interventional procedures, and surgery.[36]

TREATMENT OF HIGH-FLOW VASCULAR MALFORMATIONS

Introduction

High-flow vascular malformations include *AVM and AVF. AVMs* are high-flow vascular anomalies composed of a complex primitive network of arterial and venous channels (a nidus)—a network that bypasses the normal capillary bed. Arterial inflow is diverted via these shunts into draining veins, resulting in local and occasionally systemic hemodynamic disturbances such as tissue ischemia and venous hypertension. AVMs occur in the central nervous system, limbs, trunk, and viscera.[11,17] Like that of other vascular malformations, the diagnosis of AVMs can usually be made based on history and clinical examination alone.[38] On physical examination, an AVM is commonly detected as a warm palpable mass with overlying skin discoloration and an associated palpable thrill and bruit (Fig. 173.7).[11,17,38,39] In advanced stages, AVMs can cause ulceration of the surrounding soft tissues, bleeding, and high-output heart failure. The Schöbinger staging system subclassifies AVMs according to biologic behavior and clinical effects; it is useful for determining the progression of disease (Table 173.3).[40] The Yakes classification system sorts AVMs by angioarchitecture and suggests specific endovascular treatment options for each subtype (Table 173.4).[41]

AVFs are characterized by a direct connection between an artery and a vein without the presence of an intervening nidus.[42] AVFs can be acquired or congenital, but only congenital lesions are considered vascular malformations. Trauma is the most common cause for AVFs. Congenital AVFs are rare lesions that commonly manifest in infancy as high-output heart failure and are known to occur in certain anatomic locations, such as the

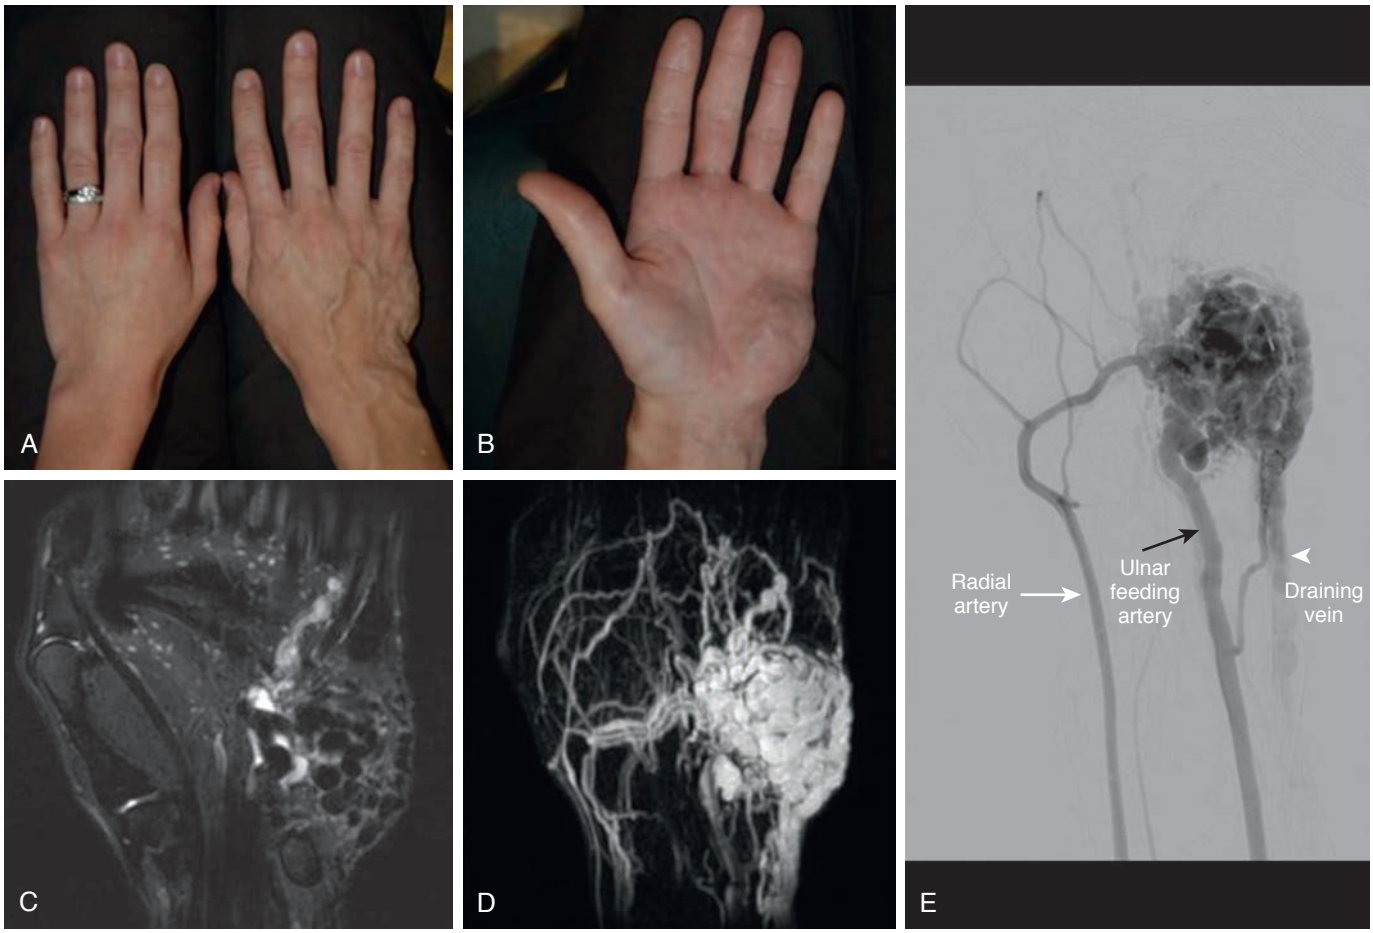

Figure 173.7 Arteriovenous malformation (AVM). (A) A 30-year-old female with a swollen pulsatile mass on the hypothenar eminence of her right hand. View of the dorsal surface of the patient's right hand compared with the left. Note the enlarged draining veins and relatively larger size of the right hand. (B) Note the mass on the hypothenar eminence of the right hand's palmar surface. (C) Coronal T2-weighted image with fat saturation demonstrates a serpiginous tangle of flow voids indicating high flow and infiltration the hypothenar eminence and subcutaneous fat. Note the absence of associated soft-tissue mass. (D) Magnetic resonance angiogram demonstrates strong enhancement of the AVM with arterial feeder from the ulnar artery and venous drainage into the basilic vein. (E) Angiogram demonstrating predominant ulnar feeder *(black arrow)* to the AVM. Note early venous drainage to the basilic vein *(arrowhead)*. Enlargement of the ulnar artery becomes more conspicuous when it is compared with a normal radial artery *(white arrow)*. The draining vein is also patulous *(arrowhead)*. (Reproduced from Tekes A, Koshy J, Kalayci TO, et al. S.E. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol*. 2014;69(5):443-457, Fig. 9.)

TABLE 173.3 Schöbinger Staging of Arteriovenous Malformations

Stage	Clinical Findings
I (Quiescence)	Warm areas of pink-blue discoloration, shunting on Doppler ultrasonography
II (Expansion)	Mass associated with thrill and bruit
III (Destruction)	Mass associated with ulceration, bleeding, pain
IV (Decompensation)	Lesion associated with cardiac decompensation

Shobinger R. In: Proceedings of International Society for the Study of Vascular Anomalies Congress, Rome I, June 23–26, 1996.

vein of Galen malformation of the deep cerebral venous system. AVFs in the extremities may be associated with ischemic complications distal to the arteriovenous shunt, such as claudication, rest pain, and ulceration.[42] AVFs detected on physical examination typically present as a pulsatile masses with an associated bruit.

Imaging

Imaging of an AVM or AVF is usually indicated to evaluate the extent of disease. Gray-scale and Doppler US demonstrate the abnormal network of vascular channels that make up the nidus and connect the feeding arteries to the draining veins. The feeding arteries have high-velocity diastolic (low resistance) blood flow resulting from the lack of a normal capillary bed

TABLE 173.4 Yakes Arteriovenous Malformation Classification

Type	Description	Treatment
I	Direct AVF	Mechanical occluding devices (e.g., coils, plugs)
IIa	Typical AVM nidus	Transcatheter and direct puncture ETOH embolization
IIb	AVM nidus with shunt into an aneurysmal vein	Transcatheter and direct puncture ETOH embolization or coiling the aneurysmal outflow vein
IIIa	Aneurysmal vein whereby the vein wall is the nidus with single outflow vein	Coiling OF the aneurysmal single outflow vein
IIIb	Same as IIIa but with multiple outflow veins	Coiling OF each outflow vein
IV	Infiltrative form of AVM	Transcatheter embolization and direct puncture embolization (50% ethanol and nonionic contrast mixture)

AVF, Arteriovenous fistula; *AVM,* arteriovenous malformation; *ETOH,* ethanol.

between the arteries and veins.[43] The draining veins demonstrate pulsatile high-velocity (arterialized) flow.[43]

Given its wide field of view, MRI is the preferred imaging modality for assessing a large AVM (Fig. 173.7). MRI can determine the extent of the lesion as well as its proximity to critical structures.[11,17,38] In general AVMs appear as T1 and T2 hypointense serpentine flow voids that demonstrate postcontrast enhancement during the arterial phase of MRA.[38,39,43] There may be surrounding edema, fibrin deposition, and tissue overgrowth. Conventional angiography has the advantages of high spatial and temporal resolution and is therefore the most accurate modality to identify and differentiate the feeding arteries, nidus, and draining veins.

Ultrasound examination of an AVF demonstrates the abnormal direct connection between an artery and vein without a nidus. The feeding artery has low-resistance flow, and the draining vein has arterialized flow. Aliasing around the AVF can occur, representing perivascular thrill. MRA similarly demonstrates the abnormal arteriovenous connection with early filling of the draining vein.

Treatment of Arteriovenous Malformations

AVMs are recalcitrant lesions with an inherent ability to persist despite therapeutic intervention. The main treatment options for AVMs are surgical resection and endovascular embolization.[11,17,38,44] Both therapies target the nidus of the lesion with the goal of eliminating the abnormal arteriovenous shunt. When the nidus is completely removed, surgical resection is associated with a reduced recurrence rate. However, the architecture of the nidus if often complex, making complete surgical resection difficult.[38,45] In these cases, embolization may be performed either as a primary treatment or as neoadjuvant therapy prior to surgical resection.[11,17,38,42,45]

Endovascular closure can be quite challenging and should be attempted only after careful study of the lesion's vascular anatomy. Treatment should be directed at the nidus, which can be difficult to identify due to the presence of multiple tortuous feeding arteries that overlap and obscure the more distal areas of shunting. Treatment of the nidus results in improved long-term outcomes and fewer complications.[46]

Embolization can be performed by approaching the AVM from the arterial side or the venous side. In approaching from the arterial side, the main feeding artery of the AVM is selected with a guiding catheter. A microcatheter is then advanced to subselect the distal branches just proximal to the arteriovenous site of shunting. A sclerosant agent like ethanol or a semiliquid embolic agent like N-butyl cyanoacrylate or ethylene vinyl alcohol copolymer (Onyx) is then injected.[38,46-48] Additional branches are subselected and treated as needed.

A venous approach is possible when there is a single draining vein or venous sac. When there are multiple draining veins, treatment from the venous side is unlikely to be successful. However, when possible, the venous approach is often preferred, as the risk of nontarget embolization of normal nutrient arteries is decreased. Additionally, treatment of the venous side often decreases the number of arterial feeders, which makes complete obliteration of the nidus more feasible.[49] The technique involves subselection of the draining vein with a catheter. Prior to the injection of a sclerosant or liquid embolic agent, the venous outflow can be occluded with a balloon catheter to prevent uncontrolled spread of the embolic/sclerosant agent. When a large sac is present, N-butyl cyanoacrylate and coils are typically used to fill the capacious channel.

When transarterial or transvenous access is not possible and the AVM is in an amenable location, direct percutaneous access and treatment of the lesion can be performed.[11,17,38] Liquid agents, semiliquid agents, and coils can all be delivered through the percutaneously placed needles.

Approximately 57% of AVMs treated with surgical resection and embolic therapy will recur within the first year following treatment, and approximately 98% of AVMs will enlarge or recur within 5 years following treatment.[38,45] The patient should therefore be followed regularly for at least 5 years. Additional interventions should be performed when lesions recur or cause symptoms.

Complications of arterial side embolization are typically related to treatments performed too proximally in the arterial feeder. Proximal treatment provides ineffective therapy; it also increases the risk of nontarget embolization of normal nutrient arteries and leads to loss of future arterial access to the nidus and recruitment of the collateral vessels that foster growth of the AVM.[11,17,38]

Treatment of Arteriovenous Fistulas

Acquired AVFs commonly resolve spontaneously within a few months, allowing for a conservative approach consisting of serial

imaging and clinical evaluation. Congenital AVFs and AVFs with large fistulous connections that do not close spontaneously require more invasive measures. Treatment options include surgical or endovascular repair.[42] Endovascular placement of a covered stent over the fistula is the most common approach. When there is a long fistulous tract, coil embolization is another possible approach.[50]

SYNDROMES ASSOCIATED WITH VASCULAR MALFORMATIONS

A number of syndromes are associated with vascular malformations (Table 173.5). These include KTS, BRBNS, unilateral limb VM, mucocutaneous VMs, Sturge-Weber syndrome, Proteus syndrome, congenital lipomatous overgrowth, vascular malformations, epidermal nevi (CLOVE) syndrome, and Maffucci and Gorham-Stout syndromes, all of which are associated with low-flow vascular malformations.[51] Parkes-Weber syndrome (PWS); hereditary hemorrhagic telangiectasia (HHT); and Cobb, Wyburn-Mason, Bannayan-Riley-Ruvalcaba, and Cowden syndromes are associated with high-flow vascular malformations.[51] The following discussion delves into some of the more commonly encountered syndromes associated with vascular malformations.

Klippel-Trénaunay Syndrome

KTS is characterized by the clinical triad of capillary malformation of the skin (port wine stain), low-flow (capillary-venous-lymphatic) vascular malformation, and local soft tissue and bony overgrowth.[52,53] KTS is diagnosed by the presence of at least two out of three of these clinical elements. The syndrome is typically sporadic, although familial cases have been reported.[54] The vascular malformation can occur anywhere in the body but typically manifests as a persistent embryonic vein.[43,52] The lateral marginal vein (also known as the vein of Servelle) is the most common anomalous vein.[55] Similar to other low-flow vascular malformations, the lymphatic and vascular malformations present in KTS may be treated with percutaneous sclerotherapy. Patients with superficial valveless varices may experience limb swelling and pain and can be treated with compression garments and intravenous laser therapy. The deep venous system can also be anomalous (hypoplasia, aplasia, valvular incompetence), and patency and adequacy of the deep system should be confirmed prior to occlusion of superficial varices to avoid exacerbating venous insufficiency.[56]

AVMs, Arteriovenous malformations; *CMs,* capillary malformations; *LMs,* lymphatic malformations; *VMs,* vascular malformations.

Parkes-Weber Syndrome

PWS is characterized by a congenital AVF with associated varicosities and overgrowth (Fig. 173.8).[52] A red vascular skin stain (also known as a "pseudocapillary malformation") may be present, representing part of the high-flow vascular malformation rather than a true capillary malformation.[53] PWS can affect any limb but most commonly occurs in the lower extremity.[57] Varicosities form as a result of high-flow shunting from the AVF. Lymphedema and lymphatic vesicles can be seen in the skin. High-output congestive heart failure can result if there are multiple AVFs. Conservative management of PWS is preferred, as invasive therapies can worsen the vascular shunting through an AVF.[53] In complicated cases, such as those associated with intractable pain or heart failure, superselective arterial embolization of the AVF can be performed.[53]

Hereditary Hemorrhagic Telangiectasia

HHT, also known as Osler-Weber-Rendu disease, is an autosomal dominant disorder characterized by the presence of AVMs in multiple organ systems including the brain, lung, liver, and gastrointestinal tract.[11,58] The diagnosis of HHT is made clinically on the basis of the Curaçao criteria, which assess for the presence of epistaxis, telangiectasias, visceral lesions, and an associated family history (a first-degree relative with HHT).[59] The HHT diagnosis is considered definite if three or four criteria are present, possible or suspected if two criteria are present, and unlikely if fewer than two criteria are present. Recurrent and severe epistaxis related to mucocutaneous telangiectasia is the most common presentation. Treatment of HHT is aimed at decreasing the amount of hemorrhage and minimizing complications. In the case of acute hemorrhage, volume resuscitation with intravenous fluid or blood products may be needed. Patients with chronic anemia should receive iron supplementation. Patients with pulmonary AVMs may have symptoms of dyspnea, hemoptysis, hemothorax, and stroke.[60] Pulmonary AVMs with feeding arteries measuring greater than 2 to 3 mm in diameter should undergo transarterial embolization with retrievable permanent embolics.[58] Hepatic involvement in HHT ranges from small telangiectasias to large AVMs.[61] Intrahepatic shunting is the result of solitary or multiple abnormal connections between the hepatic artery and portal vein, hepatic artery and hepatic vein, and portal vein and hepatic vein. Patients who experience

Figure 173.8 (A) Foot and lower leg of a 24-year-old male with Parkes-Weber syndrome. Note thickened skin lesions as outlined by *white arrows*. Similar changes are also noted in the anterior lower shin. (B) Lateral arteriogram of the foot from a popliteal injection. Note hypervascularity of the arteriovenous malformation (AVM) nidus *(white arrows)* underneath the thickened skin lesions on photo (A). Note that the dorsalis pedis artery is the feeding artery *(black arrow)*. The posterior tibial artery *(arrowhead)* is marked for orientation purposes. (C) Selective arterial phase on the dorsum of the foot on a lateral view. Note the catheter in the dorsalis pedis artery *(black arrow)*. The AVM nidus (*white arrows*) demonstrates early arterial enhancement with an early draining vein *(arrowhead)*. (D) Selective arterial phase on the dorsum of the foot on an anteroposterior view. Note the microcatheter in the distal part of the feeding artery *(black arrow)* supplying the nidus of the AVM *(white arrows)*. The draining vein is marked with an *arrowhead*. Mitchell Vascular Anomalies Flow Chart (SEMVAFC): a visual pathway combining clinical and imaging findings for classification of soft-tissue vascular anomalies. *Clin Radiol*. 2014;69(5):443-457, Fig. 15.)

complications—such as high-output cardiac failure, portal hypertension, and encephalopathy—should receive medical therapies directed at those conditions (e.g., diuretics, beta blockers, antiarrhythmics).[61] Patients who have progressive worsening of their clinical condition despite medical therapy should be considered for invasive treatment, including transarterial embolization and orthotopic liver transplantation. Cerebral AVMs may be treated with transarterial embolization, stereotactic radiation, or surgery or a combination of methods.[58] Gastrointestinal AVMs are managed with endoscopic photoablation or electrocautery, although episodes of severe acute gastrointestinal hemorrhage may necessitate segmental bowel resection.[58]

CONCLUSION

Vascular malformations are nonneoplastic vascular anomalies that are subdivided into low-flow and high-flow lesions. Common low-flow vascular malformations are VMs and LMs, which are most commonly treated with percutaneous sclerotherapy. High-flow malformations include AVMs and AVFs, which are treated with surgery, endovascular intervention, or both.

Endovascular Therapy 2285
Operative Repair Versus Endovascular Therapy 2286

The earliest description of an arteriovenous fistula (AVF), the abnormal communication between an artery and vein, is attributed to William Hunter, who in 1761 reported two cases of brachial AVFs following attempted phlebotomy. He also described the adaptive enlargement of the artery and veins proximal to the AVF, as well as the associated hissing noise ("bruit") and tremulous motion ("thrill").[1,2]

AVFs were infrequently identified and diagnosed until the introduction of high-speed projectiles during 19th-century conflicts, which altered the magnitude and complexity of military injuries. Successive military conflicts and the increase in blunt, penetrating, and iatrogenic trauma among civilians have resulted in a greater number of vascular injuries (VIs) and, as a consequence, acquired AVFs.[3-9]

Acquired arteriovenous fistulas
Etiology
Pathogenesis
Operative and Endovascular Repair

ETIOLOGY AND INCIDENCE

AVFs can be either congenital or acquired. Vascular malformations, including congenital AVFs, are discussed in Chapters 171, 172, and 173. The focus of this chapter is acquired AVFs, including those caused by trauma and the small number which occur spontaneously, usually from erosion or rupture of an atherosclerotic or infected aneurysm into an adjacent vein.

Traumatic Arteriovenous Fistulas

The anatomic distribution of VIs and AVFs is related to the mechanism of injury and varies between military personnel and civilians. Blast injuries due to improvised explosive devices (IEDs) account for 73% of VIs among military personnel, whereas penetrating trauma due to gunshot wounds (GSWs) or stab wounds (SWs) account for the majority (61.7%) of civilian VIs reported to the National Trauma Data Bank.[10,11] In an article by Robbs et al. which included 210 civilian traumatic AVFs, SWs accounted for 63%, whereas GSWs accounted for 26% and blunt trauma for 1%.[12] AVFs due to SWs involve the cervicomediastinal arteries in 54% to 75% of cases and most frequently (21%) the common carotid artery. Although extremity and abdominal penetrating VIs occur with almost equal frequency (40% vs. 32%) in the civilian population, in the military population VIs predominate in the extremities. This is secondary to the use of protective body armor. Acquired AVFs involve the upper and lower extremities in 22% and 20% of cases, respectively, whereas thoracic and abdominal AVFs are encountered in 4% of patients.[12-14]

Iatrogenic Arteriovenous Fistulas

Iatrogenic injuries that cause AVFs usually result from percutaneous cardiac and vascular procedures, central venous catheterization, orthopedic procedures on the lumbar spine and knee, diagnostic kidney and liver biopsies, and percutaneous insertion of biliary and urinary drainage catheters. The right common femoral artery (CFA) remains the most common site of iatrogenic injury (37%) in the lower extremities.[15] The increase in the number of percutaneous interventions being performed would be expected to result in a greater number of iatrogenic AVFs. However, the use of smaller gauge (21- vs. 18-gauge) angiographic needles inserted under ultrasound (US) guidance has significantly reduced the number of access site complications from 3.4% (using fluoroscopy) to 1.4 % (with US) in patients undergoing predominantly cardiac angiography.[16] US guidance reduced access site complications by 43% in patients undergoing peripheral interventions. Whether the addition of closure devices will further reduce femoral access site complications remains uncertain.[17]

Spontaneous Arteriovenous Fistulas

First described by Syme in 1831, rupture or erosion of an atherosclerotic, inflammatory, or mycotic aortic or iliac aneurysm into the inferior vena cava (IVC) (Fig. 174.1), iliac vein (Fig. 174.2), or retroaortic left renal vein (Fig. 174.3) can result in spontaneous AVFs.[18-23] There have been a few isolated case reports of spontaneous AVFs in patients with syphilitic aortitis, HIV arteritis, and Marfan and Ehlers-Danlos syndromes.[19,24]

Arteriovenous Fistulas in Specific Locations

Carotid Artery Arteriovenous Fistulas

Carotid artery injury constitutes 5% to 11% of all arterial injuries and usually results from SWs or GSWs, therapeutic or diagnostic catheterization, or blunt trauma to the skull or cervical spine. A fistula between the carotid artery and the internal jugular vein or its tributaries occurs following 4% to 27% of such injuries.[7,12,14,25-28]

(B) Aortogram demonstrating an aortic aneurysm and bilateral iliac aneurysms associated with an arteriovenous fistula between the right common iliac artery and vein treated with an aortic endograft.

Vertebral Artery Arteriovenous Fistulas

Vertebral artery (VA) AVFs occur in 0.7% to 7.4% of cases of penetrating trauma. The AVF is usually between the VA, its muscular or radicular branches, and the internal jugular and/or vertebral veins. Iatrogenic injury during operative procedures on the cervical spine and catheterization of the internal jugular vein accounts for approximately ⅔ of cases, and cervical spine fractures due to blunt trauma, chiropractic manipulation, or closed head injury, GWs, and SWs for the remaining ⅓.[29-31]

Axillary and Subclavian Arteriovenous Fistulas

Approximately 3% of all neck- and chest-penetrating trauma is associated with injury to the subclavian vein (44%), artery (39%), or both (17%).[32] Inadvertent puncture of the carotid or subclavian arteries occurs in up to 8.4% of cases of attempted central venous catheterization,[25,26] and the incidence of AVFs following subclavian vein catheterization is estimated at 0.58%.[33] Penetrating axillary artery injuries and fractures of the clavicle or first rib are rare causes of AVFs.[32,34-36]

Brachial, Radial, and Ulnar Arteriovenous Fistulas

Upper extremity trauma accounts for 25% to 40% of all VIs.[7,13] The brachial and forearm arteries are involved in 10% to 22% of cases.[6] The radial and ulnar arteries are frequently used for cardiac interventions; AVFs occur in 0.02% to 0.04% of cases. Peripherally inserted central catheters (PICC lines) may also be complicated by AVFs.[37-40]

Femoral Arteriovenous Fistulas

Penetrating injuries due to GSWs, SWs, shrapnel injuries from IEDs, or long bone fractures may result in femoral AVFs.[6,7,41-43] The incidence of AVFs as a result of such injuries varies considerably between the military and civilian populations. In a review of 558 AVFs due to military injuries, 28% involved the superficial femoral or profunda femoris arteries,[14] whereas in a civilian series of AVFs predominantly due to SWs, the CFA was involved in 12% of cases (Fig. 174.4).[12] Sporadic cases of spontaneous AVFs between the superficial femoral artery and vein have also been described.[24] Despite the less frequent use of the CFA as the preferred access site for cardiac and vascular interventions, it remains the most common site of iatrogenic AVFs, with an incidence of 0.06% to 0.86% when diagnosed by physical exam but 2.8% using duplex US.[41,42] Femoral AVFs are slightly more frequent after interventional than diagnostic procedures. The majority of AVFs close spontaneously: in one study, only 11% became symptomatic and required operative repair (OR).[44] Femoral and external iliac artery AVFs are a rare complication of endovenous laser ablation for varicose veins.[45,46] The risk factors predisposing to iatrogenic femoral AVFs are listed in Box 174.1.

Popliteal Arteriovenous Fistulas

Popliteal AVFs have similar etiologies to femoral AVFs. They account for approximately 16% of AVFs reported in the Vietnam registry and 5% to 14% of civilian AVFs.[12,14,47] Blunt trauma associated with comminuted femoral and proximal tibial fractures

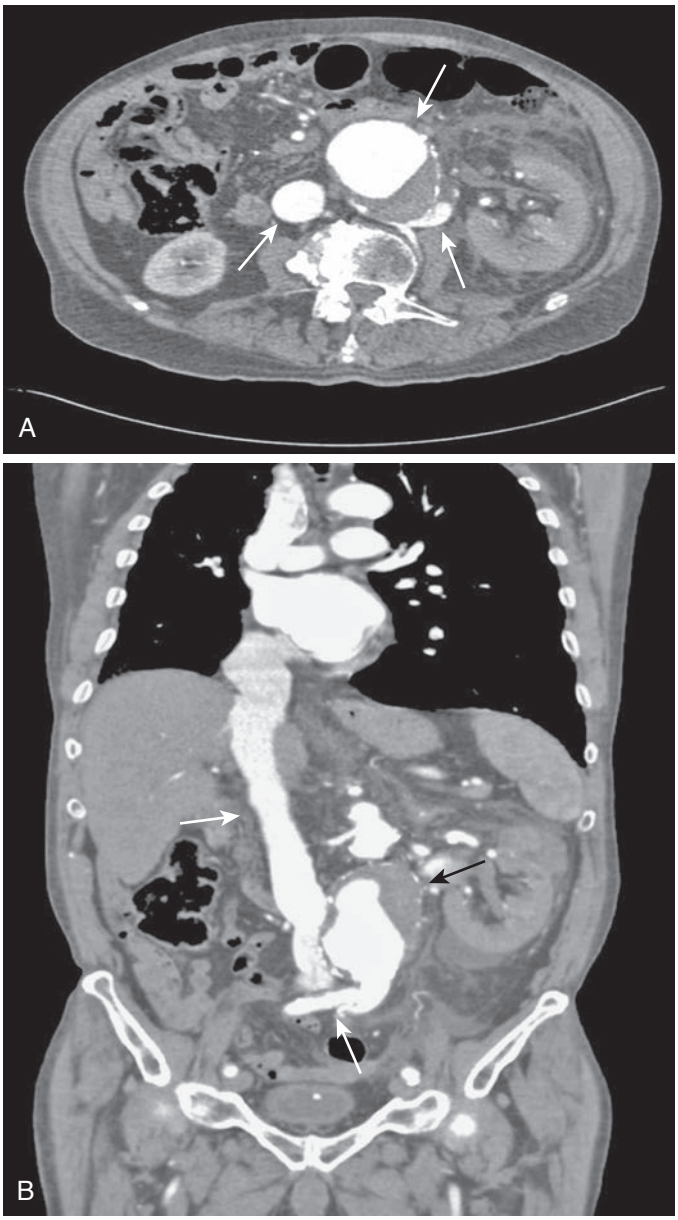

Figure 174.3 (A) Axial CT scan demonstrating an aortorenal arteriovenous fistula. Contrast material is present in the abdominal aortic aneurysm *(top arrow)*, inferior vena cava *(left arrow)*, and retroaortic left renal and lumbar veins *(right arrow)*. (B) Sagittal reconstruction of the CT scan in (A) showing contrast material in the aneurysm *(black arrow)*, inferior vena cava *(top white arrow)*, and retroaortic left renal and lumbar veins *(bottom white arrow)*.

and orthopedic procedures on the knee may also be complicated by AVFs (Fig. 174.5).[48,49] The number of iatrogenic popliteal AVFs can be expected to increase, due to the more frequent use of popliteal access for interventions to treat deep vein thrombosis and chronic venous insufficiency.

Tibial and Peroneal Arteriovenous Fistulas

AVFs of the tibial and peroneal arteries are a recognized complication of comminuted fractures, blast fragment injuries, balloon catheter thrombectomy, and atherectomy of the tibial vessels.[50,51] Approximately 24% of the AVFs reported in the Vietnam registry occurred in the tibial and peroneal arteries.[14] The more frequent use of retrograde tibial access to recanalize occluded lower extremity arteries in patients with critical limb ischemia (CLI) may increase the risk of AVFs in these locations.[52-56]

BOX 174.1 Factors Predisposing to Iatrogenic Femoral Arteriovenous Fistula

Female gender	Age >65
Emergency procedures	Sheath size >8 F
Intensity of anticoagulation	High body mass index
Low distal puncture	Severe femoral atherosclerosis
Hypertension	Left-sided/multiple punctures
Prosthetic grafts	Hostile groin

Aorto-iliac Arteriovenous Fistulas

Rupture or erosion of an AAA into the IVC accounts for 80% to 90% of acquired aortocaval fistulas (ACFs). GSWs, shrapnel, or SWs account for the remaining 10% to 20% (see Fig. 174.1).[18-22] Less commonly, iatrogenic injury during peripheral arterial or cardiac catheterization or lumbar disk surgery and, rarely, blunt trauma have been associated with ACFs.[57-60] Iliac AVFs account for 0.4% to 1.4% of AVFs and are usually the result of penetrating trauma or lumbar disc surgery.[12,14,61]

VI occurs in up to 0.05% of lumbar disc procedures. Anatomic anomalies, such as a low aortic bifurcation at L4-L5 (18%) and degenerative changes of the anterior spinal ligament, may contribute to VIs in this location.[62-64] VIs at the L3-L4 disc space predominantly involve the aorta and IVC; the majority of iliac VIs occur with L4-L5 and L5-S1 disc space surgery. The common iliac arteries, which lie immediately anterior to the L4-L5 lumbar disc space, are the most commonly injured vessels (right CIA 43%; left CIA 29%).[65,66]

Renal Arteriovenous Fistulas

The majorities of renal AVFs occur after renal biopsies but can result from trauma, surgery, percutaneous interventions, tumors, inflammation, or erosion of an aneurysm directly into a vein. The incidence of biopsy-associated renal AVFs range from 9% to 18%. Factors predisposing to biopsy-related renal AVFs include use of a large-bore needle, lack of radiologic guidance when performing the biopsy, medullary penetration, and the presence of atherosclerotic vessels.[67,68] Other causes of renal AVFs include placement of percutaneous nephrostomy tubes (Fig. 174.6), laser lithotripsy, and mass ligation of the renal pedicle.[67-70] Aortic and renal artery aneurysms may also erode into a retroaortic or normally located renal vein or its tributaries.[22,23] Isolated renal AVFs due to blunt and penetrating trauma are uncommon.[71]

Splenic, Hepatic, and Mesenteric Arteriovenous Fistulas

Penetrating injuries involving the splenic, hepatic, superior, and inferior mesenteric arteries or their tributaries may result in fistulas between their contiguous veins, the portal vein, hepatic veins, or the IVC.[72-85] Splenic AVFs may result from blunt or penetrating intraabdominal trauma, mass ligation of the splenic pedicle, iatrogenic injury during splenoportography, and, rarely,

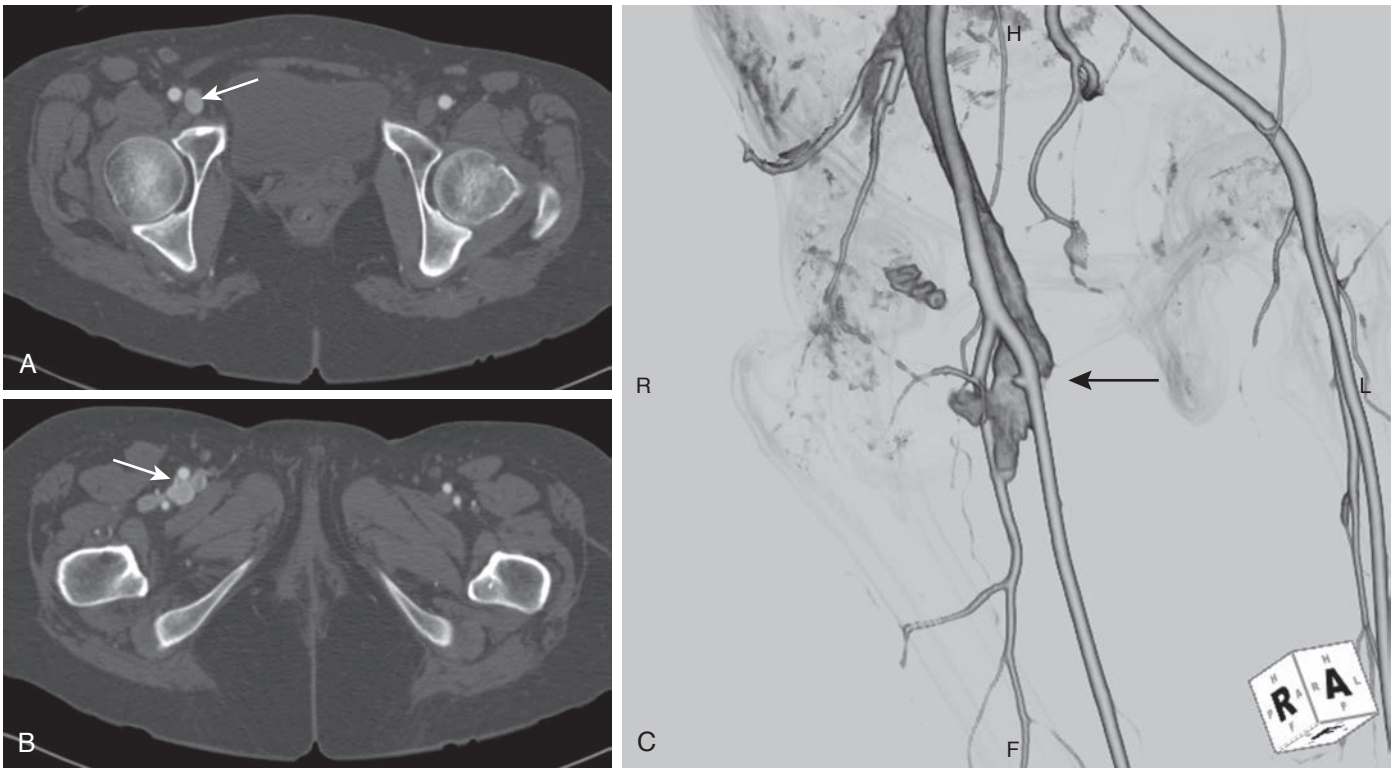

Figure 174.4 (A) Axial CT pelvis with intravenous contrast in a patient with history of prior cardiac catheterization demonstrates opacification of the right common femoral vein *(arrow)* on the arterial phase image. (B) More inferiorly, a small vascular connection *(arrow)* is noted between the right superficial femoral artery and femoral vein consistent with an arteriovenous fistula. erosion of a pancreatic pseudocyst into the splenic artery and vein.[73-77] Forty-four percent of splenic AVFs are due to rupture of a noncalcified splenic artery aneurysm (SAA) into an adjacent vein; this may be the first indication of the presence of an SAA.[5,77-83] Hepatic AVFs are most commonly the result of penetrating or vehicular trauma but may occur after percutaneous needle biopsy, transhepatic diagnostic catheterizations, biliary drainage, or TIPS procedures (Fig. 174.7).[77-83] Hepatic AVFs may be either intrahepatic or extrahepatic and occur in 5.4% of patients after percutaneous needle biopsy.[77-83] Hepatic artery aneurysms (HAAs) and carcinomas may also erode into an adjacent vein, resulting in an AVF.[79,86,87] AVFs of the superior and inferior mesenteric arteries are rare and are usually the result of penetrating trauma, iatrogenic injuries, or mass ligation of the vascular pedicle during bowel resection.[84,85]

PATHOPHYSIOLOGY

The natural history of an AVF is determined by the diameter of the artery and vein, the size and location of the fistula, the adequacy of the collateral circulation, and the competence of the distal venous valves. AVFs may close spontaneously, decrease in size, or progressively enlarge as a result of degenerative changes within the arterial wall.[88,89]

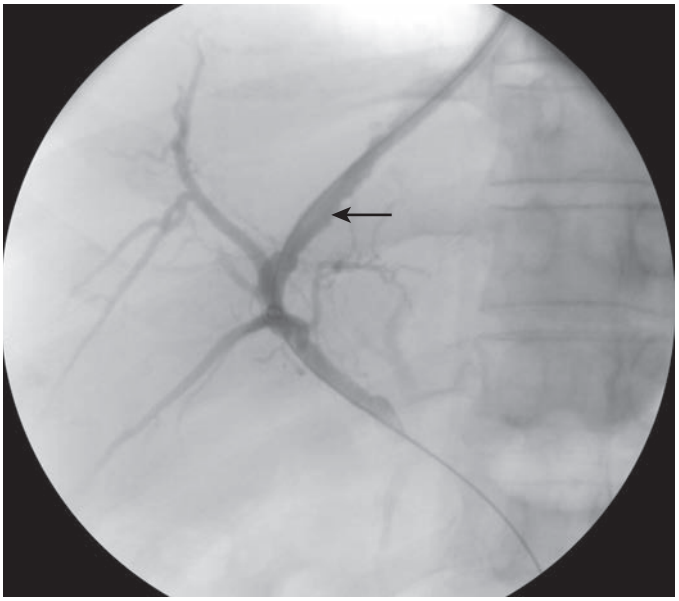

Figure 174.7 Angiography through the vascular sheath during a transjugular intrahepatic portosystemic shunting procedure demonstrates inadvertent puncture of the right hepatic artery with a fistula to the right hepatic vein *(arrow)*.

Fistula Size and Flow

Holman and Taylor established that antegrade flow in the artery distal to an AVF was maintained when the cross-sectional area of the fistula was ≤1.5 times the diameter of the inflow artery but was diminished or reversed when the fistulous opening exceeded the diameter of the inflow artery by greater than threefold.[90] Flow in the artery proximal to the fistula increased up to fivefold if the fistula was ≥1.5 the arterial diameter and eightfold if the opening was greater than 3 times the diameter of the inflow artery.[91] Flow rates of greater than 350 mL/min are associated with failure of a fistula to close spontaneously.[41] Iatrogenic femoral AVFs are usually small with low flow rates and therefore infrequently result in congestive heart failure (CHF). The larger-diameter sheaths used for aortic and complex peripheral and venous interventions, TIPS procedures, and orthopedic instrumentation of the lumbar spine and the knee may result in larger defects and AVFs with higher flow rates, and greater risk of cardiac decompensation.

Chronic Changes

In chronic AVFs the increase in hemodynamic shear stress results in attenuation of the arterial wall, accompanied by calcification and lipid deposition in the inflow artery. These structural changes result in elongation, tortuosity, and ultimately aneurysmal dilatation at the site of the fistula.[92-94] The adjacent vein also dilates and becomes tortuous and thickened or "arterialized" with pulsatile flow. The structural changes in the artery and vein become evident at approximately 2 months and established by 15 months but appear to be reversible if the AVF is repaired within 2 years.[92-94] The direction of flow in the artery distal to an AVF is determined by the size of the fistula. Flow is usually antegrade with small fistulas but is reversed with larger defects, owing to the increase in collateral flow distal to the fistula. The high venous pressure at the site of the fistula results in dilatation and valvular incompetence of the distal vein, producing chronic venous insufficiency.

Cardiac Effects

In patients with large AVFs, the increase in preload results in cardiomegaly and dilatation of the aorta and vena cava proximal to the fistula. These structural changes may develop within weeks to months or progressively increase over months to years. Young healthy males are more likely to compensate for the increase in preload than older individuals, but, ultimately, if left untreated, high-output CHF ensues.[89]

CLINICAL PRESENTATION

History

Symptoms in patients with large AVFs may arise from increased venous return (CHF), diversion of arterial blood flow (ischemia), or venous hypertension (varicosities, edema). An antecedent history of trauma, catheter-based interventions, or AAA should be elicited in all patients. The majority (75%) of patients with small AVFs are asymptomatic. The most common symptoms are thrill or bruit (61%-96% of cases) or a pulsatile mass (20%-52% of cases).[12,14] The acute onset of abdominal or back pain is the presenting complaint in 70% to 80% of patients with spontaneous aortic and iliac AVFs. Other symptoms and signs may occur as a function of the location of the AVF. Although CHF is most commonly associated with aortic and iliac AVFs, symptoms of cardiac decompensation may occur in patients with large extremity, visceral, or carotid AVFs.[95]

Physical Examination

Neck and Upper Extremities

A rapidly expanding or pulsating hematoma, carotid bruit or thrill, and dilated neck veins suggest the diagnosis of a carotid-jugular AVF. Neurologic deficits due to embolization or shunting of blood through the fistula may also be present.[13,28] The clinical diagnosis of vertebral AVFs is often unsuspected because only 50% of patients present with overt signs or symptoms of injury; neurologic symptoms are rare. Subclavian, axillary, and brachial AVFs may manifest with pulse deficits, blood pressure abnormalities, arm swelling, dilated venous tributaries, hand ischemia, or a pulsatile mass with a thrill and bruit. Radial and ulnar AVFs are usually asymptomatic and manifest as a thrill or bruit over a small pulsatile mass and, rarely, digital embolization.

Lower Extremities

A careful examination of the groin and lower extremity for evidence of an expanding or pulsatile hematoma and/or a thrill or bruit should be performed. Temporary compression of the artery proximal to the fistula should result in slowing of the heart rate and a reduction in pulse pressure (Nicoladoni-Branham sign). Leg swelling with dilated or varicose veins, pigmentation, and ulceration may be present in more chronic cases. Although signs and symptoms of arterial ischemia are rare, the presence of peripheral pulses and segmental blood pressures should be documented. Pedal access–related fistulae between the crural arteries and their venae comitantes usually present incidentally as a small mass with an overlying thrill and bruit.[96]

Chest and Abdomen

A pulsatile mass or pronounced aortic pulsation with an epigastric thrill or bruit is suggestive of an ACF. A holosystolic murmur is present in 75% of ACFs, although it may be absent if there is a large amount of thrombus present within the aneurysm. A thrill is palpable in 25% of patients.[19-22,74] In patient with AVFs to the aorta or iliac arteries following lumbar disc surgery, symptoms may not manifest until months to years after the event. In these cases a lower abdominal bruit may be the only finding. Signs of CHF and lower extremity venous hypertension are characteristic findings in patients with larger fistulas.[97]

Small renal AVFs are usually discovered incidentally by the presence of a bruit over the kidney. Blood flow through larger renal AVFs may approach 60% to 82% of total ipsilateral flow and result in ischemia of a significant portion of the kidney, leading to hypertension.[68] Patients with spontaneous aortorenal

AVFs may present with abdominal pain, hematuria, proteinuria, renal impairment of varying severity, a varicocele, non–contrast-enhancing "silent" left kidney, and hemodynamic instability[22,98] These patients often present late because they are first evaluated for hematuria by the urologist.[99]

The clinical findings in patients with visceral AVFs include jaundice, hepatosplenomegaly, prominent venous collaterals, and epigastric bruits. Hematochezia and hematuria due to rupture of mucosal veins in the rectum and bladder may be present in 11.5% to 35% of cases.[100]

DIAGNOSTIC EVALUATION

Radiographs should be obtained in all patients with suspected AVFs for evidence of prior trauma (bullet or metal fragments), abnormal calcifications, and signs of CHF. The diagnostic algorithm then proceeds to noninvasive imaging to identify the characteristics of the AVF, with either duplex US, computed tomographic angiography (CTA), or magnetic resonance angiography (MRA). Depending on the outcomes of these, additional testing, such as ankle-brachial indices or venous or carotid duplex imaging, are obtained. A 12-lead electrocardiogram and/or two-dimensional echocardiogram may be obtained if CHF is suspected. Catheter-based angiography and/or cardiac catheterization are reserved for treatment and/or diagnostic uncertainty. Endoscopy may be indicated in patients with active gastrointestinal bleeding or a history of bleeding from esophageal varices or gastric ulceration.

Color-Flow Duplex Ultrasound Imaging

Duplex ultrasound (DUS) imaging is an appropriate initial choice for the diagnosis of acquired chronic AVFs. Characteristic findings include visualization of the AVF and a color mosaic in the tissues at the level of the fistula. Loss of triphasic arterial waveforms proximal to the fistula, diminished or reversal of flow in the distal artery, and continuous high-velocity flow in the vein cephalad to the fistula are the usual Doppler findings (Fig. 174.8).[67,68,101] The diagnostic accuracy of DUS is highly technician dependent and may be difficult to perform in the

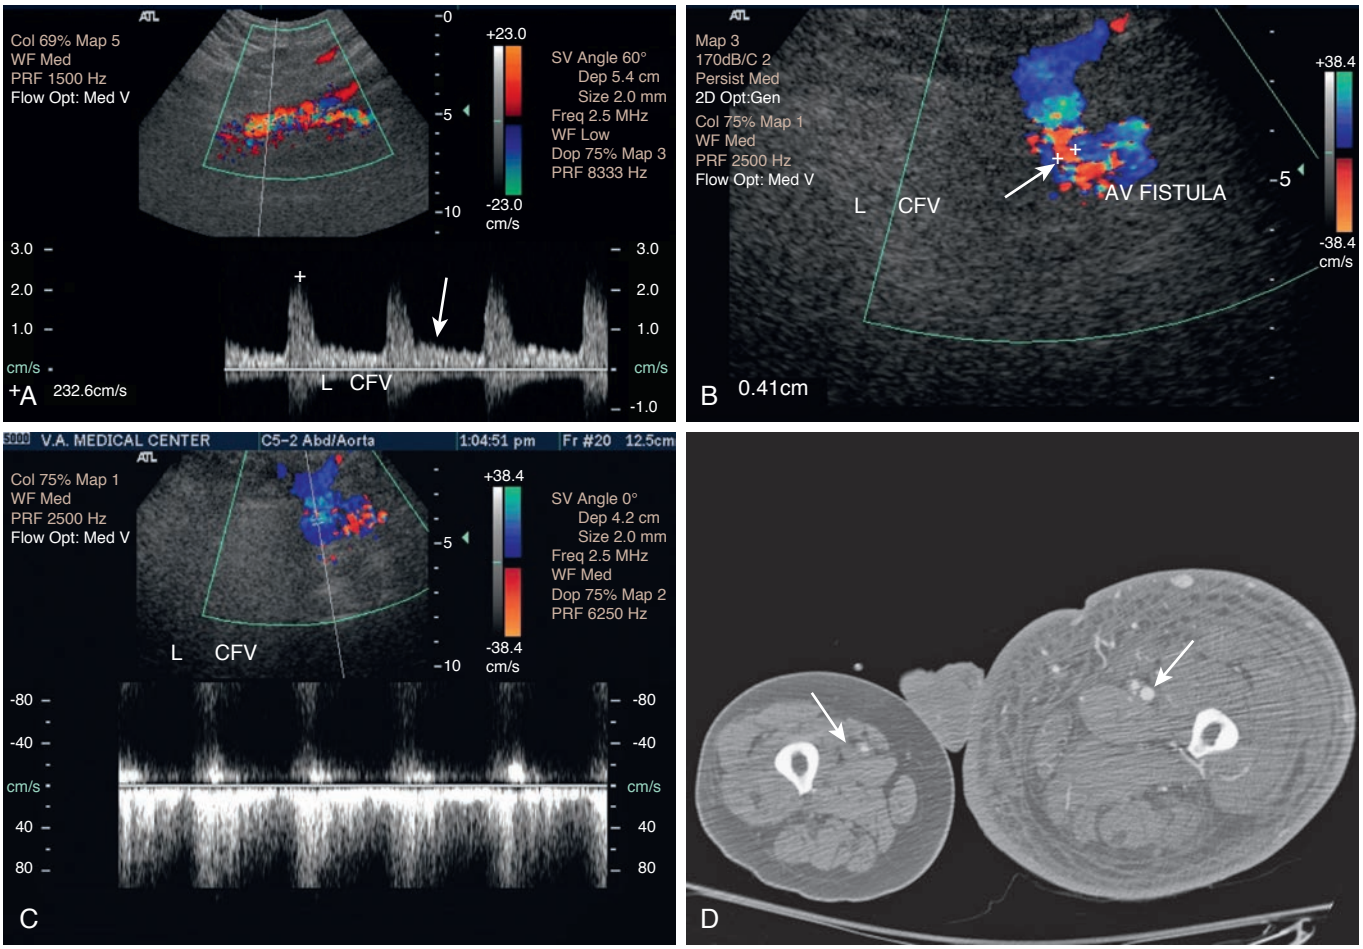

Figure 174.8 Ultrasound image and CT scan of a patient with a large common femoral AVF. Loss of triphasic waveforms is observed in the common femoral artery (CFA) proximal to the fistula (A); a large connection is demonstrated by the white arrow between the CFA and common femoral vein (CFV) (B); a pulsatile and reverse flow is seen in the CFV distal to the fistula (C); and early enhancement of superficial femoral vein *(white arrow)* on the side with an AVF (D).

presence of open wounds, subcutaneous air, hematoma, fractures, obesity, and interference from anatomic structures.[102]

Computed Tomography Angiography

CTA is an appropriate diagnostic tool for evaluation of patients with suspected AVFs because it is minimally invasive, accurate, and operator independent and allows for repeat follow-up exams. In prospective studies evaluating arterial injuries, CTA has been shown to be comparable to digital subtraction angiography (DSA) with a sensitivity of 90% to 95% and specificity of 99% to 100%.[103-107] The major limitations of CTA are exposure to ionizing radiation, the risk of contrast-induced nephrotoxicity (CIN), interference from vessel wall calcification, and the degradation of image quality by metallic, motion, and shoulder streak artifacts. However, the incidence of such interference is believed to be approximately 1%.[106]

Magnetic Resonance Imaging and Angiography

MRI and MRA facilitate the diagnosis of AVF by delineating the underlying defect, measuring flow disturbances, and defining the relationship between the fistula and adjacent soft tissue structures.[105,108,109] Among the benefits of MRA are the absence of exposure to ionizing radiation and a mild side effect profile. However, its utility is limited by the inability to monitor acutely ill or severely injured patients, longer image acquisition times, and patient intolerance. Due to heating and object deflection by the magnetic field and radiofrequency gradients, patients with certain metals (either medical devices, or bullet or shrapnel fragments) cannot enter the MRI environment. Contrast-induced toxicity and the potential development of nephrogenic systemic fibrosis (NSF) in patients with renal impairment remain a concern.[110]

Digital Subtraction Angiography

DSA provides excellent spatial and temporal image resolution, permits rotational views, and is used for both diagnostic and therapeutic for acquired AVFs. The typical angiographic features of an AVF are early venous filling and failure to opacify distal arteries. A high-quality angiogram to identify the precise location of AVFs is essential for endovascular therapy (EVT). In cases where it may be difficult to locate the fistula by arteriography alone, simultaneous catheterization of both the affected artery and vein or balloon catheter occlusion of the inflow artery with contrast injection beyond the balloon can be helpful. DSA with carbon dioxide may be an alternative to conventional angiography in patients with a history of contrast reaction or chronic renal failure.[111]

PRINCIPLES OF MANAGEMENT

The goals of therapy for acquired AVFs consist of closure of the fistula, restoration of normal hemodynamic flow, and reestablishment and maintenance of vascular continuity.[112] Although venous repair was originally considered unnecessary, data from the conflicts in Afghanistan and Iraq suggest that repair of major extremity venous injuries is desirable to reduce the sequelae of venous hypertension and improve limb salvage.[113] The majority of patients with acquired AVFs have no or only mild symptoms and do not require an extensive preoperative work-up. Massive leg swelling and ulceration are controlled with diuretics, limb elevation, or compressive bandaging. Patients with ACFs in florid CHF may be admitted to the ICU preoperatively for optimization of cardiac function.

Conservative Treatment

The natural history of stable iatrogenic femoral AVFs is relatively benign, with 38% to 81% expected to close spontaneously by 1 year.[41,42,114] Therefore patients with small AVFs and normal cardiac function can be monitored with DUS for at least a year. Angiographically, 33% to 90% of renal AVFs resolve spontaneously between 6 weeks and 4 years after the initial diagnosis. This is not entirely unexpected because procedure-related renal AVFs are usually small.[67]

Compression Therapy

US-guided compression and compressive bandaging have been advocated as first-line treatment for small iatrogenic AVFs. Successful occlusion of an AVF is unlikely if the artery and vein are closely adherent, if the defect is large or located at an arterial bifurcation, or if the communication is deep and not amenable to superficial compression. The low success rate of US compression (0%-30%) and the prolonged duration of bandage compression required (15 ± 10 days), as well as the occurrence of local skin ulceration and DVT with the latter, argue against the use of this technique.[115-118]

Endovascular Therapy

Until recently, open surgery was the only option for treating AVFs after conservative therapy had failed. However, its morbidity and mortality and the ongoing advances in endovascular techniques have increased the use of EVT to treat VIs and AVFs. EVT is the treatment of choice for poor-risk surgical candidates, older stable patients with suitable anatomy, and patients with AVFs in surgically inaccessible locations.[119] EVT can be accomplished by transcatheter embolization, placement of a stent-graft, or a combination of the two modalities. Temporary balloon occlusion is a useful adjunct to control bleeding.

Embolization

Transcatheter embolization can be used to treat many AVFs.[67,68,120-127] Available embolic agents include autologous clot, gelatin sponges, microfibrillar collagen, polyvinyl alcohol particles, metal coils, detachable balloons, and liquid embolic agents such as N-butyl cyanoacrylate (n-BCA) and ethylene vinyl alcohol copolymer (Onyx). The choice of embolic agent depends on vessel size, the caliber of the delivery catheter, and whether repeated embolization is anticipated. Gelfoam is the preferred agent for temporary occlusion, and metallic coils and

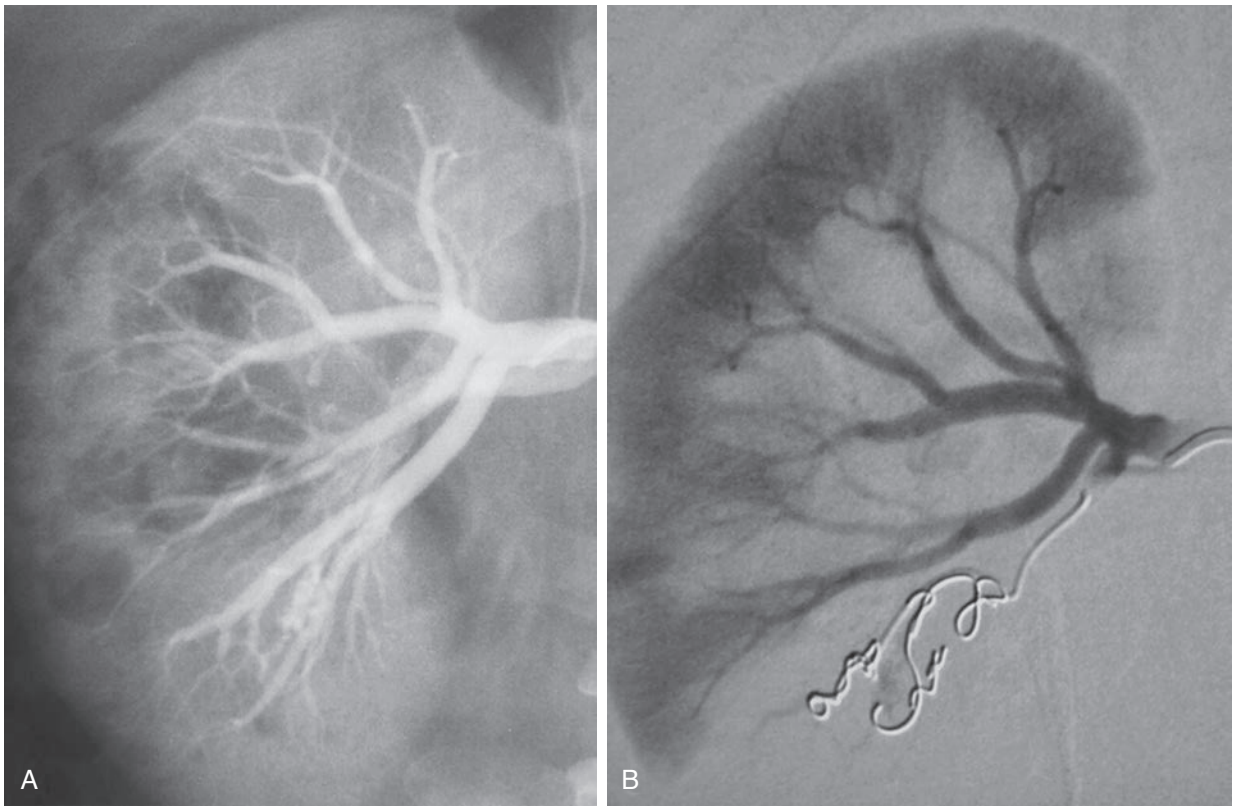

Figure 174.9 Selective right renal arteriogram demonstrating a communication between a branch of the renal artery and vein (A) that was successfully treated with coil embolization (B).

particles are used for permanent occlusion. Successful embolization requires accurate positioning of the catheter at the site of the AVF before delivering the occluding agent.[122,124] Microcoils and particulate agents deployed through coaxial microcatheters are ideal for treating small muscular and radicular branch cervical, renal, visceral, or extremity AVFs, with technical success rates of 89% to 92% (Fig. 174.9). Although a limited number of reports have been published on the embolization of visceral AVFs, principles similar to those used for the endovascular treatment of other AVFs can be applied.[122,125-129]

The major risk associated with transcatheter embolization of AVFs is embolization to arteries related to the fistula and to the lung, resulting in parenchymal or extremity ischemia or pulmonary embolism (Fig. 174.10). In high-flow fistulae, larger high radial force coils are deployed first to provide a scaffold for smaller-sized packing coils, to avoid inadvertent migration and embolization. Placement of a protective covered stent, Amplatzer plug, or temporary balloon occlusion device can reduce the risk of coil migration or embolization in these situations.[130] With careful technique, the extent of infarction related to catheter embolization of renal AVFs, for example, has been limited to less than 10% in more than 75% of patients.[68]

Covered Stent-Grafts

Covered stents can be used to bridge a fistula and preserve parent vessel flow in large-diameter AVFs. If a PSA is present, it is occluded with embolic material. A wide variety of stent-grafts have been used successfully to treat patients with acquired and spontaneous AVFs.[131-133] Because of the limited stent sizes currently available to treat tibial disease, use of a covered stent designed for the coronary arteries can be considered in AVFs involving the crural arteries.[35,119,134-137]

Penetrating injuries of the innominate, carotid, and subclavian arteries are anatomically amenable to EVT.[35,136] In a review of 54 published cases of endovascular treatment of carotid trauma, covered stents were deployed for carotid AVFs in 31% (17 of 54) of cases, with an 88% success rate.[135] AVFs also accounted for 21% of cases of subclavian trauma treated with covered stents over a 10-year period, by du Toit et al.[35]

The placement of covered stent-grafts to treat AVFs in the groin and around the knee joint, although technically feasible, has been avoided because of the perceived risk of kinking or bending in these locations. Because the CFA has been the access site for most angiographic interventions, placement of a covered stent was also believed to preclude its use for repeated procedures (Fig. 174.11).[138,139] However, the introduction of shorter length (12-28 mm) stent-grafts with a wider range of diameters has allowed for accurate bridging of an AVF in the CFA without crossing or impinging on the orifices of the SFA or profunda femoris arteries, while leaving the remaining uncovered CFA accessible for repeated interventions.[35,119,134-147]

Abdominal Endografts

Commercially available aortic endografts and their components, initially designed to treat patients with aorto-iliac (A-I) and thoracic aneurysmal disease, are currently used to treat aortic,

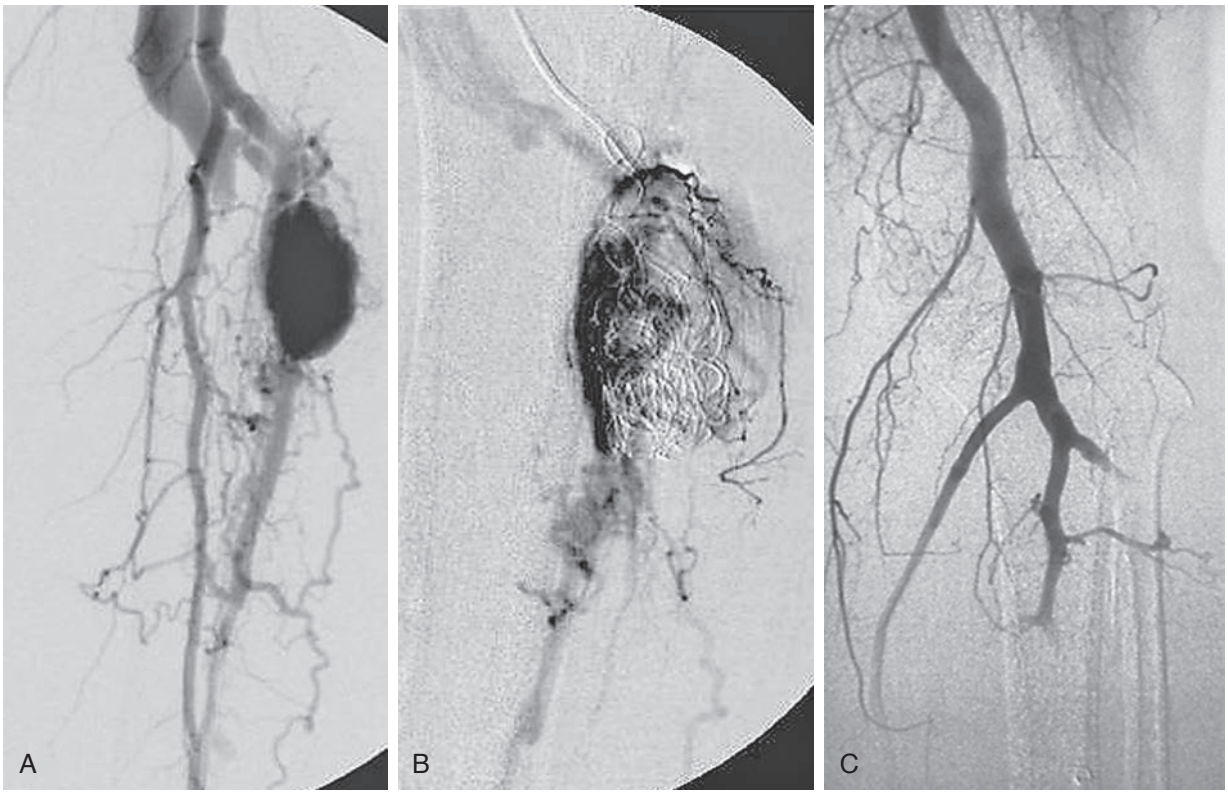

Figure 174.10 (A) Selective femoral angiogram demonstrating an arteriovenous fistula (AVF) between the anterior tibial artery and vein. (B) Coil embolization of the AVF. (C) Occlusion of the tibioperoneal trunk by a dislodged coil, resulting in severe limb ischemia requiring treatment with a popliteal-to-posterior tibial venous bypass graft.

iliac, and aortic arch branch vessel AVFs. AVFs of the descending thoracic aorta are rare but, when present, may be amenable to EVT.[119,143-146] The major limitations to the use of endografts to repair ACFs are similar to those that preclude their use in conventional aneurysm repair; the diameter, length, and angulation of the aortic neck, as well as the diameter and tortuosity of the access vessels. ARFs are also amenable to EVT. The depth of the pelvis and the presence of enlarged veins also make EVT a practical and safer option than open repair for most I-C and I-I AVFs.[148]

The introduction of smaller-diameter grafts and delivery systems has facilitated the management of younger patients with aortic and iliac trauma and AVFs, whose vessels are much smaller than older adults. Careful case selection and limiting graft oversizing has reduced the incidence of endoleaks, sac ruptures, and fistula persistence or recurrence in the short-term follow-up of small numbers of these younger patients.[119,145] The risk of air embolism and dislodgement of thrombotic material resulting in pulmonary embolism has led some surgeons to advocate prophylactic placement of a removable IVC filter or insertion of a second aortic prosthesis into the IVC to prevent this complication.[149]

Only case reports address the treatment of renal, splenic, hepatic, and mesenteric AVFs with covered stent-grafts, but coiling of these AVFs is generally effective while preserving flow in the parent vessel. Additional embolization of feeding vessels is usually required for larger AVFs to prevent endoleaks and recurrence or persistence of the fistula.[80,150,151] Amplatzer plugs have been successfully used to occlude splenic, renal, mesenteric, subclavian, and popliteal AVFs and those occurring after endovascular aneurysm repair in selected patients.[152]

Operative Repair

OR of AVFs is recommended for young, healthy patients, individuals with complex anatomy unsuitable for EVT, or when EVT has failed.

Carotid and Vertebral Arteriovenous Fistulas

Although AVFs involving vessels in zone II of the neck are repaired surgically, exposure of AVFs in zones I and III can be difficult. Median sternotomy or left lateral thoracotomy may be required. Exposure of the distal internal carotid artery (ICA), even with the recognized maneuvers used to improve exposure at the base of the skull, is associated with considerable morbidity. Therefore EVT is often the most appropriate treatment for these lesions.

AVFs in zone II are more amenable to OR. Treatment of AVFs involving the carotid arteries may include primary repair of the defect in the artery and vein, patch angioplasty, interposition grafting, or ligation. The majority of traumatic vertebral AVFs occur deep in the neck between the C2-C5 vertebrae and are difficult to treat surgically. Lesions involving the V-1 segment are the most surgically accessible. Ligation of the VA proximal to the AVF and transposition of the distal segment onto the CCA may be feasible in selected patients. Treatment of more complex lesions usually requires ligation of the VA and vein above and below the fistula, and a subclavian-VA vein bypass at the C1-C2 interspace, if the contralateral VA is atretic or occluded.[153]

Axillary and Subclavian Arteriovenous Fistulas

Exposure of subclavian and proximal axillary artery AVFs may require median sternotomy (40%), a supraclavicular incision (23%), combined supraclavicular and infraclavicular incisions (20%), or division of the clavicle (16%).[154] The axillary artery is exposed by an incision directly over the artery, beginning below the middle of the clavicle and extending into the deltopectoral groove. The extent of arterial injury determines the repair; damage from blast injuries or GSWs usually requires excision of the damaged artery and placement of an interposition graft, whereas lacerations or transections can be reapproximated and repaired primarily.

Lower Extremity Arteriovenous Fistulas

The OR of lower extremity AVFs is accomplished by isolating the involved artery and vein proximal and distal to the AVF in healthy tissue planes, separating the vessels, and repairing the defect primarily, with an autogenous or prosthetic patch or interposition graft. When the AVF involves the superficial femoral artery, application of a tourniquet can significantly reduce blood loss. The distal runoff should be carefully assessed, especially with GSWs and injuries from IEDs, where multiple arteries may be involved. If there is continuity of one or more of the infrageniculate arteries, ligation of the involved artery and vein may be undertaken.

Aortocaval and Iliac Arteriovenous Fistulas

Aortocaval (ACFs), A-I, and I-I AVFs are repaired using a midline or retroperitoneal incision, which can be extended into the chest if necessary. In patients with spontaneous ACFs secondary to AAA, the AAA and massively dilated IVC are readily recognizable, whereas a thrill with dilation of the aorta and IVC accompany traumatic or iatrogenic ACFs. Repair of the aorta is undertaken in standard fashion, with ligation of the connection to the IVC performed from inside the aorta (Fig. 174.12). Attempting to separate the IVC and aorta and repair the IVC externally can lead to extensive bleeding and should not be attempted. In 10% of patients the defect in the IVC is large enough that a prosthetic patch or interposition graft is required. Care should be taken to avoid air embolism or the dislodgement of thrombus into the IVC during surgical manipulations.

Iliocaval or I-I AVFs can be much more difficult to repair surgically due to their location deep in the pelvis and the presence of enlarged veins. Temporary balloon occlusion catheters can be placed in the iliac and femoral veins above and below the fistula to minimize blood loss before exposing the AVF. The defect in the IVC or iliac vein can then be repaired and arterial continuity reestablished.

Aortorenal Arteriovenous Fistulas

OR of aortorenal fistulae may require suprarenal aortic clamping to avoid injury to the renal artery and enlarged veins. AVFs

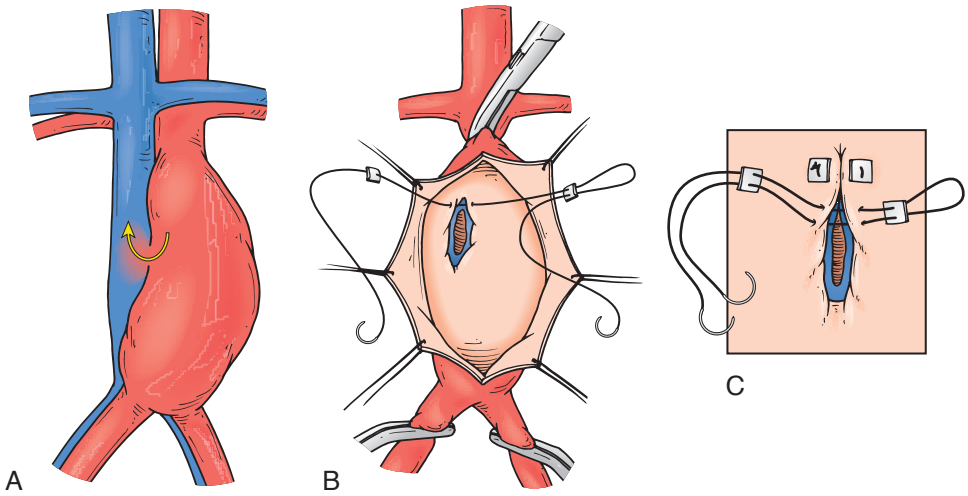

Figure 174.12 Schematic view of operative repair of an aortocaval fistula (A). The defect is closed from within the aneurysm sac (B,C). (From Crawford ES, et al. *Diseases of the Aorta: Including an Atlas of Angiographic Pathology and Surgical Technique*. Baltimore MD: Williams and Wilkins; 1984.)

associated with renal artery aneurysms or dissection are repaired in situ by aneurysmectomy with or without vein patch closure or aortorenal bypass.[155] Ex vivo repair may be required in selected cases of branch vessel involvement. Fistulae resulting from mass ligation of the renal pedicle are treated surgically by isolation and ligation of the renal artery and vein at their origins.

Visceral Arteriovenous Fistulas

Visceral AVFs are exposed via a midline or subcostal incision. The splenic artery in patients with AVFs is usually dilated and tortuous and can be controlled at its origin prior to treatment. Splenectomy is often performed for AVFs of the hilum or parenchyma.[75] The splenic vein should be ligated close to its junction with the superior mesenteric vein to minimize the risk of thrombus propagation into the portal vein. Exposure of arterioportal and arteriosystemic AVFs may require medial visceral rotation and/or thoracoabdominal extension of the incision to obtain proximal control of the celiac artery.

Definitive OR of hepatic AVFs depends on their location and etiology. Spontaneous AVFs may require placement of an interposition graft, with repair or ligation of the vein. In the case of a fistula resulting from a common HAA, proximal and distal ligation of the aneurysm is an option if collateral flow through the right gastric and gastroduodenal arteries is preserved. Lesions of the proper hepatic artery and its branches require either direct repair or a vein interposition graft to maintain hepatopetal flow. Ligation of the involved artery and segmental or partial hepatectomy may be required with intrahepatic AVFs.

Treatment options for AVFs involving the superior or inferior mesenteric arteries or their tributaries include interposition grafting or ligation and excision of the AVF if a tributary is involved and collateral flow can be preserved. Mesenteric AVFs following mass ligation of the gastric, inferior, or superior mesenteric vascular pedicles are treated by isolation and proximal ligation of the involved artery and vein.

TREATMENT OUTCOMES

In symptomatic patients, repair of A-C, I-C, or I-I AVFs are accompanied by almost immediate improvement in cardiac and pulmonary function. Normalization of renal function maybe delayed for 48 to 72 hours. Younger patients with high-output CHF can be expected to recover fully, whereas the recovery of older individuals with spontaneous AVFs is determined by preexisting comorbidities.[156,157] The comparison of treatment outcomes is listed in Table 174.1.

Operative Repair

OR of postcatheterization AVFs is successful in 89% to 96% of cases. However, in cases of unstable patients where emergent surgery is required, EVT may be safer.[41,42] Intraoperative blood loss, myocardial infarction, pulmonary embolism, stroke, and multisystem organ failure account for a morbidity rate of 36% and a mortality rate of 7.1% to 12% following OR of spontaneous ACFs. Long-term graft patency is 96% in surviving patients.[19-23,119,143-146,158,159] There are no large series documenting the treatment outcomes of OR for visceral AVFs. However, treatment outcomes can be inferred from the elective treatment of VAA; the mortality rate for elective procedures is approximately 5% and increases to 10% to 25% in patients with ruptured aneurysms. Similarly, limited information is available on the outcome of renal AVFs repaired surgically. The results from repair of renal artery aneurysms suggest that AVF repair can be undertaken with low morbidity and mortality rates in institutions with extensive experience treating these lesions.[160]

Endovascular Therapy

Stent-grafts alone or combined with embolization have been successfully deployed in 83.9% to 100% of selected patients with pseudoaneurysms or AVFs of the carotid, subclavian, and

axillary arteries. Early and late stent-graft occlusion (5%-10%), intimal thickening resulting in greater ≥50% (4%-20%) luminal stenosis, re-intervention rates of 6% to 12%, and mortality rates of 0% to 5.9% are the major complications of EVT in these patients. Although these data encompass the treatment outcomes of all types of cervical and upper extremity VIs and not only AVFs, they do provide some insight into the expected results of EVT for patients with these AVFs.[6,135-137,141,161-163]

In most cases, EVT is the treatment of choice for iatrogenic femoral, profunda femoris, and popliteal AVFs, with technical success rates ranging from 88% to 100%.[138,139,164] Whether the routine use of antiplatelet agents will limit intimal thickening and improve graft patency remains undetermined.[165-167] There are currently no long-term follow-up data addressing the use of complex tibial interventional approaches to treat AVFs in patients with CLI. Abdominal aortic endografts are successfully deployed in 84% to 94% of patients with ACFs, with morbidity and mortality rates of 12% to 46% and 0% to 19%, respectively.[158,168] Endoleaks and graft complications due to aortic remodeling, especially in younger patients, require continued monitoring.[158] Only 23% to 36% of renal AVFs require treatment. Transcatheter embolization alone or in combination with a stent-graft is accompanied by a success rate of 90%. Successful occlusion of VAAs can be achieved with coil embolization in 93.3% to 100% of cases, with an overall perioperative morbidity of 10% to 12.5% and mortality of 0.0% to 8.3%.[75,169-171] Multiple interventions are usually necessary to achieve this level of success treating VAAs, pseudoaneurysms, and AVFs.[128,172]

The endovascular treatment of SAAs is associated with 0% mortality but a 40% splenic infarction rate; embolization of HAAs, with a mortality rate of 11% without significant hepatic ischemia.[169]

Operative Repair Versus Endovascular Therapy

There are currently no prospective randomized controlled trials comparing EVT with OR in the management of patients with AVFs. Only a few studies with small numbers of patients are available for analysis. The initial results of EVT for AVFs appear promising; the complication rate is relatively low, but long-term follow-up data are limited.

Several vascular surgeons have advocated EVT as the optimal treatment of A-I and aortorenal AVFs because it is less invasive, associated with less blood loss and hemodynamic instability, can be used in surgically inaccessible locations, and has lower morbidity and mortality rates.[168,173] In contrast, Orion et al. in a meta-analysis of 67 patients with ACFs, 41 (61%) treated with OR and 26 (39%) with EVT, found no statistical differences in morbidity (46% vs. 36%) or mortality (19% vs. 12%) between OR and EVT, respectively.[158] Kotsikoris et al. reported a 7.1% mortality rate for patients with ACCFs undergoing OR.[159] OR, currently reserved for young healthy patients, individuals with unsuitable anatomy for EVT, and when EVT has failed, is curative and durable with 90% patency in surviving patients. The current literature suggests that, despite its recognized advantages, EVT cannot yet be recommended as the standard

of care for patients with aortic or iliac AVFs. Because of the small numbers of patients with acquired ACFs, there is little likelihood of a randomized controlled trial; a prospective registry may provide better comparative long-term outcome data.[174]

RESULTS 2298

As the population ages and the incidence of diabetes rises, chronic kidney disease (CKD) and end-stage renal disease (ESRD) are increasingly common diagnoses in the United States. In 2015, data from the United States Renal Data System (USRDS) showed that 117,162 new patients began therapy for ESRD, whereas the prevalent dialysis population reached 661,648. Of note, after a sharp rise in the incidence of ESRD patients in the 1980s and 1990s, followed by a leveling off in 2000 and a peak in 2006, there has been a slight but steady decline through 2015 (Fig. 175.1). Despite this, the number of ESRD patients continues to rise by about 21,000 patients per year (Fig. 175.2), with a resulting rise in healthcare costs.[1] Medicare fee-for-service spending for ESRD patients increased by 1.6%, from $30.4 billion in 2012 to $30.9 billion in 2013, accounting for 7.1% of overall claims (Fig. 175.3). Not surprisingly, most of these costs occur during the transition from CKD to ESRD and are due to the high use of long-term catheters and frequent hospitalizations for permanent arteriovenous (AV) access failures, requiring thrombectomies, revisions, and repeated access placements.[2]

INITIATIVES AND GUIDELINES

In 1997, the National Kidney Foundation-Dialysis Outcomes Quality Initiative (NKF-KDOQI) Clinical Practice Guidelines for Vascular Access were published in an effort to increase the

Abstract

This chapter reviews the current initiatives and guidelines regarding hemodialysis access placement. In accordance with these guidelines, with an access surgeon's perspective, the authors review the appropriate steps to optimizing access placement. The steps reviewed include: timing of access, pre-operative evaluation, selection of access location, surgical techniques, post-operative and long-term follow-up, and results.

placement of autogenous AV access and prolong the use of created access by detection of dysfunction prior to thrombosis. These guidelines stress the early identification of patients with progressive kidney disease, identification and protection of potential native access construction sites, and development of multifaceted quality assurance programs to detect at-risk vascular access, track complication rates, and implement procedures that maximize access longevity. These original guidelines recommended that autogenous AV accesses should be constructed in at least 50% of all new hemodialysis patients and ultimately 40% of prevalent hemodialysis patients.[3]

In 2003, in an effort to reach the goals set forth by the NKF-KDOQI guidelines, the Centers for Medicare and Medicaid Services (CMS) recommended the adoption of a National Vascular Access Improvement Initiative (NVAII); in 2005, this was expanded to the Fistula First Breakthrough Initiative (FFBI). FFBI identified clinical and organizational changes that could be adapted and applied locally by nephrologists, dialysis personnel, access surgeons, and patients to increase the production and use of autogenous AV access. They also identified national system changes, which included reimbursement of autogenous AV access at a higher rate than prosthetic AV accesses and

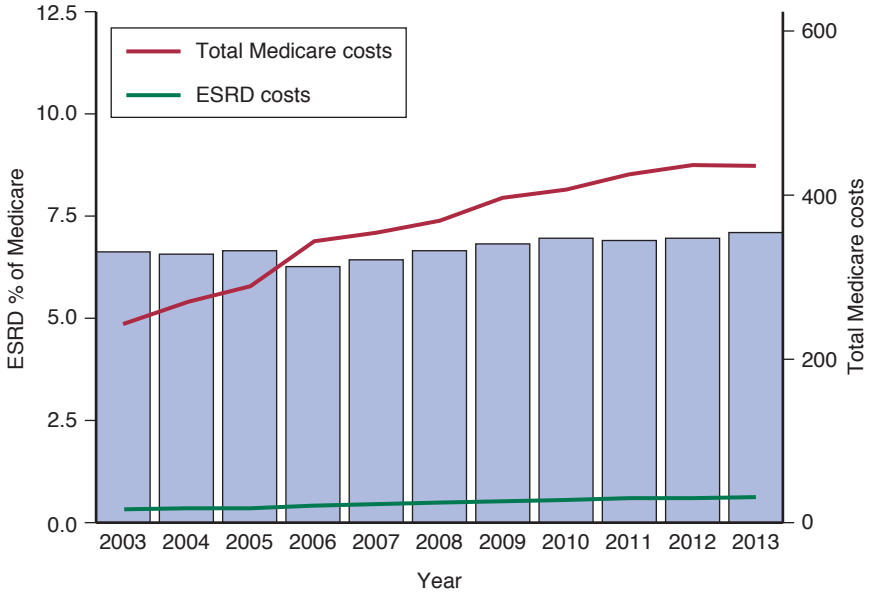

Figure 175.3 Trends in costs of the Medicare and end-stage renal disease *(ESRD)* program, 2003–2013. (Reproduced from United States Renal Data System [USRDS]. Medicare expenditures for persons with ESRD. catheters and reimbursement of preoperative vein mapping. As a result of their efforts, the national rate of autogenous access reached 40% prevalence by August 2005, followed by a steady-state incline until 2011, when it reached a plateau of about 60%.[4]

Recognizing that autogenous access may not be feasible in all dialysis patients, the FFBI recently transitioned to the Fistula First Catheter Last Workgroup Coalition (FFCL) to further focus on the development of tools and resources to help dialysis facilities and clinicians increase permanent access rates while also reducing catheter use. The FFCL coalition's current goals are to increase the utilization of autogenous AV access in all appropriate hemodialysis patients to 68%, decrease the use of long-term catheters for greater than 90 days to less than 10%, and to engage patients and all providers to work together to achieve these goals. These new goals emphasize decreasing the use of long-term catheters by changing the focus of dialysis access away from autogenous access in all patients to autogenous access in all appropriate patients. This allows the access surgeon to evaluate and act based on the individual needs of the patient; if the surgeon feels that autogenous access is not achievable or would unreasonably prolong the use of a long-term catheter, a prosthetic access should be placed.[5]

The Society for Vascular Surgery (SVS), recognizing the effect of decision making by the individual access surgeon on the successful construction of AV access, has sponsored two further initiatives. First, in 2002, the Committee on Reporting Standards published the recommended standards for reports dealing with AV hemodialysis access. The purpose of this document was to provide standardized definitions related to AV access procedures and to recommend reporting standards for patency and complications in order to permit meaningful comparisons among AV access procedures.[6] This was followed in 2008 by the clinical practice guidelines for the surgical placement and maintenance of AV hemodialysis access. After a multispecialty panel performed a systematic review of the literature, guideline recommendations were made in seven areas: (1) timing of referral to access surgeons, (2) operative strategies to maximize the placement of autogenous AV accesses, (3) first choice for the autogenous access, (4) choice of AV access when a patient is not a suitable candidate for a forearm autogenous access, (5) the role of monitoring and surveillance in AV access management, (6) conversion of a prosthetic AV access to a secondary autogenous AV access, and (7) management of the nonfunctional or failed AV access.[7] This chapter focuses on strategies to maximize successful access placement, whether autogenous or prosthetic.

TIMING OF REFERRAL

The NKF-KDOQI and the SVS Clinical Practice Guidelines both recommend that patients be referred to a vascular access surgeon for permanent dialysis access when their creatinine clearance is less than 25 mL/min. Once preoperative evaluation is completed, if the patient is felt to be an adequate candidate for autogenous AV access, the access should be constructed as soon as possible to give it adequate time to mature; ideally this should be greater than 6 months before the anticipated need for dialysis. However, since prosthetic access patency is limited by the duration of access placement, not time of access use, if a patient is felt to require a prosthetic access, the access placement should be delayed until 3 to 6 weeks prior to the initiation of dialysis.[3,7]

Early access placement, greater than 4 months before the initiation of dialysis, has been shown to decrease the risk of sepsis (relative risk [RR] 0.57) and death (RR 0.76) when compared with late access creation (less than 1 month before the initiation of dialysis or after initiation of dialysis), primarily by reducing the use of central venous hemodialysis catheters.[8] Despite this, nationwide data suggest that only 25% of hemodialysis patients initiate dialysis with permanent AV access. Lenz et al. reported

that 93% of patients in an academic medical center with a well-established dialysis unit and vascular surgery service initiated hemodialysis with the use of a central venous catheter. In a retrospective review, they identified the reason as inadequate predialysis care in 45% of patients, acute illness with failure to recover from an episode of acute renal failure in 31% of patients, and noncompliance with medical and surgical appointments in 17% of patients.[9] These studies stress the need for early referral and education for predialysis patients to prevent the use of central venous catheters and their subsequent complications.[8,9]

PREOPERATIVE EVALUATION

Thorough preoperative evaluation of the arterial and venous system is imperative if long-term, permanent AV access is to be placed successfully.

History and Physical Examination

A thorough history should include the dominant extremity, recent history of peripheral intravenous lines, sites of indwelling or previous central lines including pacemakers and defibrillators, all previous access procedures, any history of trauma or previous nonaccess surgery to the extremity, all comorbid conditions, and current medications. On physical examination, the brachial, radial, and ulnar arteries should be evaluated for compressibility and equality bilaterally. An Allen test should be performed to evaluate palmar arch patency. The superficial venous system should be evaluated with and without a venous pressure tourniquet in place, examining for distensibility and interruptions. The arm should be examined for prominent venous collaterals and edema, which may be signs of central venous stenosis.[3,7]

Medical Assessment

Multiple patient factors may play a role in AV access patency; these include age, sex, diabetes mellitus (DM), peripheral vascular disease (PVD), smoking, obesity, hyperparathyroidism (hPTH), anemia, and medications. The literature is split on many of these factors; however, best evidence to date suggests that all except sex and obesity have a negative impact on access patency rates (Table 175.1).[10] In the following paragraphs we review further some of the more studied factors that appear to negatively impact patency further.

Age

Published reports regarding age and its effect on AV access patency are mostly retrospective observational studies with conflicting results. However, these reports, along with a known shorter life expectancy for patients with ESRD, have raised the following question: Should proximal or prosthetic AV access be the first-line approaches in the elderly? To answer this, Lazarides et al. performed a meta-analysis, 13 studies in all, of dialysis outcomes in elderly patients (age range: 50 to 70 years), including studies that compared subgroups of elderly and nonelderly patients as well as forearm and upper arm accesses.

TABLE 175.1 Medical Factors Affecting Arteriovenous Access Patency

Factor	Level of Best Evidence	Best Evidence Suggests Effect of Patency
Age	Meta-analysis	Yes
Gender	Meta-analysis	No
Diabetes mellitus	Prospective series	Yes
Atherosclerosis	Prospective series	Yes
Smoking	Prospective series	Yes
Obesity	Prospective series	No
Parathyroid hormone	Prospective series	Yes
Anemia	Prospective series	Yes
Medications	Systematic review	Yes

They found a statistically significant higher rate of autogenous radial-cephalic direct AV access primary (OR 1.8), 1-year (OR 1.5), and 2-year (OR 1.4) failure in elderly patients compared with the nonelderly. They also found a statistically significant higher rate of autogenous brachial-cephalic direct upper arm access patency (RR 0.1) compared with autogenous radial-cephalic direct forearm access. They noted no statistical differences with the use of prosthetic access.[11] Based on these data, it is reasonable to recommend autogenous upper arm brachial-cephalic fistula or prosthetic access over distal radial-cephalic fistula.

Diabetes Mellitus

Published reports are mostly retrospective observational studies with similar results, stating that DM has a negative impact on AV access patency. These reports, along with a known increase in arterial calcification and atherosclerosis, have raised the following question: Should proximal or prosthetic AV access be the first-line approach in diabetics? To further evaluate the impact that DM has on the vasculature, Sedlack et al. compared preoperative noninvasive vascular mapping between diabetic and nondiabetic patients. They noted an increased number of arterial calcifications in diabetics but no difference in arterial diameter or the ability to place autogenous AV access; they did not evaluate long-term outcomes.[12] Looking at long-term outcomes in diabetic patients, Konner et al. noted an increased risk of thrombosis (0.03/patient year [PY] in nondiabetics vs. 0.07/PY in diabetics) and an increased risk of arterial steal (0.6/PY in nondiabetics vs. 7.0/PY in diabetics).[13] Further studies are needed in this area; however, given the current literature, surgeons should take inflow in diabetics as distal as possible to decrease the risk of arterial steal.

Smoking

Published reports are retrospective observational studies with similar results, stating that cigarette smoking significantly increases early and late failure of AV access.[14] ESRD patients

should be referred to a tobacco cessation program before placement of first-time or any new AV access.

Medications

Published reports are mostly observational studies that have yielded conflicting results. One of the largest studies to date, the Dialysis Outcomes and Practice Patterns Study (DOPPS), noted an improvement of autogenous access secondary patency (RR 0.56) with angiotensin-converting enzyme (ACE) inhibitors, an improved prosthetic AV access primary patency (RR 0.86) with calcium channel blockers, an improved prosthetic AV access secondary patency (RR 0.70) with aspirin, and a decreased prosthetic AV access primary patency (RR 1.33) with warfarin.[15] A study sponsored by the USRDS showed a decreased AV access patency with antiplatelet agents including ticlopidine, dipyridamole, and aspirin.[16] Others have shown that angiotensin receptor blockers (ARBs) combined with antiplatelet agents increased autogenous AV access patency by 84%, whereas ARBs alone improved prosthetic AV access patency by 59%.[17] At the present time there is a lack of consensus regarding the role of specific medications in improving AV access patency.

Arterial Assessment

If any abnormality is noted on the clinical arterial examination (absent or reduced pulse, positive Allen test, or asymmetrical arm pressures), the patient should be further evaluated with segmental pressures and duplex ultrasound scanning and/or pulse volume recordings (PVRs). For optimal outcome, no pressure gradient should be noted between the bilateral upper extremities, arterial diameter should be greater than or equal to 2.0 mm throughout the extremity, and a patent palmer arch should be present.[18] Any abnormality noted on noninvasive testing should prompt alternate site selection or be further evaluated with an arteriogram, which gives the surgeon the ability to both identify and possibly treat an arterial inflow stenosis. In patients nearing dialysis, the risk of contrast arteriography should be weighed against the need for access to mature before beginning dialysis. Renal protective agents should be used preceding arteriography; these include intravenous fluids, *N*-acetylcysteine, and sodium bicarbonate.[19-22]

Venous Assessment

If superficial veins cannot be visualized with a venous pressure tourniquet in place or any abnormality is noted on the superficial venous examination, the patient should be further evaluated with superficial venous duplex ultrasound vein mapping. Using venous duplex imaging, superficial veins should be examined for diameter, distensibility, and continuity. Minimal diameter for use of the forearm has been reported as low as 2.0 mm by Mendes et al., who noted a successful early maturation rate of 76%.[23] Using a minimal vein diameter of 2.5 mm, Silva et al. were able to perform 63% autogenous access with a 92% early maturation rate and 83% 1-year patency rate.[18] Using a minimal vein diameter of 3.0 mm, Huber et al. were able to perform 90% autogenous access with an 84% early maturation rate.[24]

Central venous stenosis should be suspected if there are any prominent venous collaterals or edema, a difference in extremity diameter, any history of previous central venous catheter placement, or multiple previous accesses in the planned extremity. If any of these abnormalities are identified, the patient should be examined first with deep venous duplex ultrasound imaging followed by venography if necessary.[3] Passman et al. compared duplex ultrasound and venography in 60 upper extremities of preoperative access patients. Five (8%) ultrasounds were nondiagnostic due to artifact from central venous catheters or incomplete visualization of the central venous system. Of the studies that were diagnostic, they noted 81% sensitivity and 97% specificity of duplex ultrasound imaging with no statistical difference as compared with venography. Venography should be performed for further evaluation and possible treatment in patients with either nondiagnostic or abnormal duplex ultrasound imaging.[25] As with arteriography, in predialysis patients the risk of contrast venography must be weighed against the need for access to mature in time for dialysis. Before venography, patients should be treated with intravenous fluids, N-acetylcysteine, and/or sodium bicarbonate.[19-22]

SELECTION OF ACCESS LOCATION

The various types of autogenous and prosthetic upper, lower, and body-wall AV access are listed in Box 175.1. In planning AV access, a few general principles apply (Fig. 175.4). For the purposes of this chapter, our focus is on upper extremity accesses. Further accesses are discussed in Chapter 176 .

1. Due to easier accessibility and lower infection rates, upper extremity access sites are used first, with the nondominant arm given preference over the dominant arm.
2. AV accesses are placed as far distally in the extremity as possible to preserve proximal sites for future accesses.
3. As long as the patient is deemed appropriate, given their superior patency rates and lower complication rates, autogenous AV accesses should always be attempted before a prosthetic AV access.
4. These autogenous access configurations should include, in order of preference, direct AV anastomosis, venous transpositions, and venous translocations.

Ultimately the following question remains: How does the surgeon decide who is an appropriate patient for autogenous access and who is not and should go straight to a prosthetic access? Multiple factors play a role in this decision, starting with the patient's medical assessment, as discussed earlier, including the patient's age, history of DM, PVD, smoking, hPTH, and anemia. Arterial and venous anatomy plays a major role in this decision and should be based on objective studies, including preoperative noninvasive duplex ultrasound and/or invasive venous and arterial imaging. The access surgeon should combine all of these factors in order to determine the feasibility of an autogenous access; the surgeon should also have a thorough discussion with the patient regarding the risks and benefits of autogenous and prosthetic access before arriving at a mutual decision.

BOX 175.1 Configurations of Arteriovenous Access

Forearm

Autogenous

- Posterior radial branch–cephalic wrist direct access (snuffbox fistula)
- Radial-cephalic wrist direct access (Brescia-Cimino-Appel fistula)
- Radial-cephalic forearm transposition
- Brachial (or proximal radial)–cephalic forearm looped transposition
- Radial-basilic forearm transposition
- Ulnar-basilic forearm transposition
- Brachial (or proximal radial)-basilic forearm looped transposition
- Radial-antecubital forearm indirect femoral vein translocation
- Brachial (or proximal radial)-antecubital forearm indirect looped femoral vein translocation
- Radial-antecubital forearm indirect saphenous vein translocation
- Brachial (or proximal radial)-antecubital forearm indirect looped saphenous vein translocation

Prosthetic

- Radial-antecubital forearm straight access
- Brachial (or proximal radial)-antecubital forearm looped access

Upper Arm

Autogenous

- Brachial (or proximal radial)–cephalic upper arm direct access
- Brachial (or proximal radial)-cephalic upper arm transposition
- Brachial (or proximal radial)-basilic upper arm transposition
- Brachial (or proximal radial)-brachial vein upper arm transposition
- Brachial (or proximal radial)-axillary (or brachial) upper arm indirect femoral vein translocation
- Brachial (or proximal radial)-axillary (or brachial) upper arm indirect saphenous vein translocation

Prosthetic

- Brachial (or proximal radial)-axillary (or brachial) upper arm straight access

Adapted from Sidawy AN, Gray R, Besarab A, et al. Recommended standards for reports dealing with arteriovenous hemodialysis accesses. *J Vasc Surg*. 2002;35:603-610.

Forearm Access

Cephalic Vein

For autogenous forearm access, use of the cephalic vein is preferred to the basilic vein secondary to its lateral location and the need for only minimal dissection. Possible sites of arterial inflow include the posterior branch of the radial artery in the "snuffbox," the trunk of the radial artery, the ulnar artery, and the brachial artery. The ulnar artery is usually not the first arterial option due to its distance from the cephalic vein. The access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal sites of inflow for future accesses. Therefore in patients with an adequate posterior branch of the radial artery, an autogenous posterior radial branch–cephalic wrist direct access (snuffbox fistula) is performed (Fig. 175.5). In patients with an inadequate posterior branch of the radial artery but an adequate radial artery, an autogenous radial-cephalic wrist direct access (Brescia-Cimino-Appel fistula) is recommended. In either of these cases, if the cephalic vein is felt to be too deep, as seen in obese patients, or is not located in close proximity to the radial artery in the wrist, an autogenous radial-cephalic forearm transposition is performed (Fig. 175.6). If the radial artery is inadequate, the ulnar artery may provide an alternative distal inflow site; alternatively, the entire trunk of either the radial or the ulnar artery may provide an arterial source. If the radial and ulnar arteries are inadequate but the brachial or proximal radial arteries are adequate, an autogenous brachial (or proximal radial)-cephalic forearm looped transposition is performed.

Basilic Vein

When the cephalic vein is not felt to be adequate for an autogenous AV access, the basilic vein is the preferred alternative. Secondary to its medial location in the forearm, a transposition is always required. Possible sites of arterial inflow include the distal radial artery, the ulnar artery, the proximal radial artery, and the brachial artery. Use of the posterior branch of the radial artery is not possible secondary to the distance from the basilic vein. Similar to the cephalic vein, the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal sites of inflow for future accesses. Therefore when the radial artery is adequate, an autogenous radial-basilic forearm transposition is performed. If the radial artery is inadequate but the ulnar artery is adequate, an autogenous ulnar-basilic forearm transposition is performed. If the distal radial and ulnar arteries are inadequate, a more proximal segment may be used (autogenous proximal radial-basilic forearm looped transposition). If the radial and ulnar arteries are inadequate throughout but the brachial artery is adequate, an autogenous brachial-basilic forearm looped transposition is performed.

Alternate Vein

When the cephalic and basilic forearm veins are not felt to be adequate for autogenous AV access, translocations of the femoral and saphenous veins are appropriate alternatives. Further strategies for these complex autogenous accesses are described in Chapter 176.

Prosthetic Graft

If an adequate forearm vein is unavailable, a prosthetic AV forearm access is performed. Sources of arterial inflow include the distal or proximal radial artery or the brachial artery. Similar to autogenous access, the AV graft is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal arteries for future accesses. Therefore when the distal radial artery is adequate, a prosthetic radial-antecubital forearm straight access is performed (Fig. 175.7). If the radial artery is inadequate but the brachial or proximal radial artery is adequate, a prosthetic brachial (or proximal radial)-antecubital forearm looped access is performed (Fig. 175.8A and B).

One of the interesting debates in this area is whether, after exhausting the forearm autogenous options, the surgeon should recommend a forearm prosthetic access before placing an upper arm autogenous access. As previously discussed in this chapter,

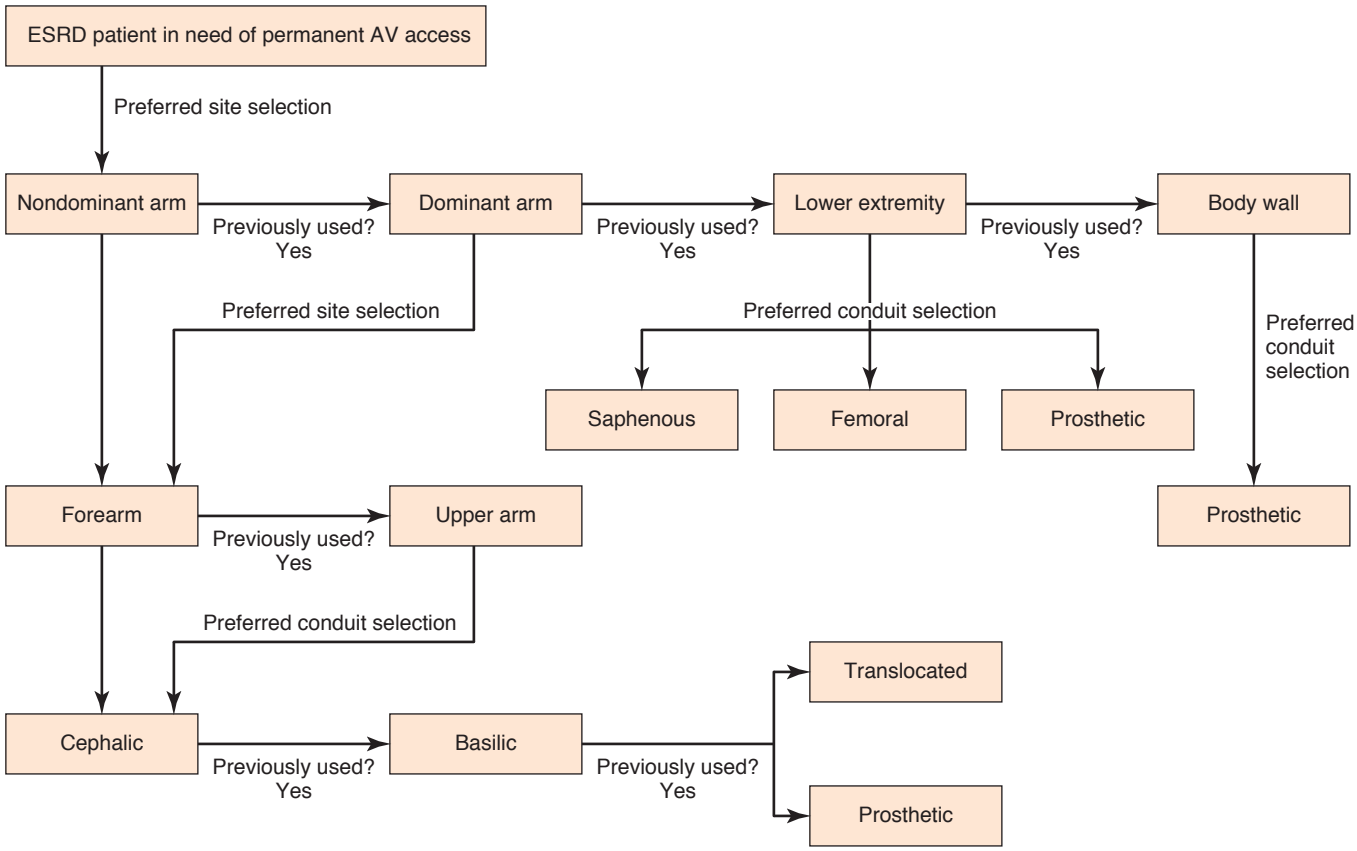

Figure 175.4 Algorithm: selection of access location. *AV,* Arteriovenous; *ESRD,* end-stage renal disease.

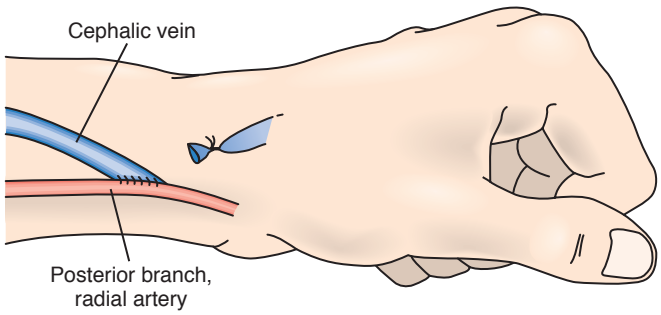

Figure 175.5 Autogenous posterior radial branch–cephalic wrist direct access (snuffbox fistula).

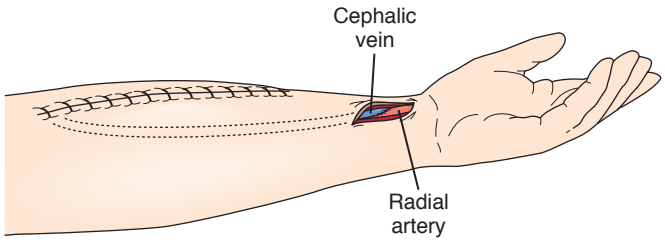

Figure 175.6 Autogenous radial-cephalic forearm transposition. (Reproduced from Silva MB, Hobson RW, Pappas PJ, et al. Vein transposition in the forearm for autogenous hemodialysis access. *J Vasc Surg*. 1997;26:981-988.)

the access surgeon should consider all of the patient and anatomic factors, particularly, the adequacy of the upper arm vein. A mutual decision should be made between the surgeon and patient after a thorough discussion about the risks and benefits of autogenous and prosthetic access. Most importantly, if a prosthetic forearm access is chosen, this should be considered a "bridge" to an autogenous upper arm access. Access surgeons should minimize the number of attempts to salvage the access with endovascular means to avoid damaging the venous outflow. A plan for eventual conversion of the forearm prosthetic access to a secondary autogenous access should be put in place; strategies include conversion of the prosthetic access mature outflow vein to an autogenous upper arm access or the identification of a new, remote site for autogenous access construction.[7]

Upper Arm Access

Cephalic Vein

When use of the forearm has been exhausted, efforts at access are directed to the upper arm. Similar to the forearm, use of the upper arm cephalic vein is preferred to the basilic vein secondary to its lateral location and need for only minimal dissection. For upper arm access, possible sites of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to lower the risk of arterial steal. Therefore in patients with an adequate cephalic vein and an adequate proximal radial artery, an autogenous proximal radial-cephalic upper arm direct access is performed.

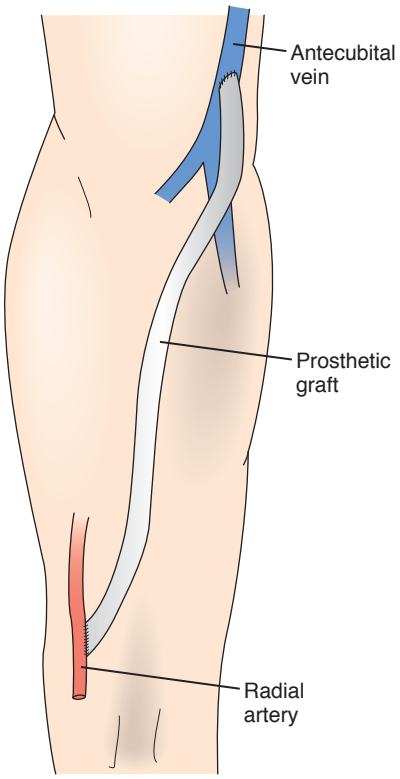

Figure 175.7 Prosthetic radial-antecubital forearm straight access.

If the proximal radial artery is inadequate and the brachial artery is adequate, an autogenous brachial-cephalic upper arm direct access is performed (Fig. 175.9). If the cephalic vein is felt to be too deep or is located far from the artery, an autogenous brachial (or proximal radial)-cephalic upper arm transposition is performed.

Basilic Vein

When the cephalic vein is felt to be inadequate for an autogenous AV access, the upper arm basilic vein is the preferred alternative. Secondary to its medial and deep location, transpositions are required for all accesses using the basilic vein. Similar to upper

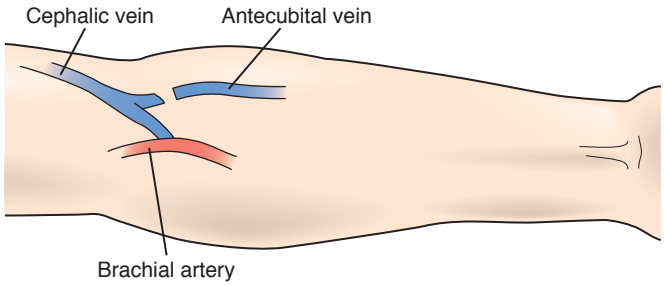

Figure 175.9 Autogenous brachial (or proximal radial)-cephalic upper arm direct access.

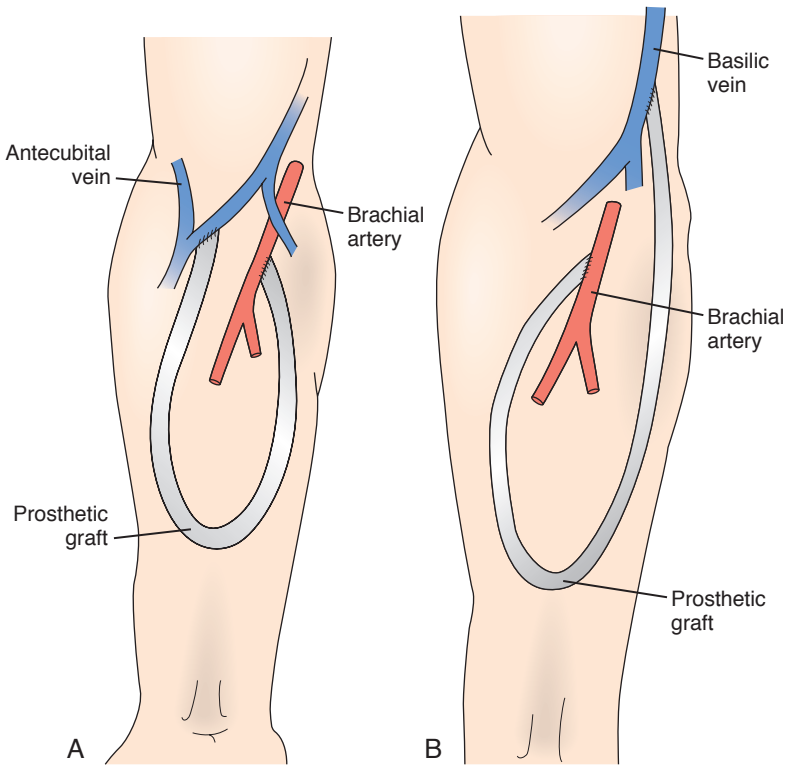

Figure 175.8 (A and B) Prosthetic brachial (or proximal radial)-antecubital forearm looped access.

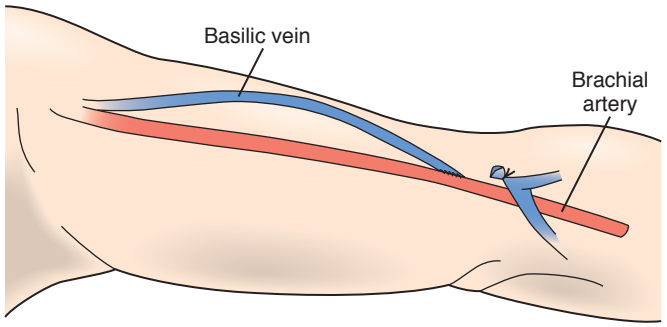

Figure 175.10 Autogenous brachial (or proximal radial)-basilic upper arm transposition.

arm cephalic vein AV accesses, possible sites of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to lower the risk of arterial steal. Therefore in patients with an adequate basilic vein and an adequate proximal radial artery, an autogenous proximal radial-basilic upper arm transposition is performed. If the proximal radial artery is inadequate and the brachial artery is adequate, an autogenous brachial-basilic upper arm transposition is performed (Fig. 175.10).

Alternate Vein

When the cephalic or basilic veins are felt to be inadequate for upper arm autogenous access, brachial vein transpositions as well as femoral and saphenous vein translocations are appropriate alternatives. Further strategies for these complex autogenous accesses are described in Chapter 176 .

Prosthetic Graft

If no vein is available, an upper arm prosthetic AV access is performed. Similar to upper arm autogenous AV accesses, possible sites of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to lower the risk of arterial steal. Therefore when the proximal radial artery is adequate, a prosthetic proximal radial-axillary vein (or brachial vein) upper arm straight access is performed. If the proximal radial artery is inadequate and the brachial artery is adequate a brachial-axillary vein (or brachial vein) upper arm straight access is performed (Fig. 175.11).

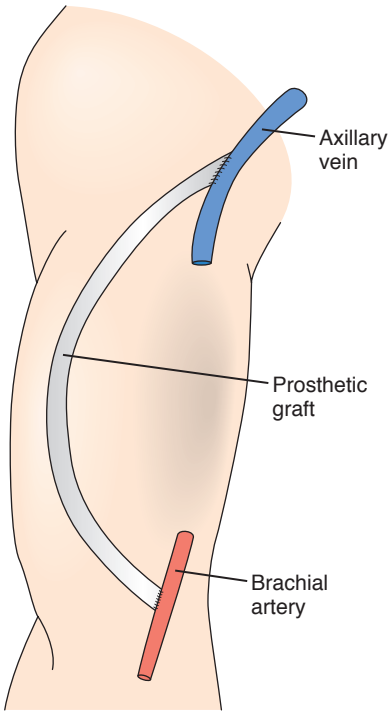

Figure 175.11 Prosthetic brachial (or proximal radial)-axillary (or brachial) upper arm straight access.

TECHNIQUE FOR PERMANENT ACCESS

Despite the multiple anatomic options for both autogenous and prosthetic AV accesses, the principles of surgical technique remain similar in all AV access procedures.

Autogenous Access

The following techniques are common to all autogenous vein accesses:

1. After identification of the vein, the distal end is transected and flushed with heparinized saline. This allows for evaluation of the caliber and extent of the vein and to identify any side branches.
2. With transposition accesses, the vein is completely dissected and mobilized, ligating all side branches, to its origin.
3. After controlling the artery, an arteriotomy of 4 to 6 mm maximal length is made. The length of the arteriotomy is limited to decrease the incidence of arterial steal.
4. The artery is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.
5. The AV anastomosis is performed between the side of the artery and the end of the vein; this configuration decreases the subsequent risk of venous hypertension.
6. The AV anastomosis is performed using a 6-0 or 7-0 monofilament nonabsorbable continuous suture to avoid subsequent anastomotic dilation.
7. With nontransposed access, after completion of the anastomosis, large venous branches can be ligated through stab incisions. This encourages flow in the main venous segment, which may promote earlier maturation.

One-Stage Versus Two-Stage Transposed Access

Whether cephalic or basilic, forearm or upper arm, if autogenous AV access requires a transposition, this may be performed with either a one- or two-stage technique. The main benefit to a one-stage technique is obvious: the patient requires only one procedure and one anesthetic. However, if this access fails to mature, the patient has undergone an extensive dissection with no benefit, often leaving him or her reluctant to try again. A two-stage procedure begins with a direct anastomosis between

the intended artery and vein, followed by a 4- to 6-week waiting period to evaluate for maturity. If the vein appears to be maturing appropriately, the second stage, transposition of the vein, is performed. This requires transection of the vein just proximal to the anastomosis, followed by its mobilization and tunneling, followed by a new anastomosis in its transposed position. The benefits of the two-stage procedure are assuring that the vein will be mature and usable for hemodialysis access before performing an extensive dissection as well as easier dissection of the maturing vein during the transposition. The drawbacks again are obvious: this requires a second procedure and a second anesthetic, putting patients at increased risk of surgery.[26] Therefore we recommend performing this procedure in two stages only with small-caliber (<4 mm) veins.

Prosthetic Access

The following techniques are common to all prosthetic access:

1. The length of the arteriotomy does not have to be limited to 4 to 6 mm. The diameter of the graft will limit the incidence of arterial steal.
2. The artery is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.
3. A 6-mm polytetrafluoroethylene (PTFE) prosthetic graft is used for conduit (see considerations further on).
4. The anastomoses are performed using a 6-0 or 7-0 monofilament nonabsorbable suture in a continuous manner.
5. Careful attention to sterile technique is paramount to avoid graft infections.

Choice of Prosthetic Material

A standard-wall 6-mm expanded PTFE (ePTFE) material is our choice for prosthetic access grafts. Variations in the standard ePTFE graft include thin-walled, extended stretch, external rings, various tapered configurations, and heparin coating. These are all meant to ease handling, provide external support, and improve patency rates. To date, there is only minimal evidence that any of these variations improve long-term results; therefore, use of these variations remains a matter of surgeon preference.[27,28]

Standard-wall grafts can be cannulated as early as 2 weeks; to improve this time further there has been recent development of early cannulation prosthetic grafts (Acuseal, W.L. Gore, Flagstaff, Arizona; Flixene Maquet-Atrium Medical, Rastatt Germany; and Vectra Bard, Covington, Georgia). They are generally constructed in three layers, with an elastomeric membrane sandwiched in between two layers of ePTFE material. This configuration hinders suture-line and dialysis needle bleeding, allowing for early cannulation reportedly as soon as 24 hours from implantation and thus offering the potential for either avoidance or early removal of short- and long-term dialysis catheters. Mean cannulation times have been reported in the literature from 2 to 15 days with minimal hematoma incidence; longer cannulation times were noted to be due to either surgeon or patient preference. Similar to other variations of prosthetic accesses, there is minimal evidence that this variation improves long-term results. Therefore use of this variation remains a matter of surgeon preference.[29-32]

POSTOPERATIVE FOLLOW-UP

From the time of its placement, autogenous AV access should be mature and ready for cannulation 12 weeks postoperatively and prosthetic AV access should be mature and ready for cannulation as early as 2 weeks postoperatively. If any access is noted to be failing to mature, it should be further examined with duplex ultrasound followed by venography if further information is necessary. Secondary procedures include open surgical procedures such as vein patches, interposition vein grafts, vein transposition to proximal arteries, branch ligations, vein superficialization, and endovascular procedures such as arterial and venous angioplasties. McLafferty et al. were able to identify treatable problems with 69% of failing autogenous accesses and successfully salvage the access to functional maturation in 83%.[33] Similarly, Berman et al. demonstrated an overall 10% improvement in achieving a successful autogenous AV access using close follow-up and secondary procedures.[34]

Despite the multitude of secondary procedures available, there are limited options for the treatment of generalized small-caliber veins that fail to dilate after AV access creation. Recent reports have discussed the use of balloon-assisted maturation (BAM); this is a procedure where repeated long-segment angioplasties are performed on the suboptimal outflow vein that is failing to dilate. By disrupting the venous wall, these serial angioplasties essentially transform the outflow vein into a larger-diameter "collagen tube."[35] Using this technique, Miller et al. reported successful maturation in 118 of 122 patients requiring an average of 2.6 procedures, with 15% 1-year primary and 77% 1-year secondary patency rates.[36] Similarly, DeMarco Garcia et al. reported an 85% maturation success rate and an 80% 1-year secondary patency rate.[37] Further reports have discussed the use of BAM at the time of AV access placement for outflow veins measuring less than 2 mm in diameter. Using this technique, Veroux et al. reported a mean fistula maturation time of 32 days, with a 5.2% reintervention rate over 7-month follow-up.[38] Challenges to both of these techniques include essentially converting an autogenous access into a prosthetic with subsequent similar long-term patency and reintervention rates of prosthetic access and the economics associated with repeated multiple procedures to achieve AV access success.[35]

LONG-TERM FOLLOW-UP

After initial maturation, the AV access should be monitored routinely while the patient is on dialysis. The preferred method of monitoring is a monthly determination of access flow by ultrasound dilution, conductance dilution, thermal dilution, or Doppler technique. Access flow less than 600 mL/min or access flow less than 1000 mL/min, which has decreased by 25% over 4 months, should be further evaluated with duplex ultrasound, followed by fistulogram if further information is necessary. Another method of access monitoring, more useful with prosthetic access, is measurement of static venous dialysis pressures; a graft-arterial ratio of greater than 0.75, graft-venous ratio of less than 0.5, or a progressive increase in the venous or arterial segment of more than 0.25 should be further evaluated

with duplex ultrasound followed by fistulogram if further information is necessary.[3,7] Measurements of dynamic venous pressures have been found to be relatively poor markers of autogenous or prosthetic access function. Other acceptable methods of access surveillance include measurement of prepump arterial dialysis pressure, measurement of access recirculation using urea concentrations or dilution techniques, evaluation of physical findings such as arm edema, altered characteristics of access thrill, notation of prolonged bleeding after needle removal, and duplex surveillance. Any abnormalities noted on fistulogram should be treated prophylactically with secondary procedures to prevent access failure.[3,7]

RESULTS

In order to accurately compare AV access procedures, standard definitions regarding patency are necessary and have been defined and published by the Committee on Reporting Standards of the SVS. To review, an AV access is functional only if it can deliver a flow rate of 350 to 400 mL/min without access recirculation to maintain a dialysis treatment time of less than 4 hours. Primary patency is the interval between the time of access placement and any intervention designed to maintain or reestablish patency, access thrombosis, or the time of measurement of patency. Assisted primary patency is the interval between the time of access placement and access thrombosis or the time of measurement of patency, including any intervening surgical or endovascular manipulation. Secondary patency is the interval between the time of access placement and access thrombosis, access abandonment, or the time of measurement of patency, including any intervening surgical or endovascular manipulations designed to reestablish functionality after access thrombosis.[6]

Using these definitions, autogenous AV access has consistently been shown to have excellent primary and secondary patency rates when compared with prosthetic AV access (Fig. 175.12).

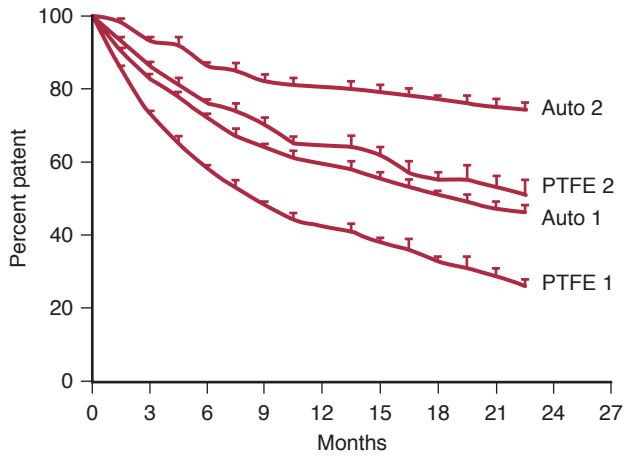

Figure 175.12 Primary and secondary patency rates of autogenous and prosthetic arteriovenous accesses. *PTFE,* Polytetrafluoroethylene. (Reproduced from Huber TS, Carter JW, Carter RL, Seeger JM. Patency of autogenous and polytetrafluoroethylene upper extremity arteriovenous hemodialysis accesses: a systematic review. *J Vas Surg.* 2003;38(5):1005-1011.)

One-year primary patency rates of autogenous AV access range from 43% to 85%[39-46] and 2-year primary patency rates range from 40% to 69%.[40,43,47,48] In comparison, 1-year primary patency rates of prosthetic AV access range from 40% to 54%[39,40,45,46] and 2-year primary patency rates range from 18% to 30%.[40,47,49] Similarly, secondary patency rates are superior in autogenous access, ranging from 46% to 90%[39,40,43-45] at 1 year and from 62% to 75%[40,47-49] at 2 years compared with prosthetic access, which ranges from 59% to 65%[39,40,43] at 1 year and from 40% to 60% at 2 years.[40,47,49] Also of note, in order to maintain these secondary patency rates, prosthetic AV access requires a higher number of interventions than autogenous AV access. To illustrate further the superior patency rates of autogenous access, Huber et al. performed a meta-analysis of the published literature from 1966 to 2001 and showed that primary patency rates for autogenous accesses were 72% at 6 months and 51% at 18 months, with corresponding primary patency rates for prosthetic AV access of 58% and 33%, respectively. Secondary patency rates for autogenous accesses were 86% at 6 months and 77% at 18 months with a corresponding secondary patency for prosthetic AV access of 75% and 55% (see Fig. 72.10), respectively.[40] These superior patency rates of autogenous access include basilic vein transpositions, which have demonstrated 1-year primary patency rates from 35% to 76%[39,42,44,50,51] and secondary patency rates from 47% to 90%, respectively.[39,44,50] Use of a two-stage technique for smaller-diameter (2.5 to 4.0 mm) basilic veins have demonstrated similar 1-year primary and secondary patency rates of 46%[52] and 84% to 96%, respectively.[53,54] These studies demonstrate that the use of the basilic vein in either a one- or two-stage procedure is a preferred alternative to prosthetic AV access when direct access is not available.

A common tradeoff for the higher long-term patency rates associated with autogenous AV access is higher primary failure rates due to failure of access maturation or primary thrombosis. Initial success rates leading to a functional AV access range from 55% to 97%.[41-44,47] These poor maturation rates do appear to correspond to the increasing use of small and suboptimal veins for autogenous access. This was demonstrated by Patel et al., who demonstrated that the use of preoperative duplex vein mapping and venography in the construction of autogenous access increased from 61% to 73%, with a corresponding decline in the functional maturation rate from 73% to 57%.[54]

SELECTED KEY REFERENCES 2313

Over the past decade, significant improvements have been made in quality of care and life expectancy for patients on hemodialysis. Consequently it is not uncommon for the surgeon to be confronted with patients who have "outlived" their arteriovenous (AV) access options in the upper extremities. In one study, nearly 7% of access placements were located at a site other than the upper extremity.[1] For many of these patients, quality of life and long-term survival depend primarily on the surgeon's ability to provide a functional and durable AV access. To meet this challenge, the access surgeon must have a number of complex vascular access procedures in his or her surgical armamentarium and must be aware of the advantages and disadvantages of each.

What is apparent from the available literature and our own anecdotal experience is that these complex access procedures are associated with a higher complication rate compared with AV access procedures of the upper extremity, and the management of these complications is generally more challenging. Although one might be tempted to avoid complex vascular access procedures by simply placing a tunneled dialysis catheter, the significant complications associated with chronic dialysis via a catheter are well established.[2–4] The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines for vascular access recommend the use of a dialysis catheter only as a bridge to AV access placement or in patients with an extremely limited life expectancy.[5] Despite the challenges of complex AV access placement and the associated complications, their placement is usually justified and preferable to the use of a tunneled dialysis catheter.

GENERAL PRINCIPLES

In facing a complex access situation, the surgeon must obtain a complete access history and delineate the causes of prior failures. A careful investigation of the vascular anatomy is important to identify arterial or venous pathology that may affect access outcome. Although noninvasive vascular testing is useful, it may provide insufficient anatomic information on patients who have had multiple access procedures; therefore, contrast angiography and venography are often necessary. Only after a complete understanding of the history and anatomy can the surgeon consider all access options and create a long-term access strategy for the patient.

Abstract

When significant improvements in life expectancy and quality of life have been made in patients on hemodialysis, it is not uncommon for surgeons to be confronted with patients who have "outlived" their arteriovenous (AV) access options in the upper extremities . To meet this challenge, the access surgeon must have a number of complex vascular access procedures in his or her surgical armamentarium and must be aware of the advantages and disadvantages of each. This chapter discusses options and techniques for complex hemodialysis access placement including venous translocation and transposition, chest wall and lower extremity access placement, as well as newer technologies and techniques.

Keywords

complex access
hemodialysis
lower extremity dialysis access

Avoiding Complex Access

As noted earlier, the complication rate of AV access procedures of the lower extremity, chest wall, and other "exotic" access sites is high, and these complications are difficult to manage. Therefore one should ensure that alternatives in the upper extremity do not exist before resorting to these locations. Even though a patient has had multiple failed AV accesses in an extremity, a venogram may reveal an alternative vein, such as a paired brachial vein or a patent cephalic vein in the deltopectoral groove that can provide venous outflow for an additional access procedure in the extremity. Such options should be used before moving to sites outside the upper extremity (Fig. 176.1). If a central venous stenosis is present and the vessels in the upper extremity appear adequate for AV access placement, the surgeon should consider angioplasty and/or stenting of the central vein stenosis and then placement of an upper extremity access rather than proceeding with a complex access elsewhere. Although the primary patency of percutaneous central vein angioplasty is only 29% at 12 months, remedial angioplasty procedures either alone or with a stent are generally easy to perform and can extend the 12-month patency to more than 70% (Fig. 176.2).[6]

Selection of a Complex Access Site

Although algorithms have been developed that define a general order of preference for access placement in the upper extremity, the development of a similar algorithm for complex access placement is problematic, given the dearth of evidence-based literature related to these procedures. It is possible, however, to provide broad recommendations regarding the clinical situations in which a particular complex AV access procedure is most helpful and those in which it should be avoided. These recommendations are outlined in Table 176.1.

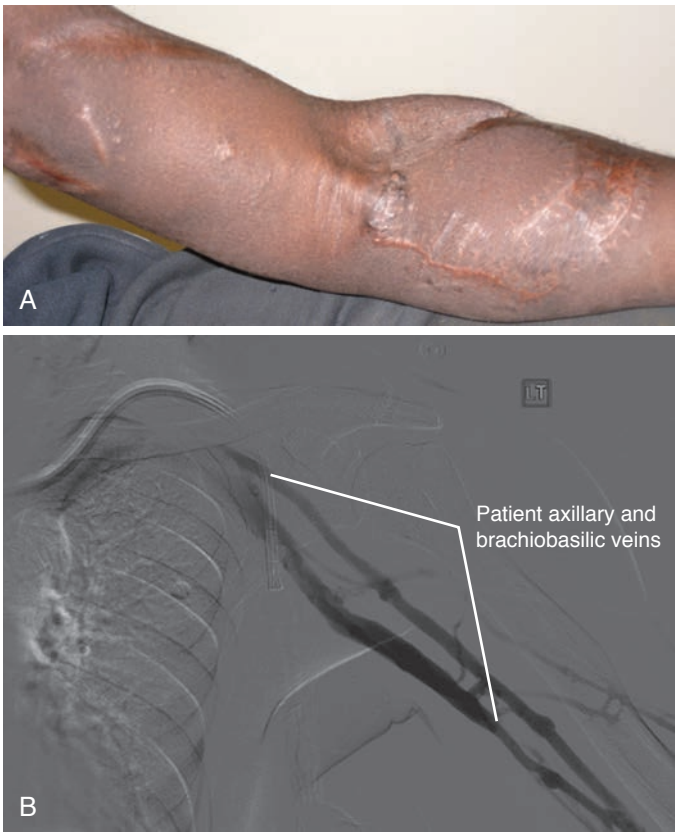

Figure 176.1 (A) Patient with failed prosthetic arteriovenous (AV) accesses in the left forearm and upper arm is referred for the establishment of a new access. (B) A venogram was obtained to determine whether any alternative to a "complex" access was available in the left upper extremity. Despite the two previous upper extremity AV access procedures, the brachiobasilic, axillary, and central veins were widely patent. A successful brachiobasilic transposition was performed.

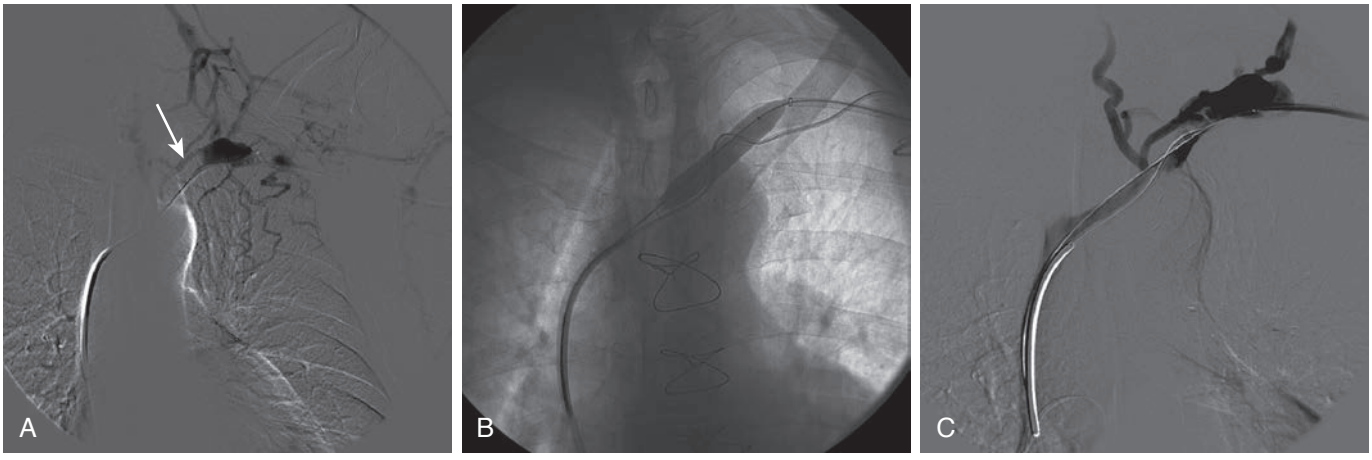

Figure 176.2 (A) Venography of the left upper extremity in a patient with an autogenous brachiocephalic arteriovenous access and symptoms of venous hypertension demonstrates chronic occlusion of the subclavian vein *(arrow)*. (B) The subclavian vein occlusion was crossed with a wire, and angioplasty was successfully performed with a high-pressure balloon. (C) Completion venography demonstrating patency of the central veins.

TABLE 176.1 Major Complex Access Procedures: Indications, Relative Contraindications, and Anatomic Requirements

Access Procedure	Specific Anatomic Requirements	Ideal Clinical Situation	Relative Contraindications
Autogenous femoral vein transposition	Patent femoral vein >3 mm in diameter Patent, noncalcified superficial femoropopliteal artery	Pediatric or young, healthy patients Patients who are hypercoagulable with no other autogenous access options Patients at high risk for infection (poor hygiene, immunosuppressed, multiple previous access infections)	Significant obesity of the thigh Patients who are elderly or "medically fragile" Access sites for temporary catheter placement not readily available Patients at high risk for access-related ischemia of the lower extremity
Prosthetic midthigh loop femoral-femoral access Prosthetic loop femoral-femoral access	Patent femoral or common femoral vein Patent, noncalcified superficial femoral artery (midthigh access) or common femoral artery	Patients who are elderly or have significant medical comorbidities	Patients at high risk for infection (poor hygiene, immunosuppressed, multiple previous access infections) Patients who are morbidly obese
Prosthetic chest wall access	Patent axillosubclavian artery and vein Patent central vein	Patients who are morbidly obese Patients at high risk for access-related limb ischemia	Patients who are reasonable candidates for autogenous or prosthetic thigh access procedures
Tunneled dialysis catheter	Patent central vein	Patients who are "medically fragile" or have limited life expectancy (<6 mo) Patients in whom all alternative access procedures have been expended	Patients who are candidates for an alternative complex access procedure (autogenous or prosthetic thigh or chest wall access)
Hemoaccess Reliable Outflow vascular access device	Guide wire access to a patent central vein Brachial artery >3 mm	A central venous stenosis/occlusion that precludes upper extremity autogenous or prosthetic access options Patients otherwise relegated to dialysis via a tunneled dialysis catheter	Active infection Systolic blood pressure <100 mm Hg Ejection fraction <20%

AUTOGENOUS ARTERIOVENOUS ACCESS

Several techniques have been described that use the saphenous and femoral veins to create autogenous AV accesses in the upper and lower extremities. These veins can be completely mobilized and disconnected both proximally and distally to create an access at a site remote from their origin (translocation). Alternatively, the distal portion of the vein can be mobilized and tunneled superficially, leaving the central portion of the vein connected to its normal anatomic position (transposition).

Given the high infection rate associated with AV access procedures of the lower extremity, use of the saphenous vein or femoral vein translocation or transposition procedures in the thigh is theoretically appealing. However, these operations have been associated with wound complications related to vein harvest and access-related ischemia or steal syndrome; therefore, their role in AV access procedures remains undefined, and they are not included in the KDOQI clinical practice guidelines.[5]

Translocation Procedures

The autogenous brachial artery–axillary vein fistula with saphenous vein or femoropopliteal vein translocation is an alternative to thigh access for patients with poor superficial upper extremity veins who are not candidates for a traditional upper extremity autogenous access. This access may also be indicated for patients with multiple failed upper extremity prosthetic AV accesses owing to infection or unexplained thrombosis.

Saphenous Vein–Forearm Translocation

Few studies have been published evaluating saphenous vein–forearm translocation for hemodialysis access. Secondary patency rates vary widely between the studies from 50% to 96% at 1 year and 66% to 84% at 2 years.[7–10] The infection rate is low, but has been quoted as high as 4%.[8] Since patency is not clearly defined in these saphenous vein–forearm translocation reports, it is unclear whether the patency results cited in those studies refers to functional patency. The saphenous vein can be translocated as a forearm loop configuration[7] or placed in a straight configuration from the radial artery to the antecubital vein.[8]

Femoropopliteal Vein–Arm Translocation

Results

Huber et al. reported a series of 30 patients who underwent translocated femoral vein–upper arm brachial axillary access.[11] They reported primary and secondary patency rates of 67% and 100% at 18 months. Although this procedure has the potential advantages of an autogenous access, they must be

balanced against a higher incidence of wound hematomas, compartment syndrome, and access-related upper extremity ischemia. Distal revascularization–interval ligation (DRIL) was employed to treat clinically significant access-related ischemia in 27% of patients in that series. Huber's group stressed the importance of using the contralateral rather than the ipsilateral saphenous vein for the DRIL procedure to reduce the risk of limb swelling and compartment syndrome.

Arm composite autogenous vascular access (ACAVA) using the great saphenous vein and the femoral vein has also been described.[12] The rationale for this technique was to decrease the diameter of the vein at the arterial anastomosis in hopes to minimize the rate of steal syndrome. At 12 months, the secondary patency rate was 81%. Of note, one patient developed steal syndrome.

Technique

Before harvesting the femoral vein, the surgeon must ensure that the patient has adequate arterial circulation to heal wounds from the vein harvest. Duplex ultrasonography of the lower extremity is necessary to confirm that the femoral vein is patent and has an adequate diameter (>6 mm).

A longitudinal skin incision is made over the brachial artery proximal to the antecubital fossa. The axillary vein is exposed through a single longitudinal incision in the axilla. To expose the femoral vein, an incision is made in the groin and extended distally along the medial border of the sartorius muscle. The vein is mobilized from the mid–popliteal fossa to the common femoral vein. Tributaries are ligated and divided. It is important to preserve the profunda vein to reduce the symptoms related to outflow obstruction. The reversed vein is connected to the brachial artery and axillary vein (Fig. 176.3). A closed suction drain is placed in the thigh wound, and the incisions are closed in layers.

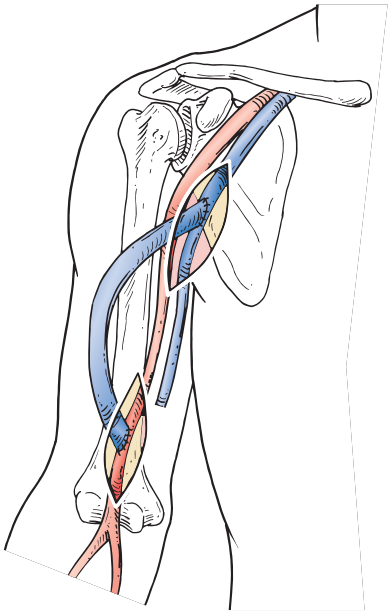

Figure 176.3 Brachioaxillary arteriovenous access using the reversed translocated femoral vein.

Transposition Procedures

Brachial Vein Transposition

Results

In 2004, Bazan and Schanzer reported two cases of autogenous brachial vein transposition in patients with inadequate superficial upper extremity veins for autogenous AV access creation.[13] No manifestations of venous hypertension occurred in either patient. After 1 year, both accesses were functional. Other series report secondary patency rates from 40% to 92% at 1 year. This procedure can be done as a single stage transposition[14] or with a two-stage technique.[15] One published series reported a 2-year patency of 55%.[16]

Technique

Although this technique has been described as a single-stage procedure, most reports recommend that brachial vein transposition be performed as a two-stage procedure whereby the AV anastomosis is created at the first stage, followed 6 weeks later by vein transposition. One-stage procedures are considered only in cases in which the brachial vein exceeds 4 mm in diameter. The first stage of the procedure involves making a longitudinal incision over the brachial pulse in the antecubital fossa in order to expose both the brachial artery and vein. When multiple brachial veins are present, the largest vein is used for the AV anastomosis. Use of the proximal radial artery, rather than the brachial artery, as the site for the AV anastomosis may reduce the risk of access-related limb ischemia. An end-to-side vein-to-artery anastomosis is performed using a running 6-0 polypropylene suture. The second stage is performed 4 to 6 weeks after the first to allow the vein wall to arterialize, thereby facilitating its mobilization. A longitudinal incision is made over the course of the brachial artery and vein in the upper arm to expose the entire brachial vein length from the antecubital fossa to the axilla.

The medial antebrachial cutaneous and median nerves are adjacent to the vein and must be protected from injury. Venous tributaries are individually suture-ligated. The anterior surface of the vein is marked to prevent twisting during transposition. The vein is divided near the AV anastomosis and passed through a subcutaneous tunnel created with a tunneling device. An end-to-end anastomosis of the vein is then performed. If the vein is too short to be transposed through a separate subcutaneous tunnel, it can be simply elevated by closing the fascia and subcutaneous tissue of the wound beneath it with interrupted 3-0 absorbable suture. A running 4-0 absorbable suture is used to close the skin over the vein containing the access. The access can be cannulated once the skin incision has completely healed, usually in about 3 weeks after the second-stage procedure.

Saphenous Vein Transposition

Results

The common femoral artery–saphenous vein loop transposition was first described in a single patient by May et al. in 1969.

Based on the limited number of series[17–19] reporting the outcome of saphenous vein translocation, the following conclusions can be drawn: (1) The use of skip incisions or endoscopic techniques to harvest the saphenous vein may decrease the wound complications associated with this procedure; (2) because the great saphenous vein does not readily dilate after access creation, only veins greater than 3 mm in diameter should be used and the vein must be tunneled just beneath the dermis to allow reliable cannulation of the access; (3) cannulation of the access must be delayed at least 6 weeks postoperatively to prevent puncture-site bleeding and hematoma; (4) the procedure may not be practical for patients who are morbidly obese or those with a large redundant pannus because access cannulation may require the patient to lie in the supine position and retract the pannus to expose the access.

Alomran et al. described an innovation of the GSV AVF in the form of a semipaneled graft, which aims to overcome the poor dilation of the GSV but requires harvest its entire length. This technique is labor-intensive because it involves longitudinal venotomy and open valvulotomy of the entire GSV and the creation of panels.[20]

Technique

The saphenous vein is exposed and mobilized from the saphenofemoral junction to the knee. Mobilization of the saphenous vein can be accomplished using skip incisions over the vein or an endoscopic vein harvest technique. The saphenous vein is transected distally at the knee, leaving the saphenofemoral junction intact. The saphenous vein is tunneled to form a subcutaneous loop and anastomosed to the superficial femoral artery.

Femoral Vein Transposition

Results

The largest experience with autogenous femoral artery–femoral vein transpositions was reported by Gradman et al. in two separate series.[21,22] The initial series reported the outcome for 25 patients who underwent the procedure. Ten of the accesses were narrowed or "banded" (i.e., flow-limited) at the time of the initial procedure to prevent postoperative access-related limb ischemia. Even with banding, limb ischemia necessitating additional surgery was common, occurring in 32% of patients. The primary and secondary patency rates at 12 months were 78% and 87%, respectively. The ankle-brachial index decreased an average of 0.21.[21]

In an effort to decrease the incidence of access-related limb ischemia, Gradman modified the technique and patient selection criteria.[22] The size of the arterial anastomosis was limited by inserting a 5-mm mandrel in the beveled vein and closing the excess vein with suture. The tapered vein was then anastomosed end to side to the distal superficial femoral artery. Patients with an ankle-brachial index less than 0.85 or absent pedal pulses were excluded. Prophylactic fasciotomies were performed in patients with weak or absent pedal pulses after access creation. The secondary patency rate was 94% at 2 years. With the modification in technique and patient-selection criteria, the occurrence of limb ischemia necessitating revascularization was reduced from 32% to 0%. Other studies report primary patency of 91% at 1 year and secondary patency of 84% at 2 years.[23] Complications of this technique includes distal limb ischemia, venous hypertension requiring fasciotomies, bleeding, and high-output heart failure.[24] Therefore, caution is necessary in creating this access in patients with congestive heart failure.

Technique

A preoperative assessment of the lower extremity arterial and venous anatomy with duplex ultrasonography is necessary.

The femoral vein is exposed and mobilized as described previously. In obese patients it is often necessary to mobilize the vein to the knee to gain adequate length. It is critical to preserve the profunda vein to prevent venous hypertension and compartment syndrome. The femoral vein is ligated distally and transected. The vein is brought through a subcutaneous tunnel lateral to the vein harvest incision and anastomosed to the superficial femoral artery in the distal thigh. The distal end of the femoral vein should be tapered to 4.5 to 5 mm, as outlined earlier (Fig. 176.4A).

In cases where the patient was considered at high risk for access-related limb ischemia or if he or she was significantly obese and superficialization of the vein provided inadequate

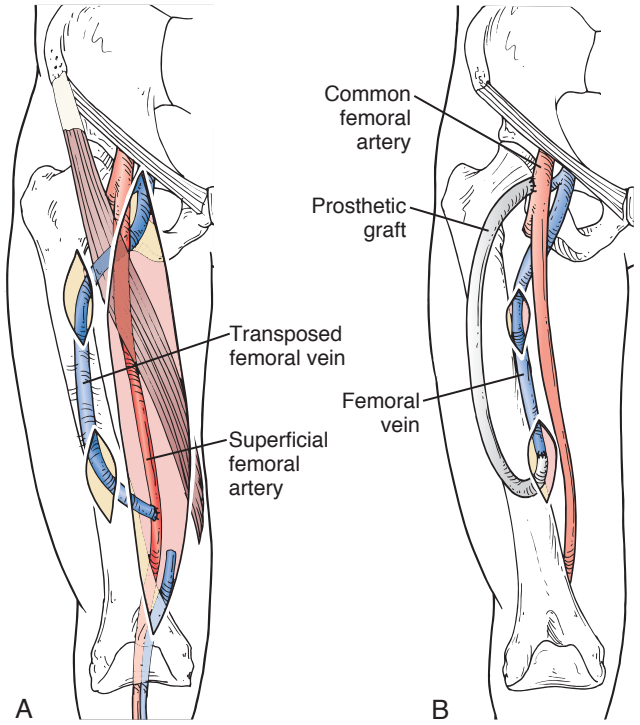

Figure 176.4 (A) Femoral vein transposition procedure. (To review the technique for exposing the femoral vein, see the section titled "Femoropopliteal Vein–Arm Translocation.") After the femoral vein has been exposed, it is transected in the popliteal fossa and mobilized to the common femoral vein, preserving the profunda vein. The femoral vein is passed posterior to the superficial femoral artery through a subcutaneous tunnel on the anterior thigh and anastomosed to the distal superficial femoral artery. (B) Composite femoral vein transposition and prosthetic access procedure. The 4- to 7-mm polytetrafluoroethylene graft is tunneled deeply to prevent needle cannulation of the prosthetic access and reduce infection. This technique is used in patients at high risk for access-related limb ischemia or in obese patients with inadequate vein length for superficialization.

length for cannulation, Gradman modified the technique by anastomosing a 4- to 7-mm polytetrafluoroethylene (PTFE) graft end to end to the femoral vein and tunneling the composite vein-graft laterally in the thigh in a loop configuration. The 4-mm end of the prosthetic graft was anastomosed end to side to the common femoral artery (Fig. 176.4B). The smaller portion of prosthetic limb of the access was tunneled deep in the subcutaneous tissue to prevent cannulation of it by dialysis technicians.

A modification of the femoral vein transposition technique has been described in patients with inadequate vein length.[25] Rather than passing the vein through a tunnel, the vein is elevated by approximating the subcutaneous tissue beneath the vein. The skin is approximated over the access using a subcuticular closure technique. After 4 to 6 weeks, the access is cannulated directly through the overlying scar.

Ankle Fistula. To date, there have only been a few case reports of ankle AV fistula formation either from the posterior tibial artery to saphenous vein or dorsalis pedis artery to saphenous vein. The procedure involves a cutdown at the ankle and end-to-side anastomosis of the greater saphenous vein to the artery. Preoperative assessment with digital pressures as well as angiogram should be performed to guide management. A patient with heavily calcified tibial vessels or absence of a palpable pulse would not be an ideal candidate for this type of fistula. Because of the paucity of literature regarding this procedure, no recommendations can be made regarding its efficacy.[26–29]

PROSTHETIC ARTERIOVENOUS ACCESS

Prosthetic Chest Wall and Cervical Arteriovenous Access

Sites for prosthetic AV access placement in the cervical region and on the chest wall are as follows: axillary artery–ipsilateral axillary vein loop access (Fig. 176.5A), axillary artery–contralateral axillary or jugular vein straight access ("necklace access"; Fig. 176.5B), and brachial artery–jugular vein straight access (see Fig. 176.5B). Although the prosthetic chest wall AV access was first described in 1978, the literature reporting the outcomes of this technique is limited primarily to case reports and small case series.[1,30–32]

Results

Necklace Access

In 1996, McCann reported outcomes for a series of 26 patients with prosthetic chest wall AV accesses.[31] He used a straight graft configuration from the axillary artery to the contralateral axillary or internal jugular vein. The secondary patency rate for AV accesses in his series was 60% at 2 years. In a more recent series, the primary and secondary patencies at 12 months were 72% and 89%, respectively.[33] All accesses in that series were monitored bimonthly with physical examination and ultrasound in order to detect access dysfunction prior to thrombosis. Because

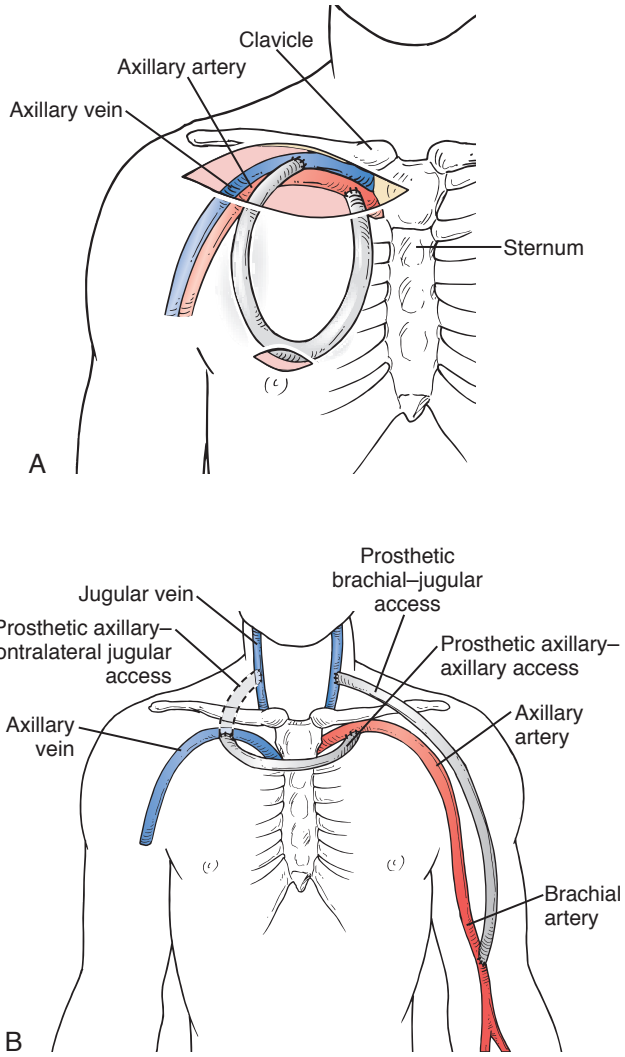

Figure 176.5 (A) Prosthetic axillary artery–axillary loop access. By situating the venous limb of the graft laterally on the chest wall and angling the venous anastomosis toward the central veins, subsequent percutaneous angioplasty is facilitated should a stenosis develop. (B) Prosthetic chest wall and cervical straight access options.

the arterial and venous anastomoses are oriented peripherally with the straight graft configuration, thrombectomy may require an incision near one or both anastomoses to effectively clear thrombus from the access and percutaneously treat an anastomotic stenosis.

Brachial to Jugular Access

Vega et al. reported a series of 51 prosthetic brachial artery–jugular vein accesses.[34] The secondary patency rate was 70% at 18 months, which is similar to the patency rate of axillary-axillary AV access. Other studies have reported a secondary patency of 93% at 1 and 2 years.[35] The prosthetic graft is tunneled over the ventral aspect of the shoulder and over the midclavicle. It is important to confirm patency of the jugular vein with a preoperative imaging study (Table 176.2).

Ipsilateral Axillary-Axillary Chest Wall Loop Access

Liechty et al. recently published their series of 67 prosthetic axillary-axillary loop access and reported primary and secondary

patency rates of 81% and 58% at 2 years. The authors also explain that if there was central venous stenosis or occlusion, an attempt should be made to recanalize the central veins. If adequate results could not be obtained, they suggest placement of the HeRO graft (discussed later).[36] The looped graft configuration, which uses the ipsilateral axillary artery and vein, preserves the contralateral axillary vessels for future access placement. Should a subsequent stenosis develop at the venous anastomosis, this orientation toward the central veins will facilitate percutaneous intervention.

No case of access-related steal was noted in any of the three largest chest wall access series.[1,31,32] In each of these series, a number of axillary artery–axillary vein accesses were placed in patients in whom previous accesses in the ipsilateral extremity had caused hand ischemia. Based on this experience, it appears that a history of access-related hand ischemia does not preclude access placement based off the ipsilateral axillary artery.

Chest wall access appears to be associated with a lower infection rate than prosthetic AV access in the lower extremity. The infection rates range from 4% to 15%, which compares favorably with series reporting the outcome of prosthetic AV accesses based off vessels in the groin. Given the technical challenge and higher complication rate associated with prosthetic AV access placement in the thigh position in patients who are morbidly obese, chest wall access may be an attractive alternative in this situation. One potential disadvantage of chest wall access, however, is that proximal control of the axillary vessels can be extremely challenging if the graft becomes infected and needs to be excised.

Technique

Most patients considered for a chest wall or cervical AV access procedure have had previous central venous dialysis catheters and multiple upper extremity AV access procedures and interventions; therefore, it is important that patients undergo venography to confirm central venous patency before surgery. If the proximal axillary, subclavian, or brachiocephalic vein has recently undergone angioplasty or stenting, an alternative site for AV access should be considered, because recurrent stenosis following central venous intervention is common and may influence access patency.

The patient is placed in the supine position with the arm extended 90 degrees on an arm board. An incision is made one fingerbreadth below the clavicle from the sternoclavicular joint to the coracoid process. The pectoralis major muscle fibers are split. The clavipectoral fascia is divided, and the axillary vein is exposed and mobilized. The axillary artery lies beneath the vein. The artery is exposed at its exit from the thoracic outlet and mobilized to the pectoralis minor muscle. The pectoralis minor muscle is not divided. Branches of the axillary artery, such as the supreme thoracic artery, are ligated and divided as necessary to achieve adequate mobilization of the axillary artery. A 6-mm PTFE graft is tunneled in a loop configuration on the chest wall. Before tunneling of the graft, the patient is placed in the reverse Trendelenburg position to reposition the breast in a dependent location. This maneuver is performed to accurately determine graft length and is particularly important for patients with pendulous breasts. The graft is tunneled using a transverse counterincision made cephalic to the areola. The venous limb of the prosthetic graft is positioned laterally on the chest. The venous end of the graft is oriented nearly parallel to the axillary vein and directed centrally (see Fig. 176.5A). The arterial end of the graft is positioned perpendicular to the axillary artery. The graft is sewn end to side to the axillary artery and vein. Dialysis technicians are allowed to cannulate the access 2 to 3 weeks postoperatively.

Hemodialysis Reliable Outflow Vascular Access Device

For patients whose options for an upper extremity vascular access are precluded by a central venous stenosis or occlusion, the hemodialysis reliable outflow (HeRO) device (Hemosphere, Inc., Minneapolis, Minnesota) is a reasonable alternative to a lower extremity access or tunneled dialysis catheter. The HeRO device is composed of two components: a graft component, which is a 6-mm PTFE graft with a titanium coupler at one end, and a venous outflow component, which is a 19-Fr silicone catheter reinforced with a nitinol braid to prevent kinking. The graft component is anastomosed to an artery such as the brachial artery and is tunneled subcutaneously as a standard prosthetic

AV access. The venous outflow component does not require a venous anastomosis but rather is percutaneously placed into the right atrium via the internal jugular or subclavian vein. The graft and venous outflow components are tunneled subcutaneously to a counterincision in the deltopectoral groove, where they are connected with a titanium coupler (Fig. 176.6). The US Food and Drug Administration has approved the HeRO device for use in catheter-dependent patients with central venous stenosis or occlusion. Relative contraindications for HeRO device placement include a brachial artery diameter less than 3 mm, systolic blood pressure less than 100 mm Hg, active infection, and/or ejection fraction less than 20%.

Results

The initial study reporting results for the HeRO device was an industry-sponsored, multicenter, nonrandomized trial that included 36 patients who were receiving dialysis via a tunneled catheter due to a central venous stenosis or occlusion.[37] HeRO device outcomes were compared with the results of a meta-analysis of the tunneled dialysis catheter literature. The primary and secondary patency rates for the HeRO device at 8 months were 39% and 72%, respectively. A mean of 2.5 interventions were required annually to maintain patency of the HeRO device. No studies have directly compared outcomes of the HeRO device with those of other complex access procedures. The four centers involved in the original industry-sponsored trial subsequently reported their collective experience.[38] The primary and secondary patency rates at 1 year were 49% and 91%, respectively. A recent meta-analysis included 409 patients with primary and secondary patencies of 22% and 59% at 1 year. The incidence of steal syndrome was 6.3%.[39]

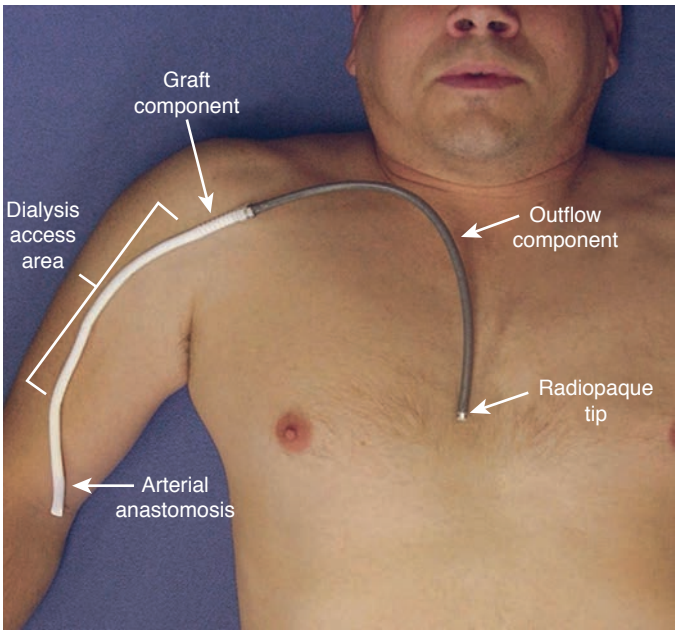

Figure 176.6 Placement of a device for hemodialysis reliable outflow (HeRO) vascular access. The silicone catheter component of the HeRO device is placed into the central veins using a similar technique to that of placing a tunneled dialysis catheter. To facilitate passage of the catheter component of the HeRO device, it may be necessary to dilate the tract with an over-the-wire angioplasty balloon. A tunneling device is used to pass the silicone catheter from the neck incision to the counterincision at the deltopectoral groove. An end-to-side anastomosis between the graft component and the distal brachial artery is performed and the graft is tunneled retrograde to the incision at the deltopectoral groove. Silicone catheter and graft components are connected using the titanium connector. (From Katzman HE, McLafferty RB, Ross JR, Glickman MH, Peden EK, Lawson JH. Initial experience and outcome of a new hemodialysis access device for catheter-dependent patients. *J Vasc Surg.* 2009;50:600-607.)

Technique

An operating room with both open surgical and endovascular intervention capabilities is required. The procedure is performed with the patient under general anesthesia. The patient is placed in the supine position with the upper extremity extended 90 degrees on an arm board and the head turned away from the side through which the HeRO device is to be implanted. An incision is made over the brachial pulse in the distal upper arm, and the brachial artery is exposed and mobilized. A counterincision for connecting the graft and catheter components is made in the deltopectoral groove. Using a tunneling device, the graft component of the HeRO device is brought through a subcutaneous tunnel from the exposed brachial artery into the counterincision. Ideally, the venous component of the HeRO device should be placed using a new venous stick under ultrasonic guidance. However, if both internal jugular and subclavian veins are occluded, an existing tunneled dialysis catheter can be wired and exchanged with the venous outflow component. To enable passage of the introducer sheath and silicone catheter through the established tract, it may be necessary to dilate the tract with an over-the-wire high-pressure angioplasty balloon. After dilation of the tract, a dilator/introducer sheath is inserted over the guidewire. The dilator and guide wire are removed and the silicone catheter is inserted using the tear-away sheath. Fluoroscopy is used to ensure correct positioning of the catheter tip in the right atrium. A tunneling device is used to pass the end of the venous component from the neck incision to the counterincision in the deltopectoral groove. After systemic heparin is administered, an end-to-side anastomosis between the graft and the distal brachial artery is performed in standard fashion. The graft and catheter are trimmed to the appropriate length at the incision in the deltopectoral groove and are then connected using the titanium connector. The clamps are removed and flow is established through the graft. A thrill should be palpable over the graft component of the access. After 2 to 4 weeks, the graft component of the device is accessed in the same manner as a conventional prosthetic AV access. Occasionally, it is necessary to exchange a functioning tunneled dialysis catheter for the venous component of the HeRO device over the wire, and there are no alternative sites to place a new tunneled catheter for dialysis while awaiting incorporation of the graft. In such cases, the author has used a Super HeRO adapter (Merit Medical, South Jordan, Utah) designed to connect an early cannulation graft, such as an Accuseal (W.L. Gore, Newark, Delaware) to the venous outflow component of the HeRO device. The graft can be cannulated immediately after HeRO placement and this eliminating the need for the placement of a tunneled dialysis catheter.

Prosthetic Lower Extremity Arteriovenous Access

The sites and graft configurations most commonly used for prosthetic access placement in the lower extremity are femoral artery–greater saphenous or femoral vein loop AV access and popliteal artery–greater saphenous or femoral vein straight AV access (Fig. 176.7).

For most surgeons, prosthetic lower extremity AV access is the preferred site once options in the upper extremity have been exhausted. Advantages of the procedure include the following: the operation is relatively simple to perform owing to the accessibility and size of the femoral vessels; patency rates for these accesses are comparable, if not superior, to those of upper extremity accesses; the surgical management of complications, such as graft infection and anastomotic stenosis, is easier than for chest wall accesses; and both of the patient's hands are free to self-cannulate the access or to perform activities during dialysis. The major disadvantages of the prosthetic lower extremity access are a higher infection rate compared with AV accesses in the upper extremity as well as an increased risk of lower extremity ischemia.

Results

A number of series reporting the outcome of prosthetic lower extremity AV accesses have been published. However, different methods of reporting outcomes prohibit the direct comparison of some results. Antoniou et al. published a meta-analysis discussing 660 upper-thigh AVGs and 60 midthigh grafts. The average secondary patency rates at 1 year were 71%, with an average 2-year secondary patency rate of 60%; there was no difference in the patency of upper-thigh grafts compared with midthigh grafts.[40] These investigators included only studies reporting outcomes using the convention established by the Committee on Reporting Standards for AV Accesses of the Society for Vascular Surgery and the American Association for Vascular Surgery (AAVS) (Table 176.3). The infection rates reported in thigh-access series ranged from 8% to 41%.[8,41–46] Two reports suggested that prosthetic thigh AV access may be associated with a high incidence of limb loss; however, neither study objectively documented access-related ischemia as the cause of limb loss.[41,47] Although other studies reported clinically significant access-related ischemia in up to 11% of cases, limb loss occurred in only 1% to 3% of cases.[42–46]

There are significant disadvantages of prosthetic femoral-femoral AV access for patients who are obese. The abdominal pannus that overlies the groin and the depth of the femoral vessels in obese patients not only make the placement procedure more technically difficult but also increase the risk of complications. The largest series of prosthetic femorofemoral AV accesses noted significantly higher rates of access reintervention in obese compared with nonobese patients.[41]

Reports have been published describing the technique and outcome in a series of patients who underwent prosthetic looped AV access based off the mid–superficial femoral artery and femoral vein in the midthigh rather than the groin (Fig. 176.8).[48,49] This modification avoids the node-bearing tissue and the panniculus and may, therefore, be associated with a lower infection rate. Furthermore, the prosthetic midthigh loop access also preserves the proximal femoral vessels for future access placement.

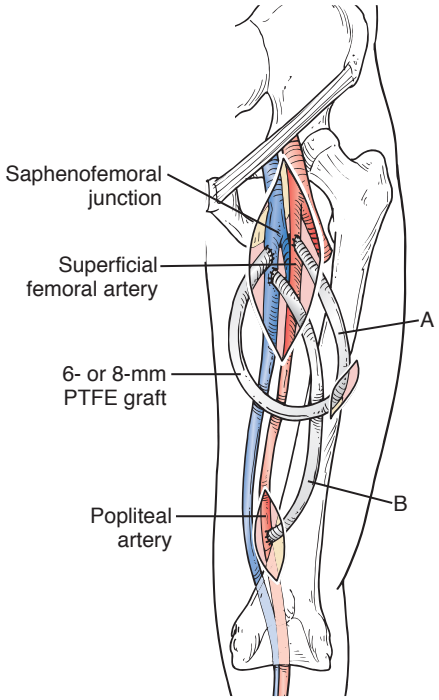

Figure 176.7 Prosthetic thigh access options: femorosaphenous loop access (A) and popliteosaphenous straight access (B). *PTFE,* Polytetrafluoroethylene.

Technique

Patients should undergo duplex ultrasonography of the femoral vessels before access placement to verify patency of the artery and vein and to determine the degree of calcification of the arterial wall. This is particularly important if a midthigh access is planned, because the superficial femoral artery is often diseased or significantly calcified. In selected cases, contrast angiography of the artery or vein may be necessary.

For a proximal loop graft, the femoral artery and great saphenous vein are exposed using a single longitudinal groin incision positioned over the femoral pulse. The proximal superficial femoral artery and greater saphenous vein near the saphenofemoral junction are mobilized for a distance of 3 to 4 cm. The superficial femoral artery is the preferred site for arterial inflow, but the common femoral artery can be used. The greater saphenous, femoral, or common femoral vein can be used as the site for the venous anastomosis. The same tunneling technique described for prosthetic forearm loop AV access is used for the placement of a prosthetic thigh access. Although some use an 8-mm PTFE graft for thigh access, we use a 6-mm graft to minimize the risk of access-related ischemia.

To expose the superficial femoral artery and femoral vein for the performance of midthigh loop access, an incision is made along the medial border of the sartorius muscle in the midthigh. This muscle is retracted to gain access to the femoral vessels. The superficial femoral artery and femoral vein are encircled with vessel loops. The graft is tunneled over the anterolateral thigh. This graft location facilitates graft cannulation

without requiring the patient to rotate the extremity externally. In most cases, the venous limb of the graft is situated medially and the arterial limb laterally on the thigh. In patients in whom the superficial femoral artery lies beneath the sartorius muscle, the lateral border of the muscle is mobilized and the arterial limb is tunneled lateral to it (see Fig. 176.8A).

CRYOPRESERVED VEIN ALLOGRAFTS

Cryopreserved vein allografts (cadaveric vein) have emerged as an option for AV graft reconstruction; however, indications for their use in hemodialysis access remains to be clearly defined. A recently published study discussed the use of cryopreserved vein allografts in 106 patients over a 10-year period. The investigators categorized the graft placement as central outflow (outflow to the subclavian vein, innominate vein, or right atrium), standard outflow (axillary vein, cephalic or basilic vein), or femoral outflow. The observed primary and secondary patency rates were 22.6% and 66%, respectively, at 1 year. The authors state that the potential benefit of a cryopreserved vein allograft over a prosthetic conduit is realized in patients with multiple repeat accesses and active infections (42% of patients in this series had history of active or recent infection).[51] The disadvantages of cryopreserved vein allografts are recurrent infection of the allograft and the dreaded complication of rupture, leading to loss of limb or life in our experience. Therefore this approach should be used only in select cases.

UNCONVENTIONAL VASCULAR ACCESS PROCEDURES

The literature describes a number of "exotic" AV access procedures used to obtain access when options in both the upper and lower extremities have been exhausted. These procedures are generally described in case reports; therefore, their durability and complication rates have not been established. However, their use may be justified when no other alternative exists.

Unconventional Chest or Abdominal Wall Access Procedures

In several case reports and small case series, direct surgical approaches to the central veins have been described for patients

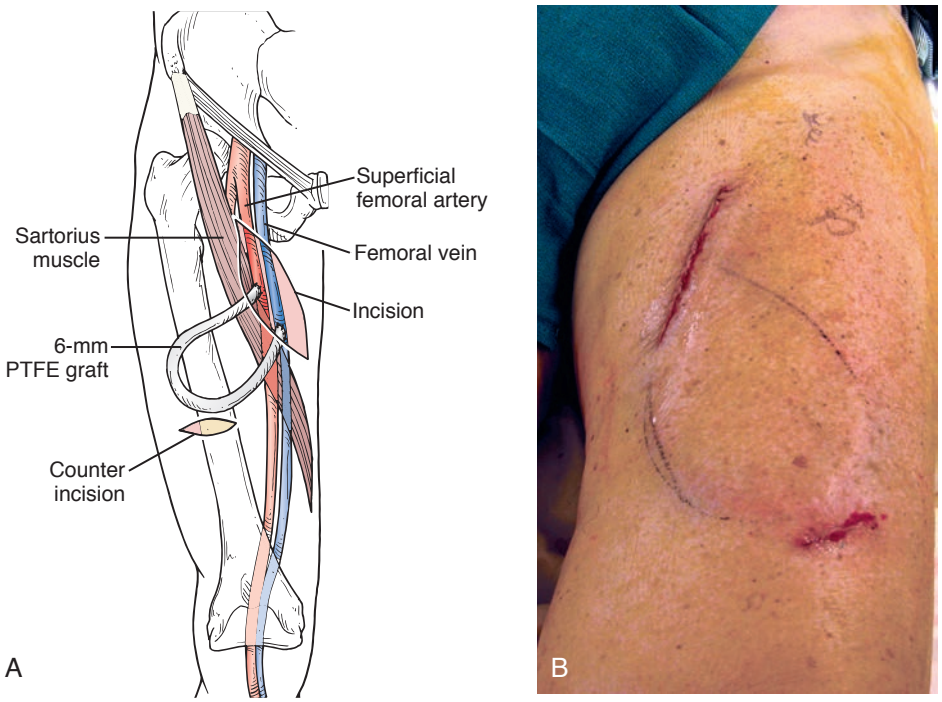

Figure 176.8 (A) Midthigh loop access with both graft limbs tunneled medial to the sartorius muscle. Alternatively, if the superficial femoral artery lies closer to the lateral edge of the muscle, the arterial limb can be passed lateral to the sartorius muscle. (B) Photograph demonstrating the location of the incisions for midthigh loop access placement and the relation of the midthigh loop access to the groin. *PTFE,* Polytetrafluoroethylene.

with central venous occlusion who require vascular access or have access-related venous hypertension. These include a bypass to the right atrial appendage through a third intercostal space, or "minipericardiotomy"; a right superficial femoral artery–superior vena cava (SVC) prosthetic access; and a femoral transposition combined with an iliac vein to a suprarenal vena cava bypass.[52–54]

Karp et al. have published a case report describing a prosthetic chest wall access from the axillary artery to the left renal vein.[55] The left renal vein was exposed through a left flank retroperitoneal incision. The prosthetic graft was tunneled on the chest wall lateral to the nipple and over the 12th rib. A polyurethane graft was used in this case to allow early cannulation of the access. Although several interventions were required to maintain access patency owing to graft kinking over the 12th rib, the access remained patent for 18 months.

The authors have placed a prosthetic external iliac–left renal vein access in a patient with no other access options. The left external iliac artery was exposed just proximal to the inguinal ligament, and the left renal vein was exposed through a retroperitoneal flank incision. To prevent kinking and allow early cannulation of the access, a ringed PTFE graft was used for the intra-abdominal graft segment, and a polyurethane graft was used on the abdominal wall. The access functioned without requiring intervention until the patient's death from a cardiac event 8 months postoperatively.

A prosthetic axillary artery–right atrium AV access in a patient with thrombosis of both the superior and inferior venae cavae has been described.[56,57] The right axillary artery is exposed through an infraclavicular incision, and a median sternotomy is used to expose the atrial appendage. An 8-mm PTFE graft is tunneled beneath the pectoralis muscles into the axilla along the midaxillary line. At the level of the ninth rib, the graft is turned medially and cephalad for subcutaneous tunneling to the infraclavicular incision and then medially and caudad to the fifth rib interspace at the sternal border. A space is created in the fifth interspace, and the graft is passed into the mediastinum. This long, tortuous course was chosen to provide a sufficient length in a subcutaneous location that would allow a large number of potential cannulation sites. The graft is anastomosed end to side to the axillary artery and to the right atrial appendage.

Arterial–Arterial Access Procedures

Bunger et al. reported the outcome of a series of 20 patients who underwent axillary artery–axillary artery interposition with PTFE grafts.[58] The interposition graft was looped on the chest wall and anastomosed end to end to the transected axillary artery (Fig. 176.9A). The diameter of the PTFE graft (range, 6 to 8 mm) was dictated by the size of the axillary artery. Operative or endovascular revision procedures were required in 30% of patients. The primary and secondary patency rates at 6 months were 90% and 93%, respectively; however, mean follow-up was only 7 months. Limb ischemia occurred in one patient whose access thrombosed, but it resolved after thrombectomy. No symptoms of limb ischemia occurred in the three other patients whose access thrombosed.

Zanow et al. recently reported a series of 36 arterioarterial prosthetic loop accesses.[59] Among their patients, 31 of the

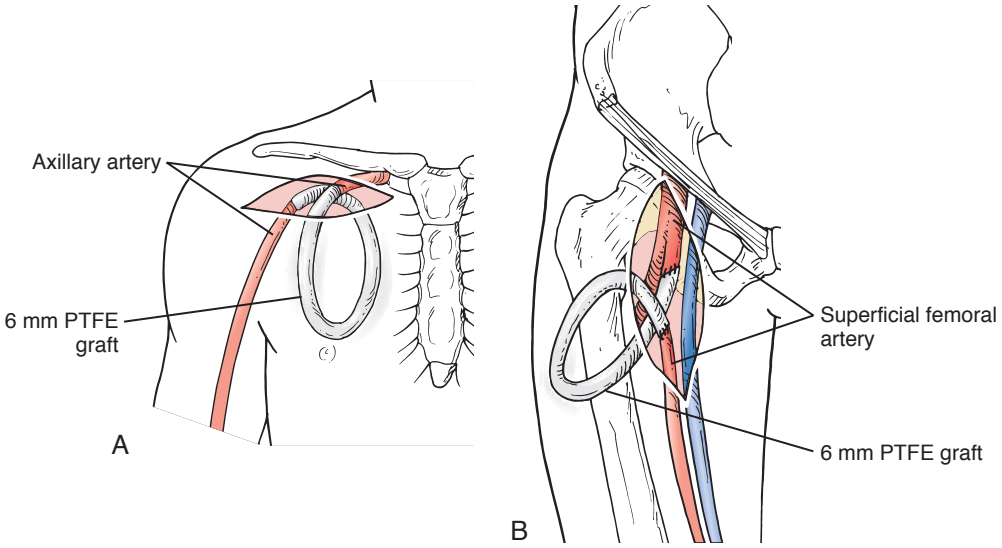

Figure 176.9 (A) Prosthetic axillary artery–axillary artery loop access. (B) Prosthetic femoral artery–femoral artery loop access. *PTFE,* Polytetrafluoroethylene.

accesses were based off the axillary artery and 5 were based off the femoral artery (see Fig. 176.9). In each case, the artery was divided and end-to-end anastomoses were used to interpose the prosthetic graft. The secondary patency rates were 96% at 1 year and 87% at 3 years. The authors noted that thrombosis of the femoral access resulted in severe limb ischemia requiring immediate thrombectomy, whereas occlusion of the axillary access caused only mild ischemia and was much better tolerated.

Salgado et al. described the technique of superficial femoral artery transposition for vascular access.[60] The technique involves the following steps: (1) transection of the sartorius muscle; (2) exposure and mobilization of the superficial femoral artery; (3) elevation of the superficial femoral artery by suturing the ends of the sartorius muscle and closing the subcutaneous tissue beneath the artery; and (4) closure of the skin over the artery. In their series of 14 patients, the authors did not report patency but rather found that these accesses "delivered 3215 hemodialysis treatments." Five needle cannulation complications were reported: bleeding due to arterial laceration ($n = 2$), pseudoaneurysm ($n = 2$), and infected pseudoaneurysm ($n = 1$). Three episodes of arterial thrombosis occurred.[60]

Lei et al. reported their series of 18 patients with superficial femoral to deep femoral artery loop access. In their study, indications for this procedure included an unsuitable upper and lower extremity deep vein, stenosis, or occlusion of upper extremity central veins, congestive heart failure, and prior access-related steal syndrome. Their primary and secondary patency rates were 94.5% and 88.8%, respectively, at 6 months; at 3 years they were 61% and 72%, respectively. Eight patients had postoperative leg swelling and there was one graft occlusion, but no lower extremity ischemia was reported. Preoperative assessment involves duplex imaging of the arteries and supplemental contrast angiography to define adequacy of the deep femoral artery as well as to rule out any arterial inflow or outflow lesions. The technique involves exposure of the superficial femoral and deep femoral arteries and subcutaneous placement of a 6-mm PTFE conduit as a loop. End-to-side anastomoses are performed from the graft to the vessels.[61]

Arterial–arterial access procedures may be considered in patients with previous access-related limb ischemia and high-output cardiac failure. It is important to note that these accesses cannot be used to infuse medications. Also, dialysis unit personnel should be instructed to hold pressure over the needle cannulation site for at least 20 minutes. The arterial–arterial access procedures do not provide flow rates as high as arterial–venous access procedures (Bunger noted a median flow rate of 165 mL/min). Since dialysis blood flow rates exceeding 400 mL/min can cause recirculation and arm pain, it may be necessary to run patients at slower blood flows for longer periods to deliver adequate dialysis treatment.

Unconventional Sites for Placement of a Tunneled Dialysis Catheter

Transthoracic Superior Vena Cava Catheters

Wellons et al. reported a series of 22 patients with bilateral internal jugular and subclavian vein occlusion who underwent placement of a tunneled dialysis catheter into the SVC via direct transthoracic puncture.[62] The catheters functioned from 1 to 7 months. The only major complications reported were hemothorax in one patient and pneumothorax in another. Both were successfully treated with tube thoracostomy.

In this procedure, a pigtail catheter is placed in the SVC via access from the femoral vein and a venogram of the SVC is performed. Anteroposterior and lateral fluoroscopic views of the SVC are obtained and used as a reference guide to pass an introducer needle from a point immediately cephalic to the head of the right clavicle to the SVC. Once the SVC is entered, a hydrophilic wire is placed into the inferior vena cava (IVC). A tunneled dialysis catheter is placed in the usual fashion.

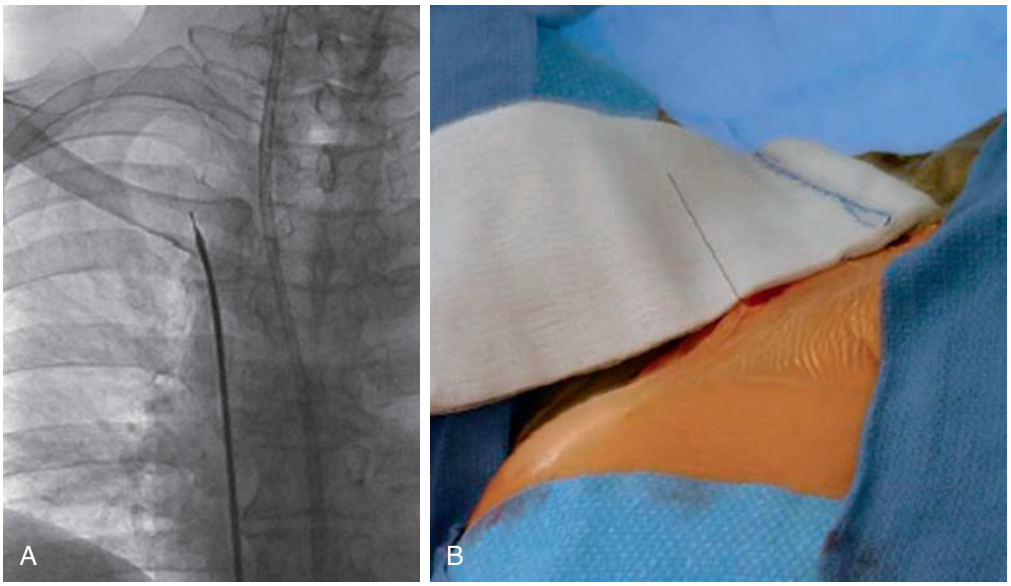

Figure 176.10 Inside-out-central venous access technique. (A) The sheath and needle or advanced to the point of obstruction in the superior vena cava. The needle and wire are then directed to the posterior aspect of the head of the clavicle. (B) The wire is then exteriorized and pulled through the skin of the supraclavicular fossa.

Another method recently described in the literature for placing a tunneled dialysis catheter through a SVC occlusion is the inside-out central venous access technique (IOCVA). This technique can be used to place a central venous catheter or the venous component (intravenous catheter) of the HeRO device as well. To cross the occluded SVC, the right common femoral vein is accessed. A 0.035 J-tipped guide wire is placed in the IVC with a 5-Fr angled tip catheter over the wire. Wire and catheter are navigated to the atrium and to the confluence with the occluded SVC. A 0.032-inch J-tipped guide wire is then placed at the level of the occlusion and the catheter is removed along with the 6-Fr hemostasis sheath. An 8-Fr SL0 sheath (SL0, Daig Inc., St. Jude Medical, St. Paul, Minnesota) is then placed with the tip next to the occlusion. A BRK transseptal needle (St. Jude Medical) is then placed in the dilator and a 0.018-inch steel core cut wire is placed inside the needle. Both the transseptal needle and steel wire are then directed from the IVC to the SVC, using lateral projections with angiography to make sure that the pathway does not go through the atrial appendage. The needle and wire are then directed to the posterior side of the clavicle. The wire is then exteriorized and pulled through the skin of the supraclavicular fossa. The SL-0 dilator and BRK needle are exteriorized as well. Wire and BRK needle are then removed from the groin and replaced with a 0.032-inch J-tipped guidewire via the dilator. Over this, wire balloon dilation using a 10-mm balloon is performed along the tract (see Fig. 176.10).[63]

Translumbar Inferior Vena Cava Catheters

An alternative technique for placing a tunneled dialysis catheter into the IVC is through a direct translumbar approach. Rajan et al. have reported a series of 58 translumbar IVC catheters, 37 of which were placed for hemodialysis access.[64] IVC thrombosis occurred in one case, and stenosis occurred in another. In several cases the catheter migrated into the subcutaneous soft tissues, retroperitoneum, or iliac veins, necessitating catheter repositioning. This was most commonly noted in obese patients. A case of retroperitoneal hematoma occurred secondary to catheter migration out of the IVC. In another study the cumulative patency rate was 52% at 6 months and 17% at 12 months. Infection of the catheter occurred in six cases.[65]

The catheter tip is positioned at the junction of the IVC and the right atrium; therefore, use of a long tunneled dialysis catheter is required. The patient is placed prone or in the left lateral decubitus position. A small stab incision is made 3 to 4 cm lateral to the midline and just above the right iliac crest at the L3 vertebral level. Through this incision, an 18-gauge long needle is inserted and advanced toward the IVC under fluoroscopic guidance. Once the translumbar needle has entered the IVC, a guidewire is placed. A second incision is made lower and lateral to the initial puncture site for the tunneled catheter. The catheter is then placed in the usual fashion.

Transhepatic Inferior Vena Cava Catheters

A percutaneous transhepatic approach has been used to place tunneled catheters in the IVC for hemodialysis. The outcome of this procedure has been reported in two series constituting a total of 57 catheters in 23 patients.[66,67] Thrombosis or malfunction of the catheter requiring catheter exchange was frequent in both series. In one series of 21 catheter placements, the complication rate was 29%, including one death from massive intraperitoneal hemorrhage. Although the average duration of dialysis via this route in the two series was 24 and 138 days, respectively, one patient was dialyzed for 599 days. Given the catheter maintenance problems associated with the transhepatic approach, this procedure should be used only as a last resort.

PEDIATRIC VASCULAR ACCESS

The preferred renal replacement therapies for the pediatric patient population are renal transplantation and peritoneal dialysis. According to the US Renal Data System (USRDS), approximately 38% of pediatric patients with end-stage renal disease receive a kidney transplant within the first year.[68] Hemodialysis is considered by many as a bridge to transplantation or as a treatment of last resort. Since the occurrence of end-stage renal disease is less common in children than adults and hemodialysis is not the preferred treatment modality, few surgeons have a sizable experience with pediatric vascular access. As a result, the literature on pediatric vascular access is limited to a few single-institution, retrospective reviews of experiences acquired over many years. Standard methods for reporting outcomes such as patency are not used for the majority of those reports. The chief limitation of the pediatric vascular access literature is the way in which studies define a pediatric patient. Most of the "pediatric" vascular access case series are primarily composed of adolescents whose body sizes approximate those of small adults rather than children. Given the limitations of the pediatric vascular access literature, it is difficult to determine the outcome of autogenous AV access procedures or to derive algorithms for vascular access for the small child younger than 10 years of age. Therefore only broad concepts related to vascular access for the pediatric patient population can be elicited from the available literature.

Kidney Disease Outcomes Quality Initiative Recommendations and Recent Trends

Given the technical challenges of autogenous or prosthetic AV access placement in very small children, the KDOQI guidelines recommend peritoneal dialysis or hemodialysis via a tunneled dialysis catheter for patients weighing less than 20 kg. Peritoneal dialysis or hemodialysis via a tunneled dialysis catheter is also recommended as a bridge to kidney transplantation if the transplant is expected to occur in less than 1 year. The KDOQI guidelines emphasize the importance of matching the length and diameter of the tunneled dialysis catheter to the size of the patient and provide a table for reference. Catheter placement considerations in pediatric patients are similar to those in adults. The most recent USRDS report shows that the rates of vascular access infection and hospitalization for infection/sepsis among hemodialysis patients younger than 10 years of age are increasing.[68] This is due in part to catheter infections resulting from patients spending more time on transplant waiting lists.

A commonly used argument against the placement of permanent access is the relative short time for renal transplantation. Catheter placement is used as a bridge to renal transplantation, which is the ideal goal of treatment, but this cannot always be achieved. Furthermore due to the finite life span of an allograft, planning for vascular access poses a unique challenge in this population. As a result, any intervention that could compromise future access must be avoided. Catheters frequently lead to stenosis or thrombosis of central veins, particularly in children who have smaller-diameter veins. These trends support the KDOQI recommendations that an autogenous or prosthetic AV access is preferred for pediatric patients on maintenance hemodialysis.[5]

Autogenous Arteriovenous Access

Autogenous AV access is considered the optimal hemodialysis access in pediatric patients. The outcomes in pediatric patients have been published for the following autogenous AV access procedures: radial-cephalic access, ulnar-basilic access, radial-basilic transposed access, brachial-basilic transposed access, brachial-cephalic access, and femorofemoral transposed access.[69–76] The secondary patency rates ranged from 70% to 98% at 2 years. However, in most of these series it is unclear whether early access failures and accesses that failed to mature were excluded from patency analysis. Nonmaturation of autogenous AV accesses in children reportedly occurs in as many as 33% of cases. For a pediatric patient with anatomy unsuitable for an autogenous access procedure, a prosthetic AV access can be placed. One study reported the outcome for prosthetic AV access in children to be equivalent to that in adults.[73]

Technique

The same considerations and diagnostic modalities used to select the appropriate autogenous or prosthetic AV access procedure in adults apply to children. The more distal anatomic sites should be used as a first access, preserving the more proximal sites for access later in life. There are key differences in the techniques used for AV access placement in children compared with adults. AV access placement is facilitated in pediatric patients by the use of microsurgical techniques and microsurgical instruments, adequate magnification, and an interrupted suture technique. The AV anastomosis is performed with 8-0 to 10-0 polypropylene suture. Second, to minimize vessel dissection and vasospasm, vascular control is obtained with a sterile tourniquet.[69,70]

Central venous catheters play an important role in the treatment of patients with end-stage renal disease. Despite initiatives to improve fistula creation, more than 80% of patients initiated hemodialysis with a catheter, a number that has changed little over the past decade.[1] Central venous catheters for hemodialysis are categorized by their intended duration as either acute or chronic. Both acute and chronic hemodialysis catheters can be placed percutaneously; however, chronic catheters have a subcutaneous cuff at the skin exit site, whereas acute catheters do not. As a result, acute catheters are at higher risk for infectious complications and can easily become dislodged. Thus acute catheters should be placed only in hospitalized patients and used for a short duration, usually less than 4 weeks.[2] This time frame is in stark contrast to chronic catheters, which can be used for up to approximately 12 months.

This chapter focuses on tunneled hemodialysis catheters and their management, but the potential complications related to placement of acute non-tunneled hemodialysis catheters mirror

Abstract

Central venous catheters for hemodialysis are categorized by their intended duration, as either acute or chronic. Chronic hemodialysis catheters are placed in a tunneled fashion and have a subcutaneous cuff at their skin exit site for tissue ingrowth. Acute catheters do not have a cuff and are placed percutaneously without a tunnel. As a result, acute catheters are at higher risk for infectious complications and can easily become dislodged. Currently, chronic hemodialysis catheters are utilized as either a first line treatment option for hemodialysis or a bridge during permanent hemoaccess creation or revisions. This chapter will focus on tunneled hemodialysis catheters (THC) and indications for placement, technical considerations for insertion, and the management of the potential complications related to placement of the catheters.

those of tunneled hemodialysis catheters. However, because of the short duration of use of acute catheters, long-term complications are less frequent but infectious complications are more common.

INDICATIONS

The most common indication for placement of a tunneled hemodialysis catheter is for urgent hemodialysis while the patient is waiting for an autogenous arteriovenous fistula (AVF) to be created or to mature. Other indications include patients in whom an AVF or prosthetic arteriovenous graft (AVG) is not anatomically feasible or who are not operative candidates because of advanced comorbidities. Temporary hemoaccess is also indicated after revision of a permanent hemodialysis access for management of a complication (e.g., access revision for pseudoaneurysm formation or infection), after placement of a peritoneal dialysis catheter, and for a chronic ambulatory peritoneal dialysis patient requiring abdominal or inguinal surgery.

The benefits of tunneled hemodialysis catheters over AVF and AVG vascular access include immediate use for hemodialysis, uncomplicated and needle-free connection to the dialysis circuit, elimination of cannulation site complications, and simple insertion technique that can be performed by many different interventional specialists.[3]

TYPES OF CATHETERS

Early cuffed catheters were straight in configuration and stiff. Due to advances, the early catheter configurations have been largely supplanted by precurved flexible catheters with various tip designs.

Design Characteristics

Catheter designs aim to achieve one main goal: adequate dialysis clearance at a relatively high flow rate of 300 to 350 mL/min.[4] In addition, the phenomenon of recirculation must be minimized to ensure adequate clearance. The "arterial lumen" of the catheter is the outflow to the dialysis machine from the patient; the "venous lumen" is defined as the inflow from the machine back to the patient. Access recirculation is the reentry of dialyzed blood from the venous lumen directly into the arterial lumen, thus bypassing the systemic circulation and leading to inefficient dialysis.[5]

Design Categories

Numerous manufacturer modifications exist in an effort to satisfy the requirements of high flow rates and minimal recirculation. The modifications fall into four general categories.

Split Tip

Split-tip catheters have a double-lumen, single-body configuration in the midbody but separate into two distinct distal tips, each with side holes in all directions (Fig. 177.1A).

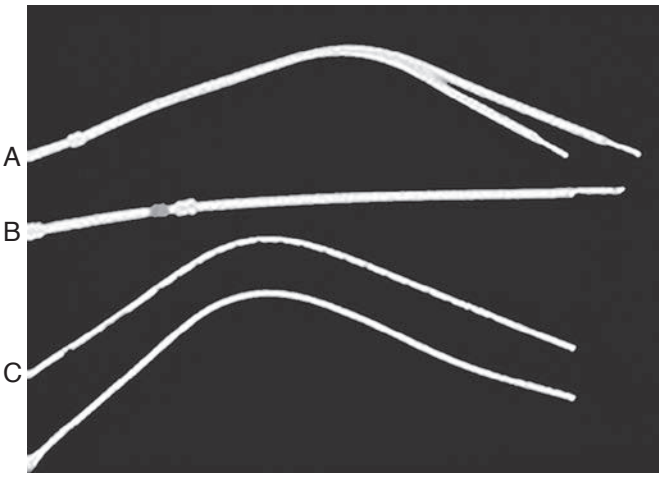

Figure 177.1 Three types of tunneled hemodialysis catheters: split-tip catheter (A), staggered-tip or step-tip catheter (B), and dual catheter (C). (From Richard HM, 3rd, et al. A randomized, prospective evaluation of the Tesio, Ash split, and Opti-flow hemodialysis catheters. *J Vasc Interv Radiol*. 2001;12:431–435.)

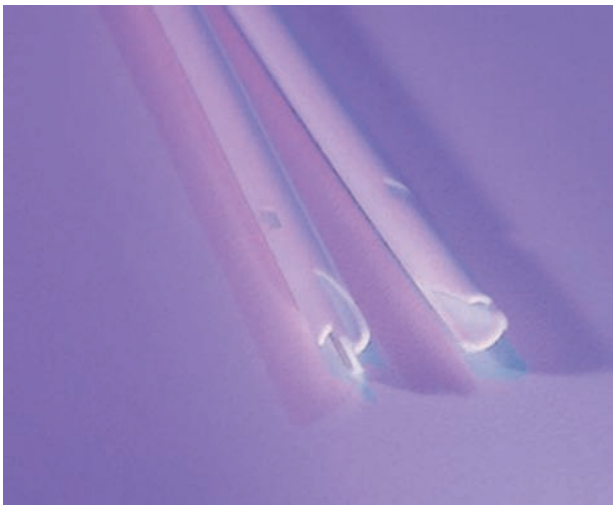

Figure 177.2 Tal Palindrome catheter. (Courtesy Covidien.)

Step Tip

The staggered-tip or step-tip catheter is a double-lumen, single-body catheter with the venous limb extending at least 2.5 cm beyond the inflow tip (see Fig. 177.1B).

Dual Catheter

The dual catheter design consists of two completely separate catheters that can be inserted in two different locations (see Fig. 177.1C).

Symmetric Tip

The Tal Palindrome (Covidien, Mansfield, Mass) is the only catheter that has a symmetric tip design with equal length of arterial and venous limbs and biased spiral ports. The design of the ports allows inflow to occur through the most proximal portion of the port and outflow to occur as a jet directed away from the catheter tip (Fig. 177.2).[6]

Numerous reviews directly compare performance of individual tunneled hemodialysis catheters with specific outcome variables of flow rate, recirculation time, and patency. Unfortunately, despite isolated beneficial characteristics of a particular catheter, no universal significant benefit has been demonstrated by one catheter over the competitors.[3-5,7] In one of the few randomized trials, a symmetric-tip catheter and a step-tip catheter demonstrated no difference in risks for thrombosis, infection, and overall catheter survival.[8]

PREOPERATIVE EVALUATION

History and Physical Examination

As with any clinical assessment, the proper preoperative evaluation of a patient begins with a detailed history and physical examination. Specific inquiries should include details such as prior long-term central line placement, prior AVF or AVG placement, prior tunneled hemodialysis catheter infections, history of a coagulation disorder, and history of a pacemaker. Physical examination of the neck and chest is critical. Evidence of a previously placed tunneled hemodialysis catheter, previous permanent accesses, upper extremity or facial edema, and ipsilateral venous distention with visible venous collaterals should alert the clinician to the possibility of central venoocclusive disease.

Numerous specialists have the skill set to properly place a tunneled hemodialysis catheter. However, there is a significant advantage in terms of continuity of care when the same practitioner places the tunneled hemodialysis catheter and the permanent access or when a team approach coordinates these procedures. There are a finite number of access sites available for both tunneled catheter and permanent access placement. Therefore a comprehensive plan that embraces all forms of hemodialysis access may provide maximum benefit of each crucial access site.

Central Venous Imaging

Color-Flow Venous Duplex Imaging

Noninvasive color-flow duplex imaging is the first line method of preoperative imaging for the tunneled hemodialysis catheter. Patency of internal jugular veins and axillary veins is easily identified with compression of the vein. However, as imaging moves toward the central chest, the air interface with the lung tissue, as well as obstructing bone structures, makes central vein imaging virtually impossible.

Magnetic Resonance Venography

Three-dimensional gadolinium-enhanced magnetic resonance venography (MRV) has been shown to be highly sensitive in identifying central vein occlusions and stenoses greater than 50% when directly compared with digital subtraction angiography.[9] Despite the accuracy of MRV, gadolinium must be administered with caution in patients with a glomerular filtration rate of less than 30 mL/min because of the risk of gadolinium-induced nephrogenic systemic fibrosis, which is rare even in this patient population, but has not been described in patients with normal renal function.

Computed Tomographic Venography

Computed tomographic venography (CTV) is similar to MRV in being able to image multiple vessels in the chest in one setting. However, CTV does have the advantages of being readily available in most medical centers, fast acquisition times, and fewer deleterious contrast agent concerns. In medical centers dedicated to use of this imaging modality for the evaluation of hemodialysis patients, anecdotal evidence points to an acceptable level of accuracy for the evaluation of central venous disease. A study of 18 patients comparing CTV and digital subtraction venography for the diagnosis of benign thoracic central venous obstruction demonstrated that CTV findings correlated closely with those of digital subtraction venography.[10]

Catheter-Based Contrast Venography

Catheter-based contrast venography remains the "gold standard" for diagnosis of central vein stenosis or occlusion. Contrast venography has the distinct advantage of allowing the clinician to initiate endovascular treatment if a significant stenosis is detected at the time of venography. In addition, it is often possible to perform catheter-based venography with a much smaller volume of contrast material than what is required for CTV, reducing the risk of nephrotoxicity.

CATHETER INSERTION

Site Selection

The right internal jugular vein is the preferred access site for tunneled hemodialysis catheter placement because it has the best patency, presumably owing to less kinking. In a prospective evaluation, factors affecting long-term survival of tunneled hemodialysis catheters were analyzed in a cohort of 812 catheters in 492 patients.[3] A tunneled hemodialysis catheter placed in the right internal jugular vein demonstrated significantly longer survival compared with one placed in the left internal jugular vein. Tunneled hemodialysis catheters placed in the femoral vein had the worst long-term survival. The subclavian vein should be avoided if possible to prevent catheter-induced subclavian stenosis, which would negatively affect the future placement of ipsilateral permanent access.[3,4]

A tunneled hemodialysis catheter from the right internal jugular vein should be 17 to 19 cm in length; catheters from the left are slightly longer. When femoral access is used, long catheters (24-31 cm) should be placed so that the tip can reach into the inferior vena cava to produce the best flow rates.

Technique

Tunneled hemodialysis catheter insertion should be performed in a procedure room under fluoroscopic guidance. Bedside placement is discouraged because of the need for proper sterility, the possibility of additional endovascular procedures (such as venography and venoplasty), and the requirement for fluoroscopy.

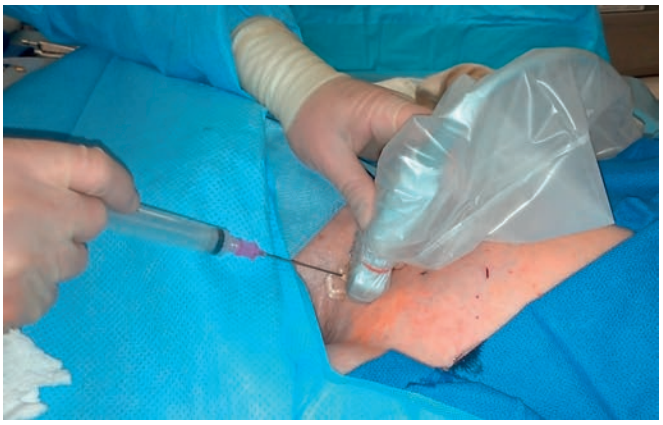

Figure 177.3 Ultrasound-guided puncture of the internal jugular vein with a micropuncture needle.

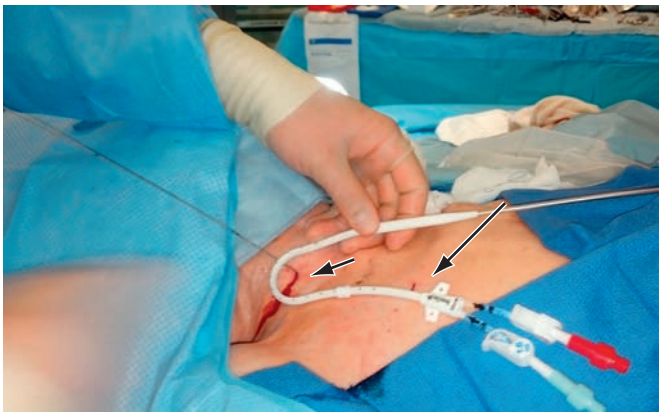

Figure 177.4 Placement of the tunneled hemodialysis catheter alongside the anticipated catheter course to determine where to position the exit site. Internal jugular vein puncture site *(short arrow)*; upper chest catheter exit site *(long arrow)*.

The procedure is usually performed under local anesthesia with conscious sedation. Preoperative antibiotic prophylaxis directed at gram-positive bacterial strains is administered before skin incision in each case. The skin is then prepared with isopropyl alcohol and chlorhexidine solutions.

Ultrasound evaluation with a sterile covered transducer confirms access vein patency. The site of vein cannulation should be 3 to 4 cm cephalad to the clavicle. Real-time ultrasound guidance is used to access the vein with a micropuncture 21-gauge needle, 0.018-inch guide wire, and 5F coaxial catheter (Fig. 177.3). After successful cannulation, the introducer and 0.018-inch wire are removed and exchanged for a 0.035-inch wire. A 1-cm skin incision is made surrounding the wire entry site (Fig. 177.4, *short arrow*). Fluoroscopic imaging should be used during all wire maneuvers to confirm wire position.

Because of the large size and stiff nature of most tunneled hemodialysis catheters, a moderate amount of forward pressure may need to be applied during insertion. It is highly advisable to have the guide wire course in the superior vena cava to inferior vena cava channel and not enter the right heart chambers. This is especially true for left-sided placement of a tunneled hemodialysis catheter. Because of the tortuous path from the left internal jugular to the heart, it is possible for the dilator to push the midportion of the guide wire, creating a loop that could perforate the side wall of the central vein. The incidence of this can be reduced by use of a stiffer wire than the one provided in the insertion kit and direct fluoroscopic visualization during passage of all dilators and sheaths over the wire.

Figure 177.5 Tunneling of the catheter subcutaneously from the chest incision to the neck incision anterior to the clavicle.

Figure 177.6 Dilatation of the track of the wire.

Antegrade Placement

A small incision is made on the anterior chest where the tunneled hemodialysis catheter is to exit the subcutaneous tunnel (see Fig. 177.4, *long arrow*). The exit site of the tunneled hemodialysis catheter should be inferior and lateral to the vein entry site. The exit site should also be positioned such that the felt cuff on the catheter shaft is 1 cm proximal to the exit site. Placement of the tunneled hemodialysis catheter alongside the anticipated catheter course is useful in determining where the exit site should be positioned. The tunneled hemodialysis catheter is then attached to the tunneling device and passed subcutaneously from the chest incision up through the vein entry site incision in the neck, traversing anterior to the clavicle en route (Fig. 177.5). The track of the wire is sequentially dilated, and the final introducer and peel-away sheath unit is inserted until the sheath is "hubbed" at the skin (Fig. 177.6). The introducer and wire are removed, and the tunneled hemodialysis catheter is inserted through the peel-away sheath (Fig. 177.7). Once the tunneled hemodialysis catheter is fully inserted, the peel-away sheath is withdrawn.

Figure 177.7 Insertion of the tunneled hemodialysis catheter through the peel-away sheath.

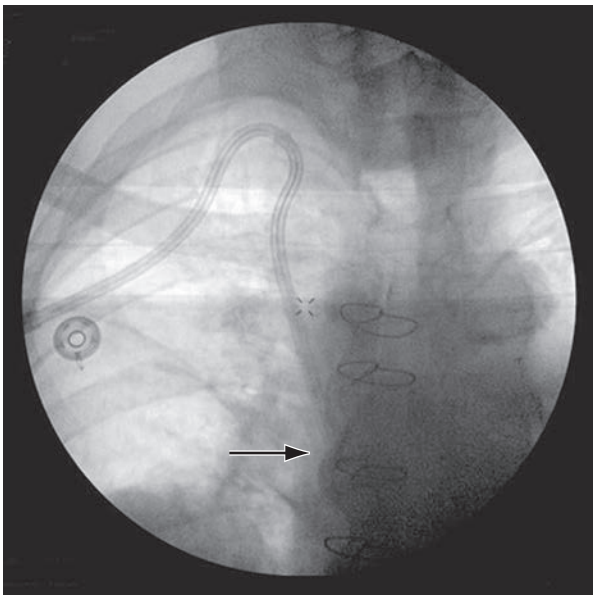

Figure 177.8 Chest radiograph demonstrating proper position of the tip of the tunneled hemodialysis catheter *(arrow)* at the level of the right mainstem bronchus.

Each lumen of the catheter is aspirated and flushed with dilute heparin (100 units of heparin sulfate per milliliter of normal saline). Both of these actions should be easily accomplished without resistance. If resistance is encountered, the catheter should be examined under fluoroscopy to rule out a kink in the path of the catheter or malpositioning of the tip. Ideally, the most distal tip of the catheter should be in the distal superior vena cava/proximal right atrium border. This preferred position corresponds to the shadow of the right mainstem bronchus (Fig. 177.8).

The chest wall and vein entry site incisions are closed with absorbable sutures, and the tunneled hemodialysis catheter is secured to the chest wall with nonabsorbable sutures. Each lumen of the tunneled hemodialysis catheter is filled with the manufacturer-indicated volume of concentrated heparinized saline (1000 units/mL) to protect against intracatheter thrombosis. In a meta-analysis comparing low doses (<5000 units/mL) heparin lock versus high-dose heparin (≥5000 units/mL), low-dose heparin was shown to be associated with a significantly lower risk of bleeding-related complications with no difference in the incidence of catheter thrombosis.[11] Sodium citrate 4% solution can be used in patients with heparin allergies.

Retrograde Placement

Tunneled hemodialysis catheters have been developed that can be placed in a "reverse-tunneled" or "retrograde" fashion; these catheters do not have ports attached initially. The catheter is inserted into the vein before tunneling in the same fashion as the standard tunneled hemodialysis catheter. The catheter is then tunneled from the neck incision to the chest incision, and the ports are attached after tunneling. The advantage of this type of insertion is that it allows precise positioning of the catheter tip.

Unconventional Catheter Sites

Patients who have exhausted conventional sites for vascular access may require placement of tunneled hemodialysis catheters in unconventional sites, such as the transhepatic and translumbar routes.

Translumbar catheters are generally placed with the patient in the prone position by percutaneous puncture of the inferior vena cava above the right iliac crest. The catheter is tunneled through a right lateral abdominal exit site. For transhepatic catheters, percutaneous access to the right or middle hepatic vein is obtained through the eighth intercostal space in the midaxillary line under fluoroscopic guidance. The catheter is then tunneled to a lateral anterior chest wall exit site. The tip of the catheter is positioned in the right atrium in both approaches.

The reported mean total catheter service lifespan of transhepatic and translumbar catheters in the literature ranges from 70 days to 1948 days.[12-14] In addition, unique to this type of access is the high rate of subsequent interventions for maintenance of adequate hemodialysis access. Two of the largest published series reported that more than 60% of their patients required at least one catheter exchange. Catheter migration, thrombosis, and infection are the most commonly reported reasons for catheter exchange.[12-15] Translumbar catheter exchanges may be more difficult than exchanges through the transhepatic approach because of retroperitoneal fibrosis that develops along the track.[12]

PERIOPERATIVE CARE AND COMPLICATIONS

The perioperative management of patients after placement of a tunneled hemodialysis catheter centers on the evaluation for and treatment of potential acute complications. In a compilation of data from 1794 central venous cannulations in critically ill patients, the overall complication rate was 7.1%.[16] Failure to place the central line and arterial puncture were the

most common mechanical complications, followed by pneumothorax. The keys to successful management of these complications are awareness, prompt recognition, and expeditious treatment.

Pneumothorax

An end-expiratory upright chest radiograph should be performed after placement of a tunneled hemodialysis catheter to confirm tip placement and to exclude a pneumothorax.[17] If acute, severe symptoms and signs of pneumothorax develop, a tube thoracostomy should be performed immediately and the patient should be given oxygen by mask. In the setting of tension pneumothorax, decompression of the pleural space with an intravenous catheter placed in the second intercostal space in the midclavicular line can be lifesaving. More frequently, the air leak is relatively small, and the pneumothorax develops during a period of several hours.

When a small pneumothorax is encountered (<20%) and there are no symptoms or signs of respiratory compromise, decrease in peripheral oxygen saturation, or hemodynamic impairment, a "watchful waiting" approach with repeated chest radiographs is appropriate.[18] If symptoms develop or there is an increase in the size of the pneumothorax on subsequent chest radiographs, tube thoracostomy should be performed. If the pneumothorax is initially noted to be large (>20%), tube thoracostomy should be performed regardless of whether symptoms are present

Hemothorax

A hemothorax can develop when the back wall of either a vein or artery and the parietal pleura are perforated by an advancing needle tip, dilator, or sheath.[19] The subclavian vein or artery, the innominate vein, or even the superior vena cava may be involved. The lack of effective tamponade combined with negative respiratory pressure may result in a large blood loss through a small puncture. Clinically, patients may develop respiratory compromise accompanied by dullness to percussion and decreased breath sounds on the affected side. A decreased hematocrit and evidence of fluid in the pleural cavity on the chest radiograph strongly support the diagnosis. Drainage of the pleural space with a tube thoracostomy is generally adequate therapy and should be performed for significant hemothorax to prevent entrapment of the lung. Rarely, bleeding must be controlled surgically or, if possible, percutaneously with the use of covered stents.

Wire Embolism

Wire embolism occurs when control of the wire is lost during the procedure or the guide wire is sheared off by the access needle as it is withdrawn. If resistance to wire removal is encountered, fluoroscopic imaging should be used, and removal of the wire and needle together as a unit may be required. Fortunately, guide wires can usually be removed fluoroscopically with use of a wire snare retrieval system.[20]

Cardiac Arrhythmia

Cardiac complications related to central venous catheterization are rare. Arrhythmia during placement of a tunneled hemodialysis catheter is associated with the guide wire irritating the myocardium. The problem can be minimized by use of guide wires that have distance markings and fluoroscopy to visualize the location of the tip of guide wires and catheters. If cardiac arrhythmias develop after the placement of a tunneled hemodialysis catheter, the catheter position should be checked fluoroscopically or with a chest radiograph and the catheter tip should be withdrawn if the tip is near or traversing the tricuspid valve. Rarely, in less than 1% of cases, patients will have arrhythmias that require chemical or electrical cardioversion.[21]

Cardiac Perforation

The soft, flexible hemodialysis catheters that are currently used are unlikely to perforate the heart. More common causes of cardiac perforation are guide wires, dilators, and rigid introducers. Cardiac perforation may result in acute pericardial tamponade from bleeding or fluid infusion into the pericardial space. Signs and symptoms of pericardial tamponade can develop rapidly and include shock and cyanosis with marked cervical venous distention. Tachycardia and muffled heart sounds are generally present, and a large globular cardiac silhouette may be present on a chest radiograph. Any intraluminal catheter devices should be removed and pericardiocentesis or a pericardial window created. If the tamponade recurs after pericardiocentesis or creation of a window, median sternotomy with formal cardiac repair may be necessary.

Thoracic Duct Laceration

Percutaneous catheterization of the superior vena cava through the left internal jugular or the subclavian approach carries a small risk of thoracic duct laceration. Cirrhotic patients are more prone to the development of this complication. If a lymphatic leak becomes apparent, the catheter should be removed and a pressure dressing should be applied. Nearly all such leaks resolve spontaneously.

Nerve Injuries

The brachial plexus is the nerve structure that is most vulnerable during percutaneous catheterization by virtue of its large size and proximity to the subclavian vein and artery.[22,23] Acute upper extremity pain referred along a neural anatomic pathway suggests impingement on the brachial plexus and necessitates immediate withdrawal of needles or catheters. Permanent injury is rare. The vagus, recurrent laryngeal, and phrenic nerves are also in proximity to the internal jugular vein but are small nerves and infrequently injured. The development of hoarseness after catheter placement suggests injury to the vagus or recurrent laryngeal nerve. Phrenic nerve injuries are generally asymptomatic and are incidentally identified on radiographic examination when an elevated hemidiaphragm is seen.[24] The development of Horner

syndrome has also been reported by inadvertent trauma to the stellate ganglion during percutaneous cannulation of the internal jugular vein.

Catheter Misplacement

In a prospective study of 1619 patients the incidence of catheter tip malposition, defined as extrathoracic or ventricular positioning, was 3.3%.[25] The use of fluoroscopy during catheter placement should eliminate the occurrence of catheter tip malposition. If there is a question as to the location of the tip of the catheter during placement, contrast material can be injected through the catheter under fluoroscopic guidance to help define the anatomy.

Venous

If the catheter tip is left in the subclavian, axillary, jugular, or hepatic vein, the catheter tip or turbulence generated during hemodialysis may cause intimal injury, which leads to thrombosis of the vein.[26] Stiff catheters or introducers left abutting the wall of the superior vena cava or more peripheral veins can also erode through the vessel wall and produce a hemomediastinum or hydromediastinum.

Arterial

Catheters may be inadvertently placed into the subclavian or carotid artery and go unrecognized. This is more common in a hypotensive or poorly oxygenated patient who may not have return of bright red, pressurized blood when an artery is punctured. Because tunneled hemodialysis catheters are generally placed on an elective basis, arterial placement is rare. If there is a question of arterial placement, the pressure can be transduced through the catheter to see if the waveform is arterial or venous. A sample from the catheter can also be sent for a blood gas analysis to determine if the values are consistent with an arterial or venous blood gas. If the injury is recognized in a timely fashion (<4 hours), most of the catheters placed in the carotid artery can be simply removed and pressure applied for a prolonged time (15-20 minutes).[27] If the injury is recognized later, the catheter should be removed in the operating room with open repair of the artery because the incidence of track formation and accumulation of thrombus on the catheter is increased.[27] Injuries to the subclavian artery are more difficult to compress because of the lack of bone structures to compress against and should be monitored closely for evidence of hemothorax. Open or endovascular repair of the artery may be required.[28]

LONG-TERM CARE AND COMPLICATIONS

The long-term management of tunneled hemodialysis catheters is primarily performed by the staff at the dialysis center where the patient receives dialysis. Patients with tunneled hemodialysis catheters usually do not come to the attention of the vascular surgeon unless a late complication of the catheter develops.

Air Embolism

Air embolism is a rare but potentially lethal complication of central venous catheterization that can be either an acute or a late complication.[19] In its late form, air embolism generally occurs when air enters the catheter either before attachment of the tubing or when the tubing becomes disconnected.[29,30] Air embolization can also occur through cracks in the catheter or its hub, as well as through the catheter track after the removal of a central venous catheter.[31] Patients should be instructed that in the event the catheter becomes disconnected or uncapped, a critical complication could result. Patients should be instructed to cap the open catheter with a thumb or finger and to call for help immediately. An occlusive dressing should be placed over the skin puncture site when the catheter is removed to allow adequate sealing of the track.

If sudden cardiorespiratory collapse develops in a patient with a tunneled hemodialysis catheter, air embolism must be strongly considered. Further embolization must be prevented by capping or clamping of the catheter while the patient is simultaneously placed in the Trendelenburg and left lateral decubitus position (Durant maneuver).[32] This position displaces air away from the pulmonic valve, which relieves the right ventricular outflow obstruction. The catheter can be advanced into the heart to aspirate the air.[33]

Catheter Embolism

Fractures can develop in the material of chronically indwelling catheters. This usually occurs at sites of stress, such as the thoracic inlet especially with catheters based in the subclavian vein.[34,35] Fractures can result in breaking off and embolization of the distal aspect of the catheter, which can typically be removed in the angiography suite with use of a wire snare retrieval system.[36]

Catheter Occlusion

Catheter occlusion occurs in 30% to 40% of patients with tunneled hemodialysis catheters.[37] Occlusion of the catheter generally is a consequence of the development of a fibrin sleeve or plug at the catheter tip. The ability to infuse fluid into the catheter but the inability to withdraw blood often indicates impending occlusion.

Prevention

Use of antithrombotic agents is not recommended to prevent catheter thrombosis. Low-dose warfarin is ineffective in reducing catheter thrombosis. Both therapeutic warfarin, titrated to an INR of 2 to 3, or aspirin 325 mg/day decrease the risk of catheter thrombosis but are associated with an unacceptable risk of gastrointestinal bleeding, particularly in the elderly.[38,39] A meta-analysis of 13 studies of heparin lock solutions versus all other types of catheter lock solutions, including citrate, recombinant tissue plasminogen activator, antibiotic with heparin, ethanol, and taurolidine (a novel antimicrobial agent used in Europe) with a total of 1883 subjects, demonstrated no difference in patency between heparin versus other lock solutions.[40]

Treatment

Local infusion of fibrinolytic agents has been used in the salvage of occluded central venous catheters.[41,42] Currently, alteplase is the only fibrinolytic agent that is approved for treatment of occluded central venous catheters. Most commonly, 2 mg of fibrinolytic agent in 2 mL of solution is injected and allowed to dwell in the catheter for 2 to 3 hours. The catheter is then irrigated and flushed, with removal of any residual clot. This process can be repeated until patency is restored. In a study of 815 catheter occlusion episodes, success was achieved in 77% of cases with the first infusion of alteplase and in an additional 10% of cases after the second infusion.[43] However, use of this technique may result in only a limited number of additional dialysis sessions before the treatment must be repeated. A study of 570 catheters during a 2.5-year period demonstrated a median of five to seven additional dialysis sessions after each treatment.[44] Guide wires should never be passed through catheters in an effort to relieve an obstruction because of the risk of dislodging part or all of the occlusion and causing an embolic event.

Because of the frequency of recurrent occlusion and the difficulty in delivery of a highly concentrated fibrinolytic agent to the fibrin sheath around the tip of the catheter, techniques have been developed to mechanically eliminate the fibrin sheath. These techniques generally involve the insertion of a wire snare device through another venous access site, such as the femoral vein, to strip the fibrin sheath from the catheter and remove it. In a study of 131 sheath-stripping procedures on 100 catheters, the technical success of the procedure was 95.6% and the mean primary patency after the first stripping was 89 days.[45] An alternative technique is to remove the catheter over a wire, then use an angioplasty balloon to rupture the sheath, and finally replace the catheter over the wire. A retrospective review of these two techniques compared with simple catheter exchange demonstrated no difference in patency.[46]

Central Venous Thrombosis

Catheter-related thrombus is present in approximately 30% of all patients with central venous catheters.[47] However, less than half of these thrombi are clinically significant.[47] The incidence of pulmonary embolus from catheter-related thrombus ranges from 0% to 17%, although catheter-related thrombus has rarely been reported to be the cause of death.[47] The more clinically significant implication of catheter-related thrombosis is its association with infection. In a study of patients with catheter-related *Staphylococcus aureus* bacteremia, 71% were found also to have central venous thrombus.[48] Nevertheless, the routine use of low-dose warfarin prophylaxis is not recommended.[49]

Venous thrombosis should be suspected in patients with tunneled hemodialysis catheters who present with arm, neck, or facial swelling; prominent collateral venous patterns; signs or symptoms of embolic complications; or unexplained fever. Duplex scanning generally is diagnostic, although venography is required on occasion for definitive diagnosis and determination of the extent of thrombosis. Conventional therapy consists of anticoagulation and elevation of the symptomatic arm. If possible, the catheter should be removed. Because patients with tunneled hemodialysis catheters often do not have other sites available for access placement, anticoagulation therapy with the catheter left in place can be considered.[50]

Central Venous Stenosis

Catheter-associated central vein stenosis develops as a result of injury to the intima of the vein by the catheter.[51] The association between subclavian vein cannulation for hemodialysis access and subsequent subclavian vein stenosis is well described.[52,53] The incidence of subclavian vein stenosis after placement of a tunneled hemodialysis catheter is significantly higher than that of internal jugular vein stenosis. In a study comparing venography in 50 patients dialyzed through a subclavian vein catheter and 50 patients dialyzed through an internal jugular vein catheter, 42% of patients in the subclavian group had a stenosis versus 10% in the jugular group.[54] As such, cannulation of the subclavian vein for hemodialysis access should be avoided if at all possible.

Presentation

Central vein stenosis can be completely asymptomatic. Often, an ipsilateral upper extremity access is created without knowledge of a central vein stenosis, which results in the rapid development of symptoms, the most common of which is arm edema. Patients with brachiocephalic vein stenosis can also present with facial edema. Other manifestations of central vein stenosis are aneurysmal dilatation of the extremity veins and the ipsilateral AVF, thrombosis of the access, inadequate dialysis, prolonged bleeding after use of the access, and superior vena cava syndrome.[51]

Treatment

Elevation and compression of the upper extremity can occasionally be enough to relieve the edema associated with central venous stenosis but is unlikely to be effective if there is an AV access on the ipsilateral extremity. NKF KDOQI guidelines recommend percutaneous transluminal angioplasty with or without stent placement as the preferred treatment for central venous stenosis.[2] In a small randomized study of percutaneous transluminal angioplasty and stent placement, 1-year primary patency in both groups was dismal at 12% and 11%, respectively.[55] However, the secondary patency at 1 year was 100% for percutaneous transluminal angioplasty and 78% for stenting. This marked difference in primary and secondary patency underscores the fact that multiple procedures are usually needed to maintain patency after endovascular management of central venous stenoses. Some authors have reported the use of custom-made paclitaxel-coated balloons with diameter up to 14 mm prolonging the restenosis interval from a median of 4 months with a standard balloon to 9 months with the paclitaxel-coated balloon.[56]

Catheter-Related Infection

There are three categories of catheter-related infection: exit site infection, tunnel infection, and bacteremia.[2] The NKF KDOQI

guidelines define an exit site infection as "inflammation confined to the area surrounding the catheter exit site, not extending superiorly beyond the cuff if the catheter is tunneled, with exudate culture confirmed to be positive." A tunnel infection is defined as "the catheter tunnel superior to the cuff is inflamed, painful, and may have drainage through the exit site that is culture positive." Finally, catheter-related bacteremia is defined as "blood cultures are positive for the presence of bacteria with or without the accompanying symptom of fever." The incidence of catheter-related bacteremia ranges from 0.6 to 6.5 episodes per 1000 catheter days.[57] Consequences of bacteremia include infective endocarditis and metastatic abscesses, the incidence of which increases when catheter salvage is attempted.[57]

Treatment

The predominant organism isolated from infected lines is gram-positive (52%-84%), with *S. aureus* making up 21% to 43%.[57] Ideally, the management of an infected hemodialysis catheter includes removal of the catheter.[57] Initial empirical antibiotic therapy should include broad-spectrum coverage of potentially resistant strains of gram-positive organisms as well as gram-negative organisms.[58] This coverage should be adjusted to a focused regimen when culture results become available. Amphotericin B or caspofungin, which has a more favorable toxicity profile, should be used if there is evidence of disseminated fungal infection or if patients demonstrate persistent fungemia after catheter removal.[49] Uncomplicated *S. aureus* catheter-related bacteremia is generally treated with 4 to 6 weeks of antibiotic therapy; gram-negative bacilli or enterococcus bacteremia is usually treated with 7 to 14 days of therapy. Bacteremia with *Candida* is usually treated with a minimum of 14 days of antibiotic therapy. Complicated bacteremia with septic thrombophlebitis or endocarditis is usually treated for 4 to 6 weeks and osteomyelitis for 6 to 8 weeks.[58]

Catheter exit site infections alone can usually be salvaged with topical and systemic antibiotics without the need for catheter replacement.[58] Presence of a tunnel infection or catheter-related bacteremia requires catheter removal with delayed placement of a permanent access. The NKF KDOQI Work Group recommends delay of placement of a new permanent access until culture results have been negative for at least 48 hours after cessation of antibiotic therapy.[2] Depending on the length of antibiotic therapy, this may or may not be reasonable. Strategies for catheter salvage include exchange over a wire and catheter salvage with or without antibiotic lock. A meta-analysis of 28 studies encompassing 1596 patients found that antibiotic lock solution and guide wire exchange had similar cure proportions that were both superior to systemic antibiotics alone.[59] Cure proportions were highest for coagulase-negative staphylococci, followed by gram-negative rods and *S. aureus*. Where catheter salvage has been described, it is associated with failure rates greater than 65%.[57] As such, the safest course of action is most often to remove the catheter.

TREATMENT OUTCOME 2333

Although placement of arteriovenous (AV) hemodialysis access is an important step in the management of patients with end-stage renal disease (ESRD), the maintenance and remediation of a failing or thrombosed AV access is almost as important. Dialysis access is a lifeline for ESRD patients, so access maturation and continued function are critical for these patients' overall well-being. The specific treatments for a nonmaturing or failing AV access may be slightly different from those for a thrombosed AV access; however, the long-term management of all dialysis patients centers on preserving the adequacy of their dialysis treatments for as long as possible with minimal intervention.

The flow disturbances and hemodynamic changes associated with an AV access can initiate an intimal hyperplasia (IH) response.[1-4] The IH occurs primarily at the outflow anastomosis of a prosthetic AV access (Fig. 178.1) and anywhere along the outflow vein in an autogenous AV access (Fig. 178.2). It can also involve the distant, ipsilateral central veins (e.g., subclavian), even in the absence of previous indwelling catheters.[5-7] Some patients develop intractable IH with the early onset of a critical stenosis, whereas others have a more limited response without any significant hemodynamic impact. The underlying mechanisms responsible for AV access IH are ill-defined, but the resulting lesions are common, occurring in the majority of patients with dialysis access, whether autogenous or prosthetic.

MEASURING ACCESS FUNCTION

The optimal management of a failing or thrombosed AV access is partially contingent upon detecting access dysfunction. The most common measurement of access function is urea clearance with dialysis, or Kt/V, where K is the rate of clearance of urea, calculated from the pre- and postdialysis measurements; t is the duration of dialysis; and V is the patient's urea distribution volume. In this fashion, the "dose" of dialysis in a given session

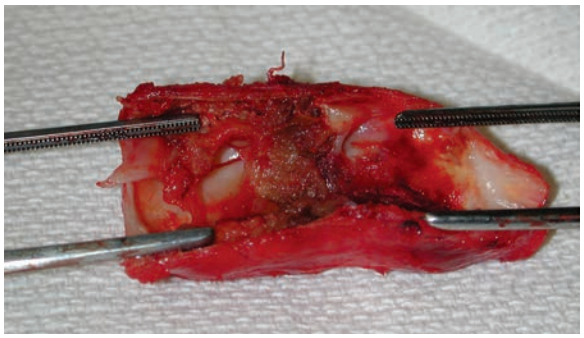

Figure 178.1 Surgical specimen demonstrating typical intimal hyperplasia at the venous anastomosis of prosthetic arteriovenous access.

Figure 178.2 Fistulagram demonstrating intimal hyperplasia throughout an upper arm arteriovenous access.

can be calculated objectively.[8-10] Kt/V is generally monitored to ensure that it remains over 1.2.

The function or quality of the AV access affects the maximum dialysis dose in several ways. First, adequate flows in the access are needed for the dialysis machine to function efficiently. Currently, high-flow dialysis is the norm in the United States, with pump speeds of 350 mL/min or more common. As long as the dialysis membranes can tolerate this high flow, the dose of dialysis can be given in a shorter time, reducing both costs and resources needed. Nonetheless, this high-flux technique requires much more efficient access function and is less tolerant of problems related to recirculation or high venous pressures. Recirculation, the retreatment of blood already filtered by the dialysis machine, can be insidious, often showing up as poorer solute clearances with each subsequent dialysis treatment.[11,12] Pressure limits are typically set on the dialysis machine; as a result, increasing venous pressures result in more prolonged dialysis because of efforts to reposition the efferent needle and thus remedy the high pressures.

Mechanisms of Access Failure

Flow Limitation

A functional AV access requires flow rates that exceed the pump speed of the dialysis machine by several-fold. With modern, high-flux dialysis, pump speeds may approach 500 mL/min. Thus flows of 1000 to 1200 mL/min are needed in the AV access to avoid recirculation.[13,14] In addition, adequate cardiac output is essential to maintain these flow rates. If cardiac output is marginal, decreased access flow may occur over the course of the dialysis session because of decreased preload associated with successful fluid removal during dialysis. Limitation of the access flow, by whatever mechanism, results in the recirculation of already dialyzed blood to the dialysis machine, greatly limiting the effectiveness of dialysis.[9,15,16] Recirculation can result when the afferent needle pulls blood that has just been returned to the patient via the efferent needle. This partially dialyzed blood is then dialyzed a second time, with decreased removal of substrate caused by lower concentrations in the partially dialyzed blood. This results in a decreased effective dialysis dose, with a longer duration of dialysis required to achieve the same clearance. There are several mechanisms by which recirculation can occur.

Venous Outflow Stenosis

The classic cause of recirculation is venous outflow stenosis, resulting in decreased flow through the AV access and increased recirculation of blood to the afferent needle. Regardless of the adequacy of arterial inflow, an outflow stenosis limits flow and increases recirculation. This is a common problem seen with failing prosthetic AV accesses.

Arterial Inflow Stenosis

Arterial inflow stenosis can similarly limit flow through the AV access, but in this case, both needles are distal to the stenosis. The limited arterial inflow results in recirculation from the distal efferent needle to the proximal afferent needle. This is a common mechanism of failure of autogenous AV access, occasionally leading to complete collapse of the outflow vein during dialysis.

Cannulation Location

Another important cause of recirculation is inadequate separation of the cannulation needles. Specifically, recirculation will occur if the needles are positioned too close together, even in the presence of a high access flow rate. Repeatedly puncturing the access at the same convenient location, rather than rotating puncture sites, can cause false aneurysms or pseudoaneurysms. If these are sufficiently large, recirculation can occur because of the stagnant flow within the pseudoaneurysm. In addition, these pseudoaneurysms are problematic because they are often the sites of infiltration and bleeding (Fig. 178.3).

Conduit Access Limitation

Although access flow is of fundamental importance, the conduit itself may be the cause of problems, or there may be secondary issues that limit the ability to puncture the AV access for reliable dialysis. If the vein is too deep or too small for reliable

Figure 178.3 Repeated cannulation at the same site resulted in a pseudoaneurysm associated with infiltration and ulceration.

cannulation, dialysis may be problematic, even with adequate flow. In a morbidly obese patient with ESRD, a vein of any size may be inadequate because of the depth of the overlying skin and soft tissue through which the vein must be cannulated.[17-19] In these patients, superficial transposition or elevation of the vein conduit may be necessary to allow maturation and reliable cannulation.[20-23]

CAUSES OF ACCESS FAILURE

Once dialysis access is established, the mode of failure is usually related to the type of access constructed. In the case of tunneled dialysis catheters, failure usually results from thrombus or the development of a fibrin sheath surrounding the catheter (see Chapter 177). For both autogenous and prosthetic AV accesses, the issue is often the development of venous outflow stenosis or stenosis of the autogenous access itself resulting from IH, leading to limited clearance.[24-28] Autogenous AV accesses may have limited patency after thrombectomy, so intervention is recommended before thrombosis occurs. Prosthetic accesses thrombose at a higher overall flow rate than autogenous accesses, but they may have better patency after thrombectomy. Thrombosed prosthetic accesses can often be remediated multiple times before they need to be abandoned.

As stated previously, IH is one of the unresolved issues affecting both the establishment and maintenance of a functional AV access. Although IH can occur anywhere in the outflow veins, certain anatomic factors can predispose to local or remote stenoses. For example, central venous stenosis is common in both autogenous and prosthetic AV accesses (Fig. 178.4). In the past, this was often attributed to the use of subclavian catheters, because the subclavian veins were the most common sites of central venous access.[29-31] In most modern dialysis centers, use of the subclavian veins for catheter access is avoided, specifically for this reason; yet there is still a high incidence of subclavian vein stenosis with upper extremity accesses. It is likely that the high flow across the subclavian vein at the thoracic inlet generates a perturbation in flow that leads to IH and stenosis. In this fashion, almost any vein used in the outflow of an AV access

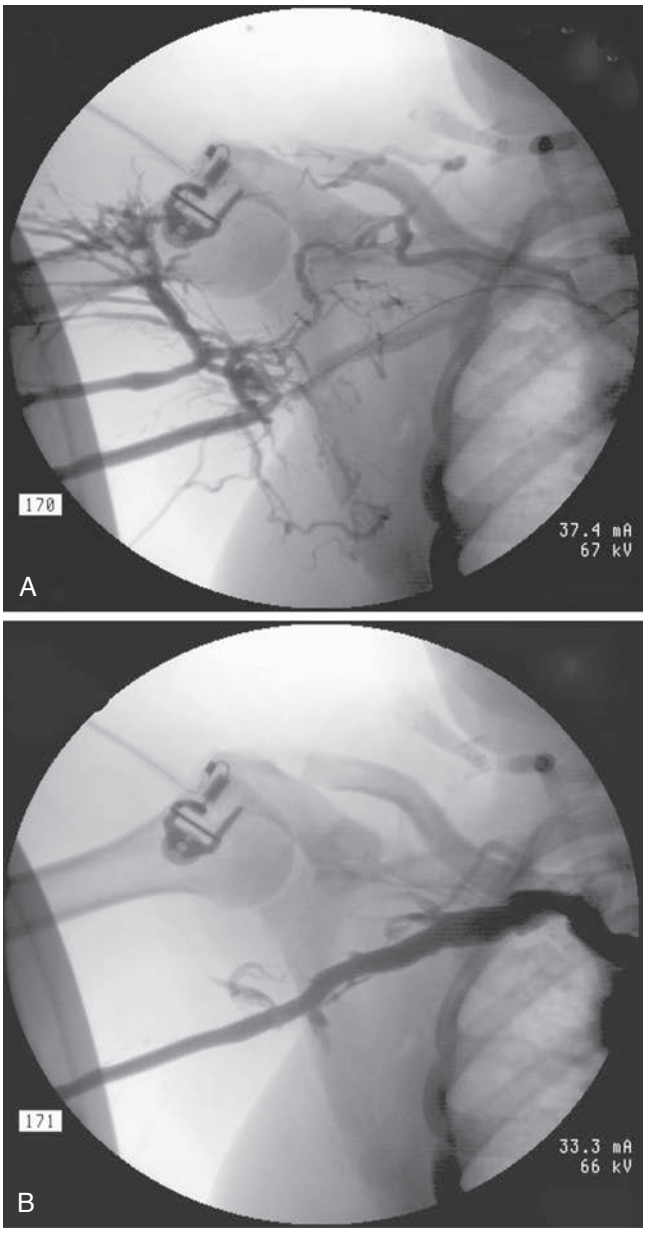

Figure 178.4 A stenosis in the axillary vein secondary to intimal hyperplasia is shown (A) before and (B) after successful treatment with an 8-mm high-pressure angioplasty balloon. Note the resolution of the venous collaterals.

can develop IH and stenosis. Another unavoidable factor is puncture of the conduit that leads to IH in autogenous conduits and to local tissue ingrowth in prosthetic accesses, simulating IH. Finally, IH occurs at the venous anastomosis of prosthetic AV access, theoretically aggravated by the excess turbulence associated with the size and compliance mismatch between the prosthetic graft and the outflow vein (see Chapter 5).

Detection of Access Failure

Clinical Evaluation

In many cases, clinical examination may be sufficient to assess access function with a reasonable degree of certainty. If an access is functioning well, a continuous thrill should be present near the arterial anastomosis, and it should be detectable for several

centimeters into the outflow vein. If a pulse is present near the venous outflow, then venous outflow stenosis is likely. In most cases, a thrill distal to an area of pulsatility suggests the location of the stenosis. Pseudoaneurysms of the access may result in local pulsatility in the areas of enlargement, independent of venous outflow issues. Only areas of normal diameter can be assessed by physical examination for pulsatility caused by venous outflow stenosis; aneurysmal or pseudoaneurysmal areas will often have increased pulsatility.

Collateral Veins or Edema

Collateral veins around areas of stenosis or occlusion are important indicators of elevated venous pressures. Typically this occurs around the shoulder or the anterior chest wall for upper extremity accesses as a result of a subclavian vein stenosis or occlusion. Thus the physical examination in these patients should include special attention to the head, neck, chest, and shoulder. Similarly, patients with a significant venous outflow stenosis without adequate collaterals may present with upper extremity edema alone.[32-34]

Access Bleeding

High venous pressures can lead to excessive access bleeding after removal of the cannulation needles, and this is often discovered by the dialysis center staff because of the prolonged time required to obtain hemostasis.[35-38] This may be the first indication of increased venous pressures and is a common indication for interrogating the access with either duplex ultrasound or venography. Venography may be better than ultrasound in this situation because it affords the opportunity to both diagnose and treat any venous outflow lesion (see the section on "Interventions for Failing Access"). The central vein stenoses responsible for the elevated pressures can lead to an insidious decrease in the access flow rates, often not recognized until later by the dialysis staff. Thus excessive access bleeding should initiate an evaluation that can lead to intervention before access failure; this is especially important for autogenous AV access.

Failure to Mature

The increased blood flow through the outflow vein of an autogenous AV access causes the vein to dilate and its wall to thicken or become "arterialized." Although this process varies by patient and specific vein, the outflow vein usually matures sufficiently for cannulation within 3 to 4 months of creation. When an autogenous AV access fails to mature, the underlying causes may be difficult to distinguish on clinical examination. In the presence of an arterial inflow stenosis, a good thrill may be present, but inadequate flow through the narrowed segment may prevent reliable cannulation with the venous return needle (i.e., efferent needle). Cannulation can be assisted by occluding the venous outflow using a tourniquet to allow maximum venous distention for the puncture; however, any residual outflow vein branches close to the site of stenosis may prevent distention and lead to an inability to cannulate the access. These collateral or "accessory" veins can also theoretically inhibit the maturation process of the main outflow vein by the diversion of blood away from the main channel, even in the absence of an arterial inflow stenosis. It is somewhat paradoxical that low resistance venous outflow improves dialysis function by preventing recirculation, although it can make access cannulation more difficult.

Inability to reliably cannulate an autogenous AV access for dialysis may also indicate that an access has failed to mature and may require revision, despite the fact that the vein may have dilated sufficiently (i.e., 6 mm). It is important to emphasize that the ability to reliably cannulate an access is also dependent on the experience of the individual performing the cannulation in addition to the quality of the access itself. Fragile, immature veins that have not become arterialized sufficiently to withstand the trauma of repeated cannulations may lead to hematomas around the needle access site. The presence of significant hematomas may lead to further problems cannulating the access (both autogenous and prosthetic) and predispose to the development of a stenosis. In other cases, the access vein may simply be too deep to allow easy cannulation. An open dialogue between the access surgeon and the dialysis center personnel is important to determine the cause of any cannulation difficulties to both optimize maturation and prolong the functional life of the access.

Assessment During Dialysis

There are several techniques for monitoring dialysis access function, all based upon the measurements of access flow, pressure, or flow resistance. From a practical standpoint, two methods predominate: measurement of static venous pressure and measurement of flow rate using ultrasound flow measurement.

Venous Pressure Measurement

Intimal hyperplasia static venous pressure is perhaps the easiest of the surveillance techniques and the most widely used in dialysis centers.[37,39-41] To measure this value, the dialysis pump is turned off, and the circuit is allowed to equilibrate. The venous (i.e., efferent) needle pressure is then used as the static venous pressure. Individual measurements that are greater than 50% of the mean arterial pressure are considered abnormal; however, the trends over time are more reliable and predictive than a single measurement. Specifically, if the static venous pressures increase over a series of measurements, investigation is indicated even if the 50% mean arterial pressure threshold is not achieved.

Flow Measurement

The second technique for assessment is using a Transonic Hemodialysis Monitor (Transonic Systems, Inc., Ithaca, New York) within the dialysis circuit.[42-44] Using this technique, a bolus of isotonic saline is injected into the blood stream and dilutes the blood and the corresponding ultrasound velocity. As the saline passes through the blood lines, a sensor registers an indicator curve that can be used to calculate the flow rate. There are several advantages of this technique. First, flow is measured by saline dilution with the needles reversed, producing a stable measure of access flow that is independent of the volume of the saline injected. Second, access recirculation can be assessed objectively at the same time with the same equipment using the needles in their normal orientation.[12,41,45-47] Therefore access flow and access recirculation can be assessed repeatedly over time to provide two independent measures of access function.

The development of an access stenosis is highly variable in onset. Some patients develop clinically significant stenosis within a few weeks of access creation, whereas others never develop a stenosis. Generally a flow rate of less than 600 to 800 mL/min predicts thrombosis in a prosthetic access, although the thresholds for autogenous accesses are not well defined.[15,44,48] The National Kidney Foundation Kidney Disease Outcome Quality Initiative (KDOQI) Clinical Practice Recommendations for Vascular Access recommends further study and intervention when this threshold is achieved.[49] However, there is some suspicion that these rates may be too low, and that interrogation or intervention may be appropriate at a higher level (e.g., flow rates <900 mL/min). The KDOQI guidelines also recommend at least a monthly assessment of access flow using any number of techniques.

Duplex Ultrasound Access Surveillance

Although duplex ultrasound surveillance has been attempted for AV access, there are currently few data to suggest that it provides any real benefit in maintaining access function long term. Prospective trials of duplex ultrasound surveillance have not consistently demonstrated any patency benefit, with the limitation of a single study.[50] Duplex ultrasound can be useful in confirming any suspected abnormalities in access flow detected by physical examination, although it may not add much beyond a thorough examination by an experienced clinician. For this reason, duplex ultrasound for AV access is generally reserved for those situations in which the clinical examination is confusing or difficult.

Catheter-Based Contrast Imaging

Catheter-based contrast imaging is essential to any intervention to maintain or improve dialysis access function. Contrast imaging is, by definition, invasive because needle or catheter access involves skin puncture. In general, contrast imaging provides anatomic information rather than physiologic data, although access flow can be inferred from the anatomic images. For this reason, surveillance and monitoring are complementary to contrast imaging, with anatomic contrast imaging providing supporting evidence for the alteration of access function identified by physiologic monitoring techniques.[51,52] In addition, once the underlying anatomic defects are identified, intervention can be performed in the same setting as the diagnostic study. Performing the diagnostic and therapeutic procedures at the same time can avoid the risk of access failure during the intervening time associated with a staged approach.

INTERVENTIONS FOR FAILING ACCESS

Open Surgical Techniques

Revision for Stenoses

Open surgical revision of a stenotic segment within the AV access can improve both flow and function. The challenge is to define the underlying lesion responsible for the diminished flow. As with all access interventions, complete imaging from the arterial inflow to the central veins is necessary, and this is generally done at the time of operative revision. The advantage of simultaneous imaging is that questions concerning the access can be answered in "real time." Repeat imaging is often necessary to further define the relevant anatomy when the diagnostic imaging is performed at an earlier time.

Figure 178.5 Collateral veins with venous hypertension due to central venous stenosis associated with a tunneled dialysis catheter.

Surgical revision for stenosis is generally performed using an interposition graft or a patch angioplasty (Fig. 178.5). Both techniques have advantages and disadvantages, can be effective, and are widely used. The use of an interposition graft to bypass a stenosis at the venous outflow of a prosthetic access essentially re-sites the venous anastomosis, thereby limiting the length of available vein that can ultimately be used to construct any new permanent access. Patch angioplasty simply enlarges the area of stenosis without removing the local disease process (or consuming any available length of the vein), theoretically leading to a higher incidence of recurrent stenosis. However, results of these two techniques are largely equivalent.[53-55]

Revision for Other Problems

The presence of multiple outflow vein branches can limit the available vein length for cannulation and can inhibit the dilation of the main outflow vein during the maturation period. The significance of the collaterals may not be obvious at the time of initial access placement, but may become apparent if the access fails to enlarge above a large branch. In this situation, ligation of collateral branches may help maximize outflow through a single axial venous segment.

Translocation or elevation of a deep autogenous AV access may be necessary to allow successful needle cannulation. This is a common problem, particularly in obese patients with type 2 diabetes. In these patients, overlying fat and subcutaneous tissue may limit the ability to cannulate the autogenous access, even in the presence of high flow rates and a good outflow vein. Transposition to a more superficial location may allow access utilization that would otherwise be impossible.

The technique for superficial transposition is similar to that used in the second stage of a two-stage basilic vein transposition. In this situation, the depth of the vein from the skin is generally greater than its diameter. To reliably access the vein, the access should be within one vein diameter from the skin surface or within 6 mm as recommended by the KDOQI "rule of 6s," which is among their criteria for autogenous access cannulation (i.e., vein diameter—6 mm, depth from skin—6 mm, flow rate—600 mL/min).[56] There are two basic approaches to making the vein accessible. The first is to remove the fat and subcutaneous tissues overlying the vein and then re-approximate the subcutaneous tissues, which produces a shallower tissue depth to cannulate the access. The challenge in this technique is to somehow avoid developing scar tissue in the subcutaneous space that may limit needle access or generate IH. Bronder et al.[22] reported favorable results with this technique in a large series of patients.

The second technique involves transection of the vein, with superficial transposition and re-anastomosis. Although it may be possible to simply reattach the vein to its previous anastomosis, the access surgeon should be prepared to re-site the arterial anastomosis more proximally to accommodate any loss of vein length resulting from the new, superficial tunnel. This secondary surgical procedure, although generally not a major operation, may result in significantly greater morbidity than that associated with the original access procedure, given its potential for wound complications in obese patients. After transection of the vein, the longer segment is tunneled in a subcutaneous course. The vein is then carefully re-anastomosed to avoid unnecessary tension. As with the two-stage basilic vein transposition, the vein has already adapted to arterial pressure and flow, making the surgery safer and easier because the vein is somewhat easier to manipulate, although some venous hypertension is associated with the arterial communication. Any other abnormalities in the access can be addressed at the same time. In some cases, during maturation the vein may dilate and elongate, such that simple elevation without transection can be performed.

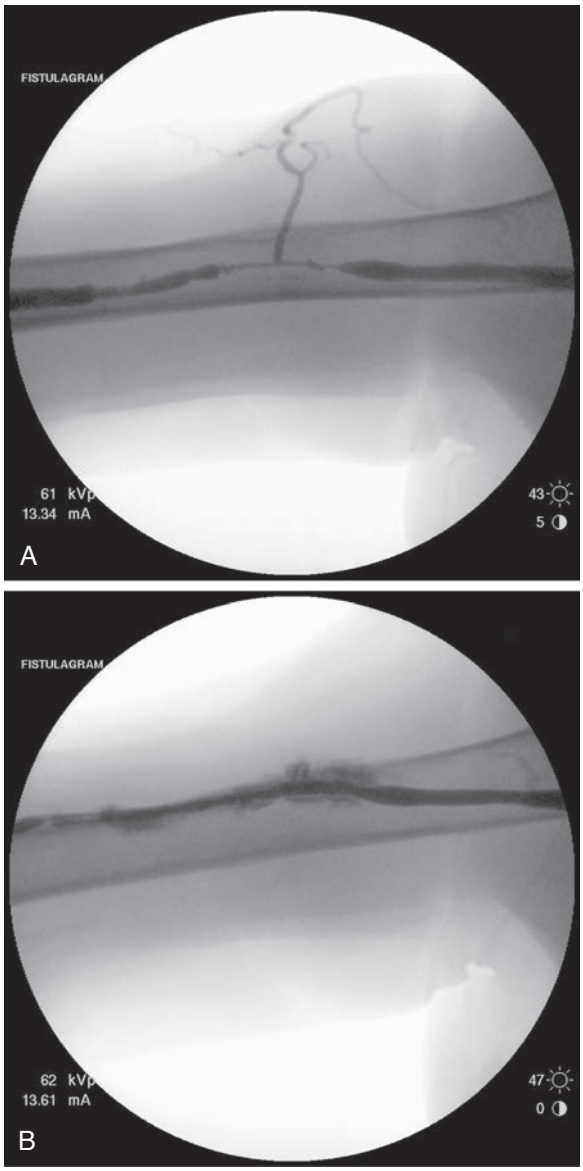

Figure 178.6 A diffuse, high grade stenosis in an autogenous access (A) with disruption and contrast extravasation (B) after balloon angioplasty with a high-pressure balloon.

Percutaneous Techniques

Percutaneous techniques for failing and thrombosed accesses are similar to those used in other vascular distributions. Once the complete circuit from the arterial inflow to the venous outflow has been imaged, specific approaches to the underlying pathology can be performed. Despite the similarities, the lesions encountered in AV access are much different from the arterial lesions, typically resulting from atherosclerosis. The fibrotic, rubbery stenoses characteristics of IH do not routinely dissect, like atherosclerotic stenoses, but more commonly tear or are disrupted as a result of the obligatory higher insufflations pressures (Fig. 178.6).

Balloon Angioplasty

Of all the percutaneous interventions performed on AV accesses, simple balloon angioplasty is the most common.[57-61] The balloon is placed within the area of stenosis and insufflated to a pressure that will eliminate any focal stenosis or "waist" seen on the distended balloon. The insufflation times are generally longer than those used in arterial disease, to allow more remodeling of the lesions to occur; this usually takes 2 to 3 minutes. Treatment is repeated until all areas of presumed outflow stenosis are adequately treated. Stenoses caused by IH routinely require high pressures to resolve, often 20 atmospheres or more. With these increased pressures, trauma to the vein can occur, which can stimulate the IH process, leading to recurrent stenoses. For this reason, some physicians advocate switching to a cutting balloon before high-pressure dilation,[62-66] allowing subsequent balloon angioplasty to be performed at much lower pressures.

A technique termed balloon-assisted maturation has been described to facilitate autogenous access maturation.[67-70] In this technique, the outflow vein is serially dilated with progressively larger balloons until a target vein diameter is achieved. The vein is allowed to heal between the serial dilations (hopefully without the development of IH), resulting in a larger venous

conduit once healing is complete. This approach was first described in 2001 by Turmel-Rodrigues et al.,[71] who reported a 97% success rate in 52 dysfunctional and 17 thrombosed forearm autogenous accesses with a mean age of 10 weeks. The corresponding primary and secondary success rates at 1 year were 39% and 79%, respectively. Subsequent authors have published similar results, advocating a policy of early intervention in patients with nonmaturing forearm autogenous accesses.[72] However, the long-term functional outcome of accesses treated by these techniques remains undefined.

Stenting

An intraluminal stent may be used to treat any residual stenoses or dissections after balloon angioplasty. However, in-stent restenosis is quite common with the use of bare metal stents.[73-75] More recently, covered stents have been used to prevent recurrent stenoses.[6,58,76-80] These devices are essentially fabric-covered stents designed to prevent the ingrowth of hyperplastic tissue, and thus avoid the early failures seen with bare metal stents. Notably, covered stents have been shown to have a patency advantage when treating stenoses at the venous anastomosis of prosthetic AV accesses, limited only by their expense.[58,76,79,81] Covered stents can also be used to prolong prosthetic AV access use in the presence of a large pseudoaneurysm or a degenerated graft.[82-87] Covered stents may allow continued needle punctures in previously aneurysmal (or pseudoaneurysmal) segments, with no apparent loss of patency. Although the durability of this method is not yet established, it may serve as a temporary bridge until further access or formal access revision can be performed.[88,89]

Hybrid Approach

Therapeutic endovascular procedures are often performed at the time of the diagnostic procedure, as outlined previously. Similarly, open, surgical revision can be performed at the same time as the diagnostic study if it is performed in an operating room, commonly a hybrid suite. The specific approach depends on the underlying pathology. A venous outflow stenosis may be treated by percutaneous techniques, whereas an arterial anastomotic stenosis may require open surgical revision. The catheter-based imaging can be performed in the operating room with either a portable C-arm or a fixed imaging system, and the choice of definitive intervention (open or endovascular) is dictated by the findings (Fig. 178.7). Thus hybrid procedures are often the most efficient for patients because all necessary treatments can be performed at the same session.

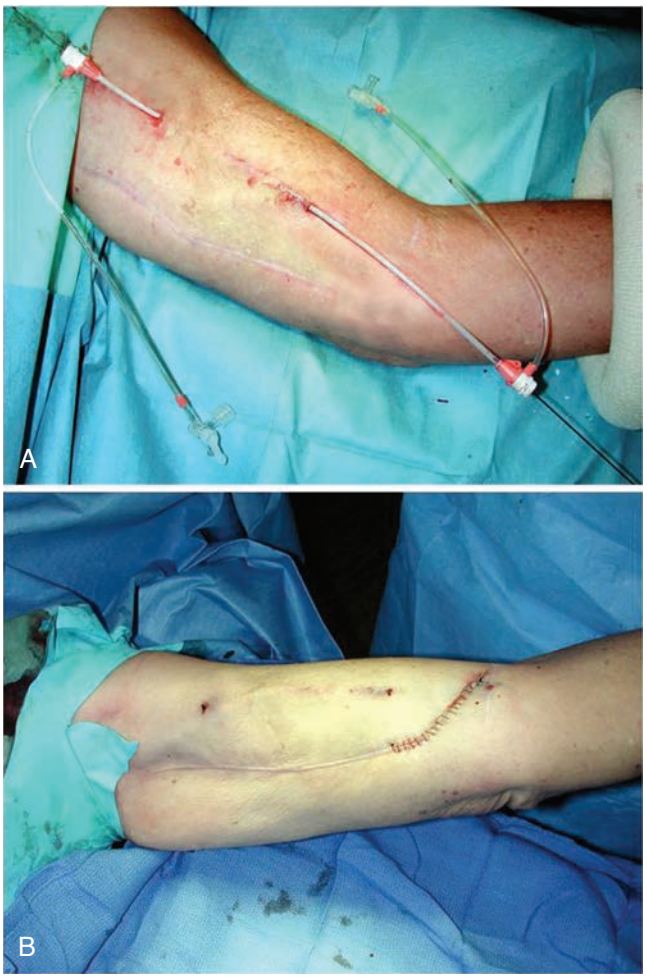

Figure 178.7 Patient with brachial-basilic autogenous arteriovenous access with stenoses at both the arterial anastomosis and within the outflow vein. A hybrid approach was performed, including (A) balloon angioplasty of the stenosis in the outflow vein and (B) open surgical revision of the arterial anastomosis.

INTERVENTIONS FOR THROMBOSED ACCESS

Autogenous Arteriovenous Access

The treatment of thrombosed AV accesses may be difficult, particularly for autogenous accesses. In this case, the endothelial surface may be significantly compromised, because thrombus rarely forms in native veins without some underlying abnormality. Thrombus removal (i.e., thrombectomy) often leads to recurrent thrombosis because the underlying flow surface is abnormal. This is further compounded by the trauma to the endothelial surface caused by the balloon thromboembolectomy catheter. For these reasons, open surgical thrombectomy has traditionally had limited value for autogenous AV accesses.[90-94] Palmer et al.[95] reported technical success in 7 of 10 patients with thrombosed autogenous accesses treated with an open, surgical approach. However, the corresponding 6-month primary and secondary patency rates were only 51% and 69%, respectively, for the accesses that were initially treated successfully. More recently, Cull et al.[96] reported excellent results and described a detailed technique to remove the thrombus. Although the role for surgical thrombectomy remains unresolved, it certainly merits consideration, and it is likely to be effective for limited or short-segment thrombotic occlusions.

Other series reported better results with percutaneous mechanical thrombectomy, but long-term data are still lacking.[97-100] Shatsky et al.[101] reported their experience using the Arrow-Trerotola device (Teleflex Medical, Research Triangle Park, North Carolina) in a series of 44 thrombosed autogenous accesses. Their primary patency rates were 38% at 6 months

and 18% at 12 months; secondary patency rates were 74% and 69% at 6 and 12 months, respectively. Although primary patency was limited, repetitive treatments seemed to be possible.

Prosthetic Arteriovenous Access

Prosthetic AV accesses tend to thrombose more frequently than autogenous accesses. Because the most common failure mode is IH at the venous anastomosis, they can usually be salvaged, providing long-term access without a significant disruption in a patient's dialysis schedule. In addition, prosthetic AV accesses tolerate balloon thrombectomy better than autogenous accesses because they do not have a viable endothelium, which is potentially susceptible to mechanical injury with thrombectomy, as in the case of autogenous accesses. Segments of the prosthetic graft itself can also be replaced as necessary to remediate any graft degeneration or localized soft tissue infections, oftentimes continuing the dialysis schedule using the residual, unaffected segment. A recent publication suggests that the shorter maturation times associated with prosthetic access (compared with autogenous accesses) may significantly reduce the number of catheter days for patients on dialysis, particularly with revisions performed with early access grafts.[102]

Open Surgical Techniques

The open, surgical treatment of a thrombosed AV access is predicated on the rapid removal of clot and definitive treatment of the underlying cause of failure. Most commonly, the access thrombosis is a result of venous outflow stenosis, although there are other mechanisms of failure. For example, a large pseudoaneurysm at a cannulation site may result in pooling of blood within the dilated segment with the stagnant flow leading to thrombosis. Similarly, inadequate arterial inflow may lead to graft thrombosis in the absence of venous outflow issues. Therefore the surgeon's first task is to determine the underlying cause of the thrombosis. The operative plan and the site of the incision are both dictated by the presumed underlying pathology.

The thrombus within an AV access can usually be removed using an appropriately sized balloon thromboembolectomy catheter; typically a 4F catheter is used for 6-mm diameter grafts. The location of the incision is based upon the anticipated revision. In the absence of any other obvious pathology, venous outflow stenosis is the probable cause and the focus of the likely revision. If the access has another significant obvious pathology, such as large pseudoaneurysms, it may be appropriate to incorporate this finding into the planning as well.

Once the access is cleared of thrombus, its full extent should be imaged from the arterial inflow to the venous outflow, including the central veins, ruling out any lesion that may predispose to a recurrent thrombosis. All venous anastomotic or outflow lesions should be repaired using conventional, open techniques. Patch angioplasty may be used to manage typical venous outflow stenosis (Fig. 178.8). This approach has the advantage of preserving the outflow vein, but it requires an extensive dissection in a scarred operative field. As an alternative, an interposition graft can be used to essentially re-site the venous anastomosis more proximally on the vein, avoiding scar tissue and providing the best-quality outflow.

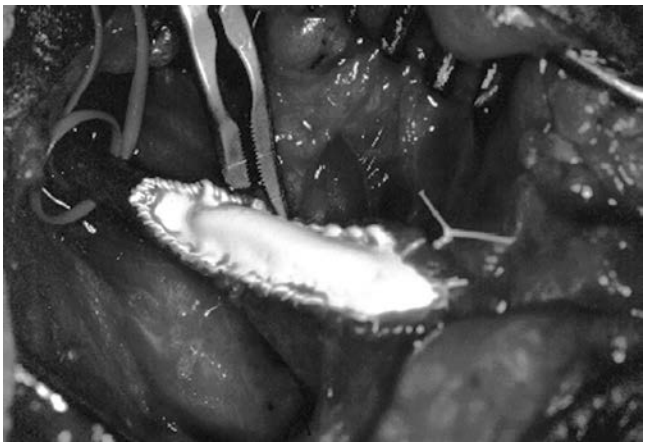

Figure 178.8 Surgical patch angioplasty using an expanded polytetrafluoroethylene patch at the venous anastomosis of a thrombosed prosthetic access.

Prosthetic AV accesses can usually be used for dialysis after open, surgical thrombectomy because there is often a sufficient length of the graft left undisturbed. For example, if the access-related problem occurs near the arterial anastomosis of a C-shaped configuration (e.g., brachial-axillary configuration), a distal segment closer to the venous anastomosis can be used for cannulation. Similar options for immediate cannulation may exist after open, surgical thrombectomy of autogenous accesses, but the need for a temporary catheter is likely increased.

Percutaneous Techniques

The use of percutaneous techniques for prosthetic access thrombosis was described in 1984 by Glanz et al.[103,104] in an effort to both avoid the loss of vein associated with surgical revision and to allow outpatient treatment. Since that time, the use of balloon angioplasty for venous outflow stenosis associated with AV access failure has grown dramatically. In these percutaneous techniques, the thrombus within the prosthetic access is generally removed as the first step, with treatment of underlying pathology as the second component.

Thrombolysis

The thrombus can be removed from the prosthetic access in a number of ways using percutaneous techniques. In most cases, crossed sheaths are placed within the clotted access, and a thrombolytic agent is infused to remove the bulk of the thrombus and provide some antegrade flow (Fig. 178.9).[105-111] Typically, 2 to 4 mg of tissue plasminogen activator is placed into the clot. The arterial and venous ends of the prosthetic access are intermittently occluded to allow the entire prosthetic graft (and thrombus) to be infused with lytic agent (Fig. 178.10). In the "lyse-and-wait" technique, the thrombolytic agent is given, and the patient is monitored in the holding area for a "return of flow."[107,110-113] In the "lyse-and-go" technique, the patient is immediately taken to the operating room or interventional suite for further percutaneous intervention. Typically an 8-mm

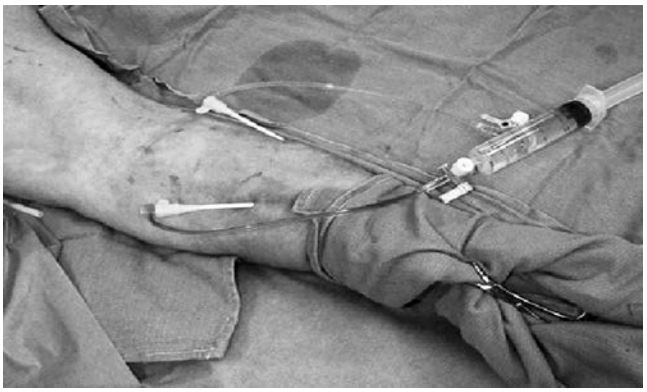

Figure 178.9 The crossed sheaths, typically used for endovascular treatment of a thrombosed prosthetic access, are shown with sheaths directed toward the arterial and venous ends.

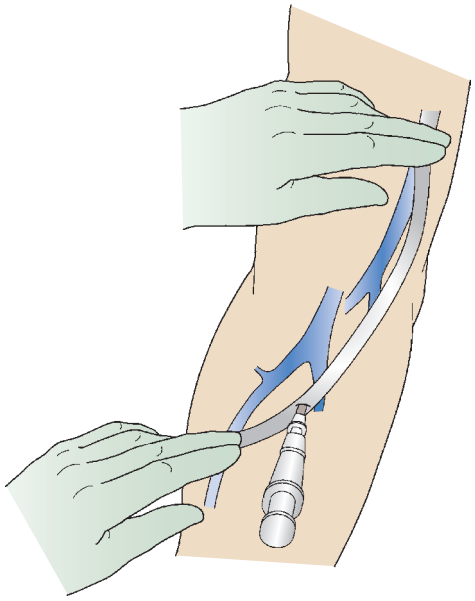

Figure 178.10 Thrombolytic agent is infused into the thrombosed prosthetic access, and both the arterial and venous ends are serially occluded to diffuse the agent throughout the thrombus.

by 8-cm high-pressure balloon (i.e., 8 × 80 balloon) is introduced through a sheath within the prosthetic access, and balloon angioplasty of the entire graft, including venous outflow, is performed. Any areas of residual stenosis are treated with balloon angioplasty using long-duration insufflations (typically >3 min). If there is a residual thrombus or "plug" at the arterial end, a balloon catheter is introduced through the venous sheath to facilitate extraction (Fig. 178.11). Any residual, partially lysed clot is further fragmented by repeat balloon angioplasty. Ultimately, the residual debris is released into the pulmonary circulation, although this is not usually associated with any systemic effects or complications.[114-118]

Alternatively, a mechanical thrombectomy device can be used alone or in combination with the lytic agent to debulk or remove thrombus within the prosthetic access. The most common devices used for this purpose are the AngioJet,[119-123] the Arrow-Trerotola device,[111,124,125] and the Hydrolyser (Cordis Corp, Bridgewater, New Jersey).[126-129] All these devices have their proponents, but none has proved superior in clinical settings.

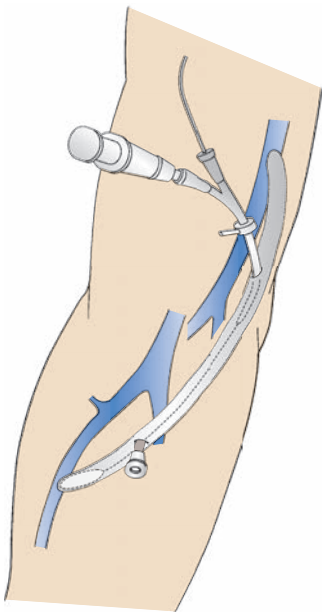

Figure 178.11 If a thrombus or plug persists at the arterial anastomosis, a conventional thromboembolectomy catheter can be passed through the sheath to facilitate removal.

Stenosis Treatment

Once the prosthetic AV access is cleared of thrombus, the next challenge is to treat the underlying cause of failure. Again, complete imaging from the arterial inflow to the superior vena cava is necessary to fully define the potential problems leading to the failure. Once the cause or causes have been defined, treatment is focused on the offending lesion(s). In general, a 6-mm prosthetic graft can easily tolerate balloon dilation to 8 mm. The fibrotic nature of IH may cause the offending lesion to recoil significantly, and thus prolonged high-pressure insufflations are often needed. Although ultra–high-pressure balloons may allow dilation of stubborn lesions in the venous outflow, tearing or disruption of the vein can occur with release of the balloon "waist." Some physicians advocate the use of cutting balloons followed by balloon angioplasty for refractory stenoses in an effort to better control the applied force (discussed previously).

Balloon angioplasty is appropriate for any significant central vein stenosis. Although balloon angioplasty alone in this situation is commonly associated with early recurrence, bare metal stents do not seem to provide any significant patency advantage because of recurrent IH within the stented segment or "in-stent" stenosis. Covered stents appear to improve patency for central venous lesions and should be considered for any recurrent lesions. Covered stents may also be beneficial in anastomotic venous outflow stenoses, which are more traditionally treated by balloon angioplasty alone. In a recent publication, Haskal et al.[130] showed that covered stents dramatically improved patency (51% in the covered stent group vs. 23% of those with balloon angioplasty alone at 6 months) in patients with failing

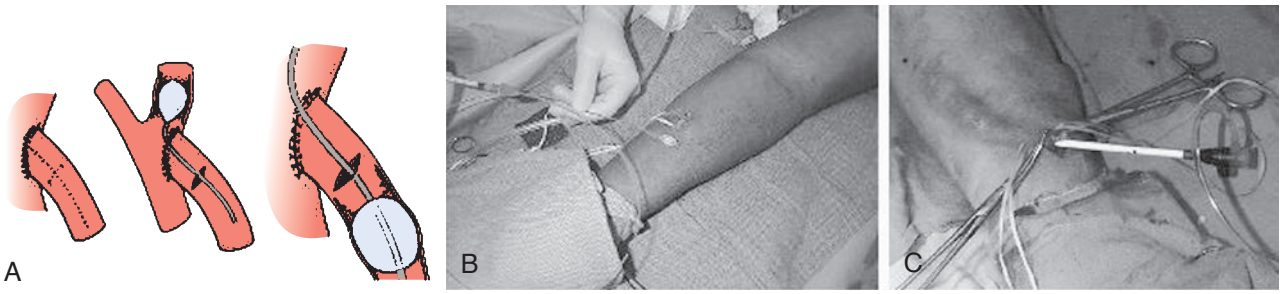

Figure 178.12 Hybrid technique for thrombectomy and angioplasty of a prosthetic arteriovenous access. (A) A thromboembolectomy catheter is passed proximally and distally through a small incision in the graft near the venous anastomosis. (B) Conventional balloon catheters are used for thrombectomy. (C) A sheath is then placed through the arteriotomy to facilitate imaging and potentially perform an endovascular intervention.

hemodialysis grafts. Although this overall patency difference is significant, the cost effectiveness of these relatively expensive devices is less clear.[131] Further studies also seem to support this concept,[78,83,132-134] but additional experience is needed to define their specific roles.

Hybrid Techniques

The two components of successful AV access thrombectomy are removal of the thrombus and treatment of the underlying cause of access failure. Removal of thrombus is often best achieved by open balloon thrombectomy; this can often be performed with the patient under local anesthesia with sedation and using a small incision over the prosthetic graft (Fig. 178.12). Once the thrombus is removed, complete imaging from the arterial inflow to the superior vena cava can be performed. With this approach, treatment of any remote, underlying lesion can be accomplished by techniques normally reserved for percutaneous treatment. The effectiveness of the thrombus removal with this hybrid approach is comparable to the open alternative, and no thrombus is left in the graft, thereby avoiding the potential to embolize into the pulmonary circulation, which may occur with the total percutaneous approach. Also, because thrombolytic agents are generally not used, the risk of bleeding (and bleeding complications) is decreased. Finally, any venous anastomotic stenoses can be treated with balloon angioplasty, thereby preserving the available length of the outflow vein, frequently compromised with the open, surgical approaches. In many ways, this hybrid procedure has the potential for improved results with reduced morbidity. Unfortunately, the published results of this hybrid technique are limited.[97,135,136]

TREATMENT OUTCOME

Unfortunately, there are few long-term data comparing these various approaches. The majority of the studies compare open, surgical thrombectomy for prosthetic access with the percutaneous approach.[137] Despite some limitations in the quality of the evidence, the outcomes for the two approaches appear to be comparable. The two variables that appear to have the most impact on outcome include the effectiveness of the thrombectomy and the treatment of the underlying cause of thrombosis rather than the specific approach. Most centers have already settled on their preferred techniques for the management of access thrombosis, and clinical protocols for management are often difficult to implement. Until alternative approaches are better validated, the "best" treatment will remain a topic of debate.

The National Kidney Foundation Kidney Dialysis Outcomes Quality Initiative (KDOQI) 2006 Guidelines recognize the following access complications: bleeding, infection, aneurysm/pseudoaneurysm, seroma, access-related hand ischemia (ARHI), venous hypertension, and neuropathy.[1,2] Cardiopulmonary complications are also reviewed.

BLEEDING

Prolonged access-site bleeding and easy bruising are the most frequent complications. However, end-stage renal disease (ESRD) is also associated with increased rebleeding in peptic ulcer disease, spontaneous retroperitoneal bleeding, and hemorrhagic transformation of stroke.[3-8] Contributing factors include anemia, thrombocytopenia, acquired defects of primary hemostasis, repeated procedures, and antiplatelet and anticoagulant agents. With appropriate medical management, the risks can be minimized.

Etiology

Morgagni first described the association between bleeding and renal dysfunction.[9] Both platelet dysfunction and anemia play a role. At normal hematocrit levels, platelets and plasma reside at the vessel periphery, thus increasing contact with endothelium and facilitating activation and aggregation at sites of injury. In anemia, rheology changes.[10-12] When the hematocrit declines, there is an increase in nitric oxide (NO) activity, causing vasodilation and platelet inhibition.[13,14]

Moderate thrombocytopenia is common in ESRD but rarely causes significant bleeding. Increased bleeding is predominantly due to uremia-induced platelet dysfunction.[9,13-15] There is no

Abstract

Non-thrombotic complications are common in the hemodialysis population. Awareness of the complications, diagnostic tests, and interventions to treat are important, both for access maintenance and for overall care of the patient. This chapter discusses bleeding, access related infections, aneurysms, seromas, access-related hand ischemia, venous hypertension, neuropathy and cardiopulmonary complications.

Aneurysms

direct relationship, but risk increases markedly when BUN is greater than 100 mg/dL (35.7 mmol/L). Uremia has been associated with defects at every stage of platelet function. Reduced expression of glycoprotein (GP) Ib impairs platelet adhesion to subendothelium,[16] and a conformational change in GP IIb-IIIa inhibits fibrinogen binding and platelet aggregation.[15] The content of dense granules is decreased, thus reducing the storage pool of platelet adenosine diphosphate (ADP) and serotonin[17] and increasing endothelial production of prostacyclin, which inhibits platelet activation.[11,18]

Many medications increase bleeding risk in CKD. Beta-lactam antibiotics (cephalosporins and penicillins) have prolonged half-lives and are only partially cleared by dialysis.[19] At high levels they cause platelet dysfunction. At extremely high levels, penicillins alter antithrombin III activity, causing heparin-like abnormalities.[20] Oral anticoagulation is common in CKD patients, as almost 20% have atrial fibrillation.[21] Most receive warfarin; however, use of novel oral anticoagulation (NOAC) agents is increasing.[22] NOACs are cleared by the kidney in varying degrees, and the initial safety and efficacy trials excluded dialysis patients.[23-27] A recent analysis of the Fresenius Medical Care North America ESRD database demonstrated that in comparison with warfarin, dabigatran and rivaroxaban are associated with a higher risk of bleeding, which can result in hospitalization or death.[22]

It should be noted that persistent or recurrent access-site bleeding should be evaluated for causes other than coagulopathy. Prolonged bleeding may be a sign of venous outflow stenosis, pseudoaneurysm formation, or access infection. At least 40% of fatal vascular access hemorrhages are preceded by a herald bleed or access infection within the prior 6 months.[28]

Treatment

There are several strategies to control bleeding and minimize surgical risk in patients with ESRD. The strategy is dictated by clinical circumstances and the urgency of intervention.

Active Bleeding and Emergent Surgery

Desmopressin (1-desamino-8-D-arginine vasopressin, or DDAVP) is a human-made form of the normal human hormone arginine vasopressin (the antidiuretic hormone, or ADH), a peptide containing nine amino acids. Compared with vasopressin, desmopressin's first amino acid has been deaminated, and the arginine at the eighth position is in the *dextro* rather than the *levo* form. DDAVP (0.3 to 0.4 μg/kg administered intravenously or subcutaneously) induces the rapid release of autologous von Willebrand factor (vWF) and factor VIII and transiently decreases the activity of protein C.[29-31] Tachyphylaxis typically develops after a second dose.[32] Platelet transfusion also works immediately but lasts for only 4 to 5 hours, as platelets become dysfunctional shortly after they enter a uremic environment.[13]

More prolonged effects can be obtained from cryoprecipitate, a plasma derivative rich in fibrinogen, vWF, and factor VIII that works within minutes. Maximal effects occur in 4 to 12 hours, lasting up to 24 hours.[13,33] The primary disadvantage is rare anaphylaxis or hemolysis.[13]

Persistent oozing during surgery or after dialysis may be secondary to heparin effects. If ACT is elevated, protamine can be administered, up to 1.5 mg/100 units of heparin, to reverse anticoagulant effect. Recombinant factor VIIa may be used "off label" as rescue; case reports describe success,[34-36] but it carries a risk of systemic thromboembolic complications.[37]

Elective Surgery

Preoperative planning should focus on minimizing platelet dysfunction and correcting anemia. Hemoglobin is below 10 g/dL in at least 20% of ESRD patients.[21] Adequate hematocrit provides a margin of safety and affects blood rheology, facilitating platelet function. Recombinant human erythropoietin induces erythropoiesis, thus correcting anemia,[13] but it takes several weeks to show an effect. Erythropoietin increases platelet expression of GP-IIb/IIIa and enhances platelet aggregation.[15,38] Platelet function can also be improved by scheduling surgery 24 hours after dialysis and by discontinuing antiplatelet medications 1 week prior.

Patients facing major operations may benefit from conjugated estrogens, 25 to 50 mg orally or 0.6 mg/kg per day IV for 5 consecutive days, which increase vWF synthesis, reduce protein S and NO, and correct bleeding time.[13,14,39-43] Effects are seen within 6 hours,[40] peak in 5 to 7 days, and last up to 14 days.[11] Transdermal estrogen administered 2 weeks prior (50 to 100 μg/24 hours) is an alternative.[14]

Postoperative Bleeding

Postoperative bleeding should be addressed by return to the operating room and exploration for surgically correctable causes. Pharmacologic adjuncts, particularly protamine sulfate, should be considered if the initial procedure involved heparin. DDAVP may also be helpful.

INFECTION

Infections are the second most frequent cause of death and loss of access site, occurring more commonly with prosthetic devices.[44-46] The risk of sepsis-related death is markedly increased in patients with CKD.[46] The Society for Vascular Surgery reporting standards recommend classifying infections as early (<30 days) or late (>30 days), culture-positive or culture-negative, and the site of infection (i.e., para-anastomotic, mid-AV access, outflow veins). Treatment is dictated by type and location of access, timing, and extent of infection. Grading of infection is as follows:

Grade 0: None
Grade 1: Resolved with antibiotic treatment
Grade 2: Loss of AV access because of ligation, removal, and bypass
Grade 3: Loss of limb

Bacteriology: Most access-related infections are due to single-organism gram-positive bacteria, *Staphylococcus aureus* predominating, Solitary gram-negative organisms account for 25%, with a small percentage being polymicrobial.[47,48]

Catheter Related: In comparison with autogenous AV fistulas, the risk of infection is highly dependent on type of access used:

2.2 ($P = .002$) for AV grafts, 13.6 ($P < .0001$) for tunneled catheters, and 32.6 ($P < .0001$) for temporary catheters.[46] Catheters, both temporary and tunneled, are the source of two-thirds of all infections and more than 80% of all bloodstream infections in hemodialysis patients.[46,49] In a study of 800 dialysis patients by the Centers for Disease Control and Prevention, use of a catheter, specific dialysis units, and malnutrition (albumin <3.5 g/dL) were identified as independent risk factors for sepsis.[50]

Epidemiology: Twenty percent of access loss is related to infection.[51] A prospective study found that the probability of infection at 1 year is 4.5% for autogenous AV fistulas versus 19.7% for prosthetic grafts.[52] A longitudinal cohort study of 4005 hemodialysis patients in the U.S. Renal Data System, found a RR for infection of 1.35 for prosthetic compared with autogenous grafts.[53]

Increased susceptibility to infection is related to impaired humoral and cellular immunity, nutritional deficiencies, frequent breaches of skin integrity, and the presence of prosthetic material.[53] Risk factors for infection include repeated cannulation, cannulation technique, poor hygiene, repetitive hospitalizations, duration of prosthetic AV access use, increased age, lower extremity location (18% vs. 1.6%; $P < .05$), and diabetes mellitus.[49,54] Gram-negative bacteria and associated remote infections or complications are more common with lower extremity prosthetic accesses (31% vs. 4%; $P = .003$).[41,42] The buttonhole technique is associated with higher infection rates than the rope-ladder technique or area techniques, due to inappropriate use of sharp needles after the tract has developed, inadequate use of disinfecting agents, and incomplete scab removal.[55,56]

Treatment

Broad-spectrum antibiotics should be initiated as soon as access-related infection is considered and tailored to the appropriate organisms as soon as possible. Most commonly, vancomycin and gentamicin are chosen because of their ease of dosing and spectrum of efficacy. In centers with a low prevalence of methicillin-resistant *S. aureus*, nafcillin, oxacillin, or cefazolin may be used.[57,58]

Autogenous Access: Most autogenous AV access infections are associated with cannulation issues or hematomas, with bacteriology similar to that seen in prosthetic infections. They may present with cellulitis or abscess. Most respond to a 2- to 4-week course of antibiotics, with surgery rarely necessary. Autogenous access with intraluminal endovascular devices requires a prolonged course (4 to 6 weeks) of parenteral antibiotics or may require resection of the prosthetic material.[46]

Prosthetic Access: Prosthetic access infections are more complex. Attempts at salvage are reasonable for limited infections, allowing uninterrupted dialysis, site preservation, limited catheter days, and decreased surgical complexity. Failure to improve with local resection may necessitate full graft excision. Greater than 50% of such infections involve only a discrete portion of the access.[59] Thigh graft infections are more likely to involve gram-negative bacteria (OR 10.22)[60] and distant seeding (15% vs. 3%, $P = .02$, OR 5.24).

Salvage is most frequently feasible when infection involves the midportion of the graft. Segmental resection is accomplished by exposure of uninfected graft, proximally and distally, and tunneling a new graft through clean tissue planes. The infected segment is then resected with the incisions left open. Early success is in excess of 90%,[61-63] but recurrent infection occurs in up to 20% of cases with secondary procedures needed in 19%. Another option includes use of a vacuum-assisted closure device after open surgical debridement.[64]

Anastomotic Infection: Anastomotic infections require aggressive therapy with complete graft excision to prevent disruption and hemorrhage.[65] Alternatively, subtotal graft excision may be considered with low-virulence organisms such as *Staphylococcus epidermidis.* This entails leaving a small cuff on the artery to decrease surgical dissection and complexity. Infection in the retained cuff has been reported in up to 17% of cases.[65] Brachial artery ligation, a last resort, is feasible in critically ill patients with grossly infected prosthetic grafts, with risk of hand ischemia dependent on the adequacy of the collateral circulation.[66] Cryopreserved vessels are an alternative to preserve the site. Matsuura achieved satisfactory 1-year primary patency (PP) and secondary patency (SP), 42%% and 68%, respectively, with a recurrent infection rate of only 2.3%.[67] Most infections presenting within days of access creation should usually be treated by complete graft excision.[46,61]

Thrombosed Grafts: Although removal of thrombosed AV grafts is not usually necessary[68] and can be technically challenging if such grafts are well incorporated, there are several studies demonstrating the potential for the thrombosed graft to serve as the source of infection.[65] One study found that 71% asymptomatic patients had positive indium scans, whereas 62% had perigraft purulence at the time of graft removal.[68] The decision to remove a thrombosed AV graft should be based on the classic signs of inflammation (rubor, dolor, calor, and tumor) combined with the absence of an alternative source of infection.

PSEUDOANEURYSM AND ANEURYSM

Pseudoaneurysms and true aneurysms create issues with cannulation difficulty, increased risk of thrombosis, pain, bleeding, cosmesis, and infection.[69] Progressive enlargement can compromise overlying skin; this may lead to rupture, which is sometimes fatal (Fig. 179.1).

Pseudoaneurysm

AV-access pseudoaneurysms develop due to trauma from repeated punctures or poor technique, with resultant perigraft hematoma formation in addition to increased intragraft pressures associated with outflow stenoses. Pseudoaneurysms occur in 2% to 10% of polytetrafluoroethylene (PTFE) AV grafts, more commonly in older grafts.[70] Surrounding tissue ingrowth limits pseudoaneurysm development, with poorly incorporated grafts at higher risk. Autogenous fistula pseudoaneurysms are less frequent but not rare.[71] Most are related to cannulation. Pseudoaneurysm changes should prompt a change in cannulation technique and

Figure 179.1 Symptomatic pseudoaneurysms with early skin erosion that appeared several years after creation of an autogenous proximal radiocephalic arteriovenous fistula.

location but is not a reason for intervention. Treatment is directed by complications.[70]

Treatment

Open: Interposition grafts involve resection of the segment with placement of interposition grafts or bypass around the lesion. This is most typical for prosthetic graft pseudoaneurysms. Although the new segment becomes incorporated, dialysis continues in incorporated segments. With extensive degeneration, options include a temporary tunneled catheter with replacement of all but anastomotic regions, or staged, segmental replacement, allowing use of the access while the new graft becomes incorporated but requiring two procedures. For extensive degeneration of an autogenous fistula, options include conversion to a graft ("graftula"), maintaining only the arterial anastomosis, and creating a new venous anastomosis. Another option is fistula reduction surgery with resection of a portion of the vein wall, typically over a 10-mm rubber catheter as a sizing dowel. This permits resection of the overlying skin and a short period of catheter access.

Endovascular: The advantages of endoluminal repair include lack of interruption of hemodialysis, avoidance of catheters, percutaneous procedures, and the ability to identify and treat concomitant venous stenosis, present in up to 73%.[69,72-74] Potential risks include stent-graft infection, continued difficulty of access due to the need to puncture the stent graft through the pseudoaneurysm, and persistent cosmetic issues. Barshes reported on 32 patients treated with Wallgraft, Viabahn, and Fluency self-expanding covered stents,[69] with 100% procedural success; PP was 82% and 28% at 30 days and 6 months, respectively. Although 73% of patients had resolution or a significant decrease in size of the pseudoaneurysms, 12.5% developed early thrombosis and 18.75% required additional interventions. Shah et al. found that simultaneous angioplasty of outflow stenosis was necessary in 56%, with 69.2% 6-month patency. Patients with skin erosions were at increased risk for failure due to infection (OR 5.0).[74] Florescu also identified infection as a significant risk of endovascular therapy, with infection occurring in 35% and thrombosis in 12%.[73] Although minimally invasive techniques are appealing, higher cost, risk of infection, and potential difficulty with access for dialysis without good long-term patency remain concerns.

True Aneurysm

Aneurysm formation in fistulas is seen adjacent to the anastomosis associated with hemodynamically significant stenosis, within cannulation areas, adjacent to stenoses midaccess, or next to vein junctions, valves, or rigid areas caused by prior catheters. Cannulation of the area should be discontinued with any type of aneurysm.

Treatment: The preferred treatment for postanastomotic aneurysms is relocation of the anastomosis to a more proximal site. Comparable SP can be achieved by balloon angioplasty of the stenotic anastomosis for small dilations, but this requires a longer time to resolution, leading to catheter use. Partial resection and patch angioplasty are alternatives. For aneurysms in the midportion, fistulogram should be performed to identify outflow stenoses that exacerbate aneurysm formation and can be treated with endovascular techniques. For diffuse degeneration, reduction of the lumen by partial aneurysmectomy is preferred. This requires a longitudinal incision along the length of the involved fistula. Woo reported reduction surgery in 19 patients with a median PP of 14 months.[75] Hossny found a cumulative patency of 85.7% at 1 year.[76] Pierce et al. reported a stapled revision in 12 cases[77] with no immediate wound complications, but 16.6% had problems, including thrombosis and persistent pain requiring ligation. Vo et al. reported 95% success, with a PP of 67% and SP 91% at 1 year, and 46% and 85% at 3 years.[78] Stapled repair can be performed with the Endo GIA stapler (Covidien, Mansfield, Massachusetts) or a TA stapler (Covidien, Norwalk, Connecticut). Reinforcement may be needed. Treatment for aneurysms along the venous outflow tract is angioplasty, with selective stenting.

Aneurysmal Degeneration of Inflow Artery

Arterial aneurysms are rare, as is arteriomegaly. Patients may present with distal embolization, ischemia, swelling, or a painful mass. Mestres et al. reported on 12 patients requiring intervention, with a median of 18.3 years of dialysis. Long-standing access with subsequent ligation or thrombosis and renal transplantation were associated factors.[79] Renal transplant and immunosuppression have been identified in association with arterial degeneration.[80,81] The decision to intervene depends on symptoms, aneurysmal size, patient comorbidities, and life expectancy. Radial artery pseudoaneurysms can be treated by ligation, whereas brachial or axillary aneurysms require bypass.

SEROMA

A perigraft seroma is a collection of sterile, clear, ultrafiltered serum surrounded by a nonsecretory fibrous pseudocapsule. Early seromas frequently resolve spontaneously and are not uncommon with prosthetic grafts. Chronic seroma is rare. Other noninfectious fluid collections include hematomas or lymphoceles. These complications are graded 0 to 3, as follows[2]:

Grade 0: No collection
Grade 1: Observed, resolved
Grade 2: Involves aspiration or surgical drainage
Grade 3: Results in loss of the graft

Most resolve without intervention.[82] Surgery is warranted when the seroma interferes with cannulation, continues to grow, or compromises overlying skin. Aspiration should be avoided, as it significantly increases the risk of graft infection and loss.

Etiology and Incidence: Seromas have been reported with both PTFE grafts and polyester fabric [82-84] at an incidence of less than 2%.[85-87] It is unclear whether location is a risk factor or facilitates recognition. Ladenheim et al. found a higher incidence, 36%, with gel-coated PTFE arteriovenous grafts[88] and concluded that they are not ideal for hemodialysis access.

The mechanism appears to involve increased graft porosity and failure of graft incorporation. Schanzer found that in prosthetic AV accesses, the seroma always occurs near the arterial anastomosis.[89] The active transudation of serum-like fluid can be observed when the prosthetic material is exposed at that point.[86] Several studies have suggested presence of a fibroblast growth inhibitor in patients' serum.[90-92] Histologic studies support this, as there are typically immature fibroblasts lining the graft.[83] Other theories include immunologic reaction, graft damage at implantation, and clinically occult infection.

Presentation: Ultrasound can help distinguish a seroma from a hematoma. Seromas generally appear within 1 month, are painless, and enlarge over time, leading to cannulation difficulty or thinning of the skin.[87] Surgical exploration reveals a fibrous pseudomembrane filled with serous or gelatinous material surrounding the prosthesis. There may also be visible graft sweating.[86,89]

Treatment: Blumenberg et al. reviewed 279 cases treated by 320 surgeons.[84] Treatment included serial aspiration, observation, incision and drainage, cyst removal, and prosthetic graft replacement. Graft replacement yielded the highest cure rate at 92%. Observation and aspiration had similar success (68% vs. 69%), but aspiration led to infection or thrombosis in 8%. Cyst removal had a 72% success rate, with infection or thrombosis in 12%. Incision and drainage had a 53% success rate, with seroma persistence in 40% and infection or thrombosis in 7%. Graft excision and cyst excision are recommended, with changing prosthetic material and rerouting through new anatomic planes. Dauria et al. reported 100% success with focal excision and bypass.[85]

Although most investigators advocate graft excision,[84,85,89,90,93] several reports suggest access preservation.[86,87,94-96] Rhodes described placement of microfibrillar collagn (Avitene; Bard Davol Inc., Warwick, Rhode Island) in the perigraft space.[95] Similarly, an 84% success was reported with fibrin sealing for PTFE grafts.[86] Borrero and Doscher report salvage by pseudocapsule excision.[87] Gargiulo et al. reported success with percutaneous Dacron-covered stents and closed suction drainage.[96]

ARHI or steal syndrome was initially described in 1969 by Storey et al.[97] It has been increasingly recognized as an uncommon but devastating complication of access. Access construction reduces digital blood flow in up to 80% of cases; however, only a few develop symptomatic ischemia.[98] Some coolness and tingling is present in up to 10%,[99] with many resolving in a few weeks. Significant ischemia incidence ranges from 1% to 2% with autogenous access at the wrist[100-103] and 4% to 8% in those with brachial-based access.[100,102-104]

Steal can be limb-threatening and must be promptly evaluated and treated if clinically significant. It is graded as follows[105]:
Grade 0: No symptoms
Grade 1: Mild—cool extremity, few symptoms, flow augmentation with access occlusion
Grade 2: Moderate—intermittent ischemia only during dialysis, claudication
Grade 3: Severe—ischemic pain at rest, tissue loss

Intervention is unnecessary for grades 0/1, sometimes needed for grade 2 and mandatory for grade 3.

Pathophysiology and Risk Factors

Creation of an access substantially alters flow dynamics and resistance in the extremity. The arterial inflow supplies two competing circuits—the low-resistance access proximally and the high-resistance peripheral vascular bed distally. The amount and direction of flow is determined by relative resistances and collateral circulation. A "physiologic steal" or reversal of flow in a portion of the arterial tree distal to the anastomosis is common after access creation. Kwun demonstrated reversal of flow in 73% of autogenous accesses and 91% of prosthetic accesses.[106] Reversal is neither necessary nor sufficient to cause distal ischemia.[107,108] Ischemia results from inadequate collateral circulation and inability of the arterial tree to meet increased demand. Under normal circumstances, the vascular system compensates via increased cardiac output (CO) and vasodilatation.[109] Diseased vessels do not vasodilate,[110,111] and stenosis leads to decreased distal perfusion pressure. Hypotension during dialysis further decreases perfusion and explains symptoms during treatment. ARHI is locoregional hypoperfusion secondary to inadequate arterial compensation.[112]

Risk factors for ARHI include diabetes, peripheral artery disease (PAD), coronary artery disease (CAD), brachial-based (proximal) access, female gender, history of ARHI, and multiple previous access procedures.[108,113-116] Hyperglycemia decreases shear-induced vasodilation, which is critical to both collateral recruitment and inflow artery remodeling.[110,111,117] Atherosclerosis increases the likelihood of flow-limiting inflow lesions and peripheral resistance. Brachial-based accesses increase flow relative to wrist accesses[118] and decrease resistance to flow in the AV access.

Prevention: The ideal strategy is prevention, which entails a thorough preoperative assessment and risk-factor evaluation. No test reliably predicts the development of ARHI. Although patients with a preoperative digital brachial index (DBI) less than 1.0 are more likely to develop steal, there is no cutoff below which steal is inevitable.[114] Similarly, Goff et al. found that an intraoperative DBI less than 0.6 had 100% sensitivity and 18% PPV for predicting eventual ARHI.[119]

Preoperative examination should include measurement of bilateral upper extremity blood pressures and an Allen test. Patients with an incomplete palmar arch with radial artery

dominance should not undergo radial artery–based fistula creation. In those with a questionable Allen test due to skin tone, a handheld continuous-wave Doppler can assess perfusion.[120] Berman et al. showed that only 0.3% of those who had a normal preoperative arterial examination could have been identified by additional physiologic testing and concluded that routine testing is not justified.[121] If patients have a blood pressure differential greater than 20 mm Hg,[121] that extremity should not be used unless the underlying problem can be corrected.

In high-risk patients, operative strategy may be adjusted to minimize the risk of ARHI. Brachial-based accesses are more likely to develop distal ischemia.[102,108,113] Consequently use of the proximal radial artery is preferable,[116] with 89% maturation and 84% 1 year patency with proximal forearm arteries.[122] Alternatively, axillary artery inflow in high-risk patients decreases ARHI, based on the larger capacity and smaller pressure drop across the anastomosis.[123]

Diagnosis

Clinical Presentation: Patients may present with a wide spectrum of signs/symptoms depending upon the severity of ischemia. ARHI may manifest as numbness, burning pain, and severe weakness within hours of access creation.[104] Acute ARHI (<24 hours) is rare but more likely with prosthetics.[124,125] Most symptoms develop over weeks to months[125] and occasionally years after access creation.[126-128] Symptoms range from coolness and paresthesias, to rest pain and weakness. Physical examination reveals a cool extremity, pallor, cyanosis, delayed capillary refill, absent pulses/signals, diminished sensation, weak grip, ulceration, or gangrene. Improvement with access compression confirms the diagnosis and predicts a good response to revision.[129]

Differential includes carpal tunnel syndrome (CTS), venous hypertension, and ischemic monomelic neuropathy. When the clinical picture is unclear, ischemia should be presumed until proven otherwise. The one exception is acute presentation, immediately after access creation, when ischemic monomelic neuropathy (IMN) must be considered.

Diagnostic Testing: Multiple studies support the diagnosis, but none is definitive. These include digital pressure measurement, photoplethysmography (PPG), pulse oximetry, color duplex ultrasound, and angiography (all performed with/without access compression). PPG is simple to perform and is recommended. Most access patients have both a reduction in digital pressure and flow reversal in distal arteries, whereas only a few are symptomatic.[98,106,107] Modaghegh et al. attempted to define clinically relevant thresholds for DBI and pulse oximetry and found that a DBI of less than 0.7 was 100% sensitive but only 73% specific. With respect to pulse oximetry, they identified a threshold of 94% (sensitivity 80%, specificity 92.5%).[130] Many patients have preserved flow at rest and become ischemic only during dialysis. In 16.6% of Berman's series, in digital waveforms flattened only during dialysis.[121] Lazarides et al. utilized the postoperative systolic pressure index (SPI, postoperative forearm pressure divided by contralateral forearm pressure) to identify a group of patients at risk. They found that 14% had mild to moderate ischemic symptoms and an SPI less than 0.4. This group was followed closely, with 50% improving over time, as did the SPI; the remaining patients required revision. An SPI less than 0.5 was predictive of abnormal NCS and indicated significant ischemia. These investigators recommend serial SPI and NCS to identify patients at risk and suggest that the deterioration of NCS should be considered an indication for revision.[104]

Angiography and duplex ultrasound help to determine the mechanism of ARHI (Figure). Inflow stenosis is a factor in 15% to 20% of cases.[103,121,131,132] Therefore angiography should be the first step in intervention and should include imaging the aortic arch to hand (Fig. 179.2). Duplex ultrasound with access flow measurements should also be obtained to determine flow rates—high (autogenous >800 mL/min, prosthetic >1200 mL/min[127]) or low—to facilitate the planning of intervention.

Treatment

Deciding which patients need intervention requires judgment. Transient, mild symptoms[99,133] often resolve within a few weeks[134] and can be managed expectantly with reassessment, warming, and antihypertensive reduction.[135] Patients experiencing ischemic pain with arm activity or during hemodialysis are at greater risk and need closer monitoring. Once severe symptoms are present (progressive numbness or pain, pallor of the hand, diminished sensation, ischemic ulcers, progressive dry gangrene, decreased motor function, or atrophy of the hand muscle), swift intervention is critical.[133] Typically symptoms occur with gradual tissue loss; if this is ignored, however, there is a rapid final deterioration leading to necrosis and gangrene.

The goal of treating ARHI is twofold: symptom resolution and access preservation. These include two basic strategies: access-flow reduction and augmentation of distal arterial flow. Options include banding, revision using distal inflow (RUDI), proximalization of arterial inflow (PAI), distal revascularization with interval ligation (DRIL), and angioplasty. Ligation is a last resort in those with limited life expectancy, severe tissue loss, or a poorly functioning access.

Reduction of Access Flow

Banding or Flow-Limiting Procedures: These procedures entail the creation of a stenosis in the AV access near the arterial anastomosis, which is accomplished via suture plication, placement of a single narrowing tie, or wrapping with a constrictive prosthetic cuff. This alters the relative resistance of the access and the peripheral vascular bed such that a higher proportion of the arterial inflow is directed toward the hand. It can be difficult to determine the precise degree of stenosis that will eliminate ischemia without endangering access patency; consequently results have been variable, both in terms of symptomatic improvement and access preservation (Table 179.1).

Many early series based the degree of banding on intraoperative assessment of distal perfusion without attention to access flow. Odland et al. found 100% symptom resolution with 62% patency at 6 months and 38% at 1 year with banding and PPG monitoring with a target endpoint digital artery pressure of 50 mm Hg or DBI of 0.6.[100] DeCaprio et al. described 11

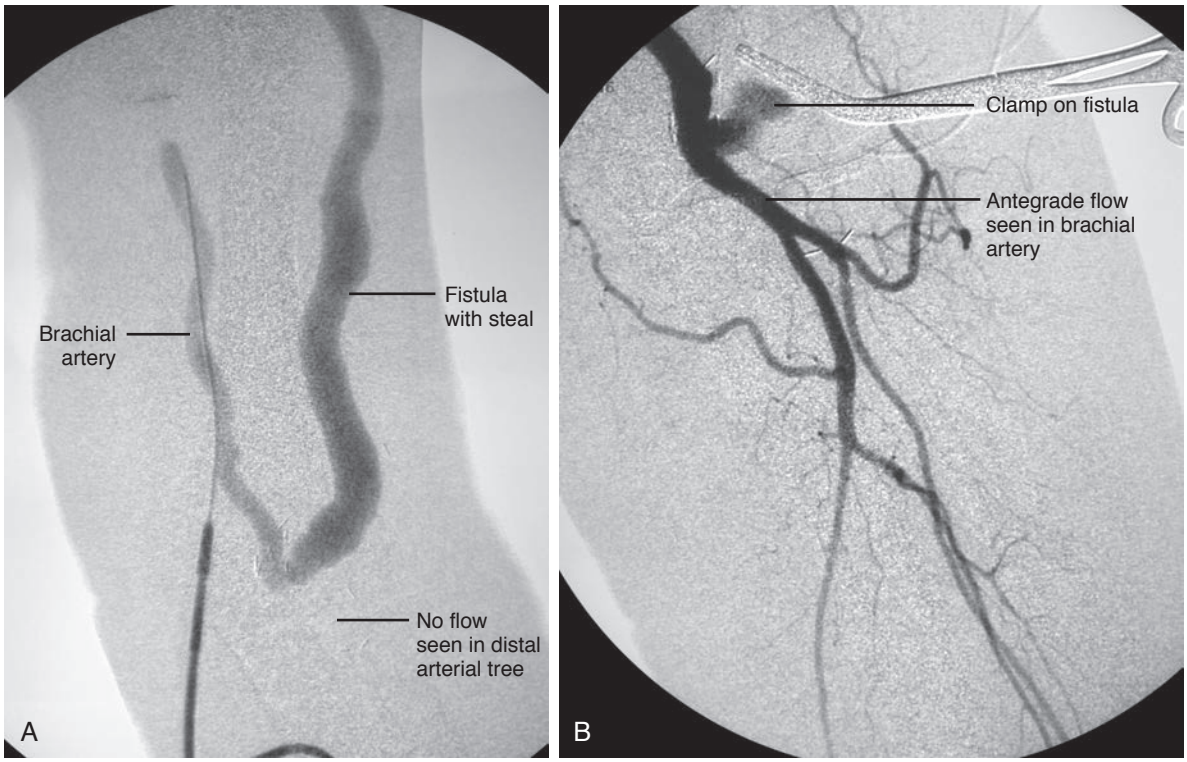

Figure 179.2 Arteriogram of a patient with steal syndrome with and without arteriovenous access compression. Note visualization of the distal brachial artery and forearm vessels with compression.

patients titrated to a pressure of 50 mm Hg with 91% symptom improvement but 91% access loss within a week.[131] Recent studies report superior results when access flow is monitored intraoperatively. Zanow achieved 86% symptoms relief and 84% patency at 1 year.

Although flow monitoring has proven beneficial,[127,136-139] access flow rates appear to be most important in prosthetic grafts. In Zanow's study, 12-month patency rates for autogenous accesses were better than those for AV grafts (91% ± 4% vs. 58% ± 12%; $P < .001$). On final analysis, access flow of 700 mL/min is an important cutoff for maintenance of access patency (38% vs. 74% patency), suggesting the reason for earlier failures with banding.[100,131,145,147]

Despite favorable results using intraoperative physiologic testing and flow monitoring, it is important to realize that anesthesia-induced changes can make these tests inaccurate. Consequently a number of groups now advocate using minimally invasive limited ligation endoluminal-assisted revision (MILLER)[149] for banding. This method uses a 4- to 5-mm endoluminal balloon placed percutaneously as a sizing dowel. A small incision is made near the anastomosis, allowing a suture to be secured around the access with the balloon inflated. Miller and colleagues achieved significant clinical improvement in 89% of 114 patients with an early thrombosis rate of only 4.4%.[145]

Revision Using Distal Inflow (RUDI): RUDI was proposed by Minion et al. in 2005[150] but had been previously described.[151] RUDI involves ligation of the fistula at the arterial anastomosis with reestablishment of flow from a more distal artery via bypass or translocation of a vein side branch (Fig. 179.3). The decision to use ulnar or radial artery is based on quality of the vessel, with preference for supply to nondominant hand. This decreases flow through the access by reducing the diameter of the fistula and taking inflow from a smaller vessel. The native arterial flow is preserved and the fistula rather than the extremity is placed at risk.

Recent case series demonstrate promising results. In a series of 20 patients, Misskey et al. achieved symptom resolution in 90% with 1-year PP and SP of 58% and 84%, respectively.[152] Leake and coworkers reported 89% clinical improvement and 95% access preservation in 19 patients. However, 22% experienced bleeding and 5.6% developed surgical site infection.

Direct Augmentation of Peripheral Flow

Proximalization of Arterial Inflow (PAI): PAI, described by Zanow et al.,[153] involves ligation of the AV anastomosis and conversion of inflow to a more proximal level using a small-caliber (4 to 5 mm) prosthetic interposition (Fig. 179.4). Some degree of flow limitation is imposed by the interposition. Uninterrupted dialysis continues via the vein. This relies on the proximal artery having a larger diameter, higher capacity, and lower pressure drop across the AV anastomosis at similar access flow rates. The primary advantage is preservation of the native artery's continuity.

Zanow et al. reported complete resolution of symptoms in 84% and significant improvement in 16% of their patients. Access PP was 87% at 12 months and 67% at 36 months.[153] In a subsequent series, Thermann and Wollert reported immediate clinical success in 90% and sustained improvement in 82% at 19 months.[154] Patients with severe tissue loss did particularly

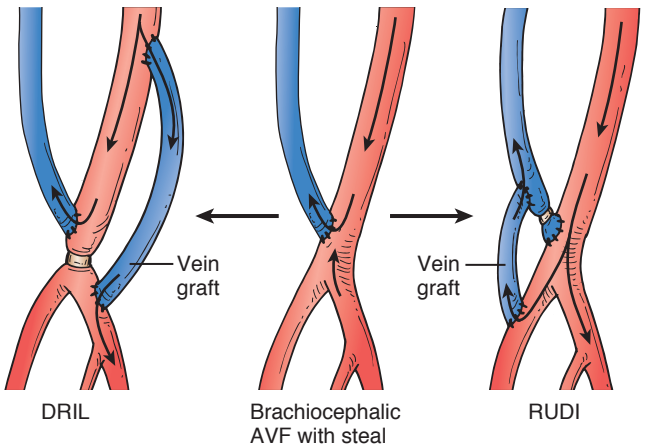

Figure 179.3 The anatomic configurations of the distal revascularization and interval ligation *(DRIL)* and revision using distal inflow *(RUDI)* procedures are illustrated for the treatment of hand ischemia or steal syndrome after an autogenous brachiocephalic arteriovenous access. *AVF*, Arteriovenous fistula.

poorly; 12 patients had 19 access thromboses and 7 required ligation for persistent symptoms.

Distal Revascularization–Interval Ligation (DRIL): DRIL was first described by Schanzer et al. in 1988.[134] Since then multiple publications have reported impressive results[121,147,155-157] and many consider it the procedure of choice.[157,158] DRIL entails the creation of a bypass originating proximal to the access anastomosis and terminating distal to it, with ligation of the artery distal to the anastomosis (see Fig. 179.3). This prevents retrograde flow from the distal vessels and creates a low-resistance pathway for blood to reach the peripheral vascular bed. Recent data suggest that the pressure augmentation from ligation contributes only 10% of the benefit of the DRIL[159] and may be avoided if circulation is adequately improved with bypass. An area of reduced pressure called a pressure sink exists in the artery just proximal to the anastomosis.[160,161] This exists because the large capacitance of the venous outflow causes pressure to

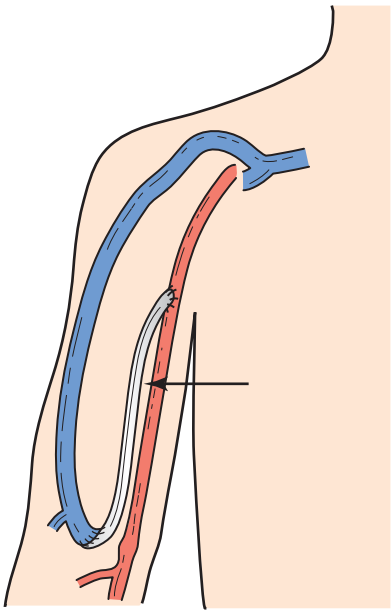

Figure 179.4 Proximalization of arterial inflow. The original arteriovenous access anastomosis.

fall rapidly, reaching central venous pressure within 1 cm of the anastomosis. Locating the origin of the bypass 7 to 10 cm above the inflow anastomosis avoids this pressure sink.

Long-term results are excellent. Schanzer et al. described 13 of 14 patients with complete recovery,[99] 82% 1-year access patency, and 100% bypass patency. Berman et al. described 21 patients with limb salvage and access patency of 100% and 94%, at 18 months.[121] Knox et al. found 90% resolution of ischemia and 15 of 20 digital ischemic lesions healed[162]; 1-year access patency was 83% and bypass graft patency was 80% at 4 years. Aimaq et al. reported a 5-year access patency of 67.1% for autogenous, 40% for prosthetic, and 97% for arterial bypass grafts.[157]

Drawbacks to DRIL include its invasiveness and perioperative mortality rates as high as 6.8%,[147] with wound complication rates of 9% to 19%.[152,155,156,162] ARHI patients are particularly frail, with a 1 year mortality of 30% in multiple series[121,155,156]—higher than that of typical ESRD patients,[163] reflecting the presence of advanced comorbid conditions. The second drawback is dependence of the hand on the bypass. However, long-term bypass patency is excellent and, in rare instances of occlusion, limb salvage is achievable via either a repeat bypass or access ligation.[155,156,162,164]

Distal Radial Artery Ligation (DRAL): Flow reversal is significant in a subset of patients with radial-cephalic AV accesses. In these cases, retrograde flow through the intact palmar arch results in inadequate digital flow. This is palmar arch steal syndrome (PASS), which is treated with ligation or coil embolization of the distal radial artery.[165-167] It is critical to evaluate patency of the ulnar artery and palmar arch prior to ligation.[166]

Treatment Selection: Treatment should be individualized based on life expectancy, severity of disease at presentation, access utility, access flow rate, future access options, and availability of conduit. RUDI, DRIL, and PAI all have good outcomes but require more extensive surgery, with morbidity and mortality exceeding those of ligation or banding.[147] Consequently the latter are better suited to patients with limited life expectancy. If a patient is healthy enough to warrant access salvage, the next factor is the severity of ischemia and risk of limb loss. If the patient has extensive tissue loss, a more definitive solution is needed. DRIL is ideally suited to this situation,[157,158,168] whereas banding is best avoided. Banding is most likely to require repeated interventions to be effective.[132,147] In extreme cases, ligation may be the best option for limb salvage.

Access-specific factors are also important. Although most cases of ARHI occur in association with high access flow rates (autogenous >800 mL/min, prosthetic >1200 mL/min),[127] flow rates are normal or low in up to one-third of patients.[108,135] Flow reduction such as banding and RUDI are suited to high-flow ARHI. However, when ARHI occurs with low or normal flow, the underlying pathology is more likely inadequate collateral circulation or atherosclerotic disease. These conditions are best treated via revascularization (DRIL, PAI, or angioplasty). Availability of autogenous conduit also affects choice of intervention. Both RUDI and DRIL traditionally require autogenous conduit, whereas PAI is typically uses PTFE.

VENOUS HYPERTENSION

Venous hypertension is a significant issue because it impacts access patency and function and causes disabling edema. Most cases are secondary to central venous stenosis (CVS) or occlusion.[169,170] The prevalence of CVS is unknown, as many patients have adequate collateral flow and consequently remain asymptomatic. CVS has been identified in 17% to 26% of patients undergoing venography for failing access or arm edema.[171-174] CVS threatens the current access and risks loss of the extremity for future access. Prevention, early recognition, and definitive treatment are crucial.

Etiology: CVS is primarily caused by catheters. Despite the efforts of the Fistula First Catheter Last Workgroup Coalition, 80.2% of patients begin dialysis with catheters.[175] Longer catheter duration is correlated with stenosis,[176,177] but catheters utilized for less than 1 month are also associated with CVS.[178-180] Subclavian access has the highest rate, 40% to 50%, whereas IJ is less than 10%.[181-183] The presumed etiology is chronic endothelial trauma due to catheter motion with cardiac and respiratory cycles.[181,184] In resected specimens, the stenosis contains fibrous tissue and neointimal fibromuscular hyperplasia.[185] The same process occurs with implantable cardiac rhythm devices[186,187]; however, only 7% to 10% of ESRD patients have such devices.[188,189] Caution should be exercised in placing access ipsilateral to cardiac devices with intravenous wires.

Although catheters account for most CVS, up to 10% of CVS occurs without catheter use.[190,191] The exact mechanism is unclear; however, is likely due to increased blood flow, natural anatomic narrowing, and valves. In a series of 30 CVS, Glanz et al. noted that most occurred in the subclavian vein between clavicle and first rib or in the axillary vein where it is compressed by chest wall during abduction.[173] Morosetti et al. used

intravenous ultrasound (IVUS) to demonstrate hyperplastic venous valves in a patient with no previous catheter use and severe stenosis at the distal cephalic arch.[192] This narrowing causes turbulent blood flow and venous deformation, which causes intimal smooth muscle cell proliferation in in vitro models.[193]

Diagnosis

Clinical Presentation: Presentation is dictated by degree of collateral flow, site of obstruction, and status of peripheral venous valves. Patients with robust collaterals and competent valves may be asymptomatic.[176] Consequently it is extremely important to maintain a high index of suspicion in considering access creation, particularly with a history of prior catheters. Often the only physical signs are scars and dilated shoulder collaterals (Fig. 179.5). In many cases, declining access function and prolonged needle-hole bleeding are the only indications of CVS.

Symptomatic venous hypertension may manifest immediately after access placement or in a delayed fashion.[172] The typical presentation is swelling, tenderness, and pain. However, severe cases may cause cyanosis, stasis, and ulceration.[194] Some edema is normal after construction of a new AV access. The magnitude varies depending on configuration, with more proximal accesses causing more swelling that typically subsides within a few weeks. Persistent swelling beyond 1 to 2 weeks requires additional assessment, as up to 25% will be associated with central stenosis.[172]

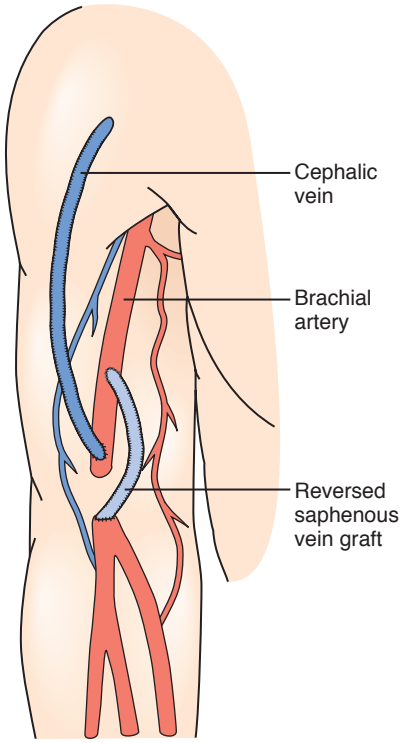

Figure 179.5 Diagram of brachiocephalic arteriovenous access and brachial artery bypass with interval brachial artery ligation and division. (Redrawn from Knox R, Berman SS, Hughes JD, et al. Distal revascularization–interval ligation: a durable and effective treatment for ischemic steal syndrome after hemodialysis access. *J Vasc Surg*. 2002;36:250–256.)

Atypical venous hypertension can occur. Pillai et al. reported bleeding esophageal varices from SVC occlusion related to a HeRO graft.[192] Kiernan et al. reported increased intraocular pressure related to a fistula in a patient with brachiocephalic vein occlusion, retrograde flow in the jugular, inferior petrosal sinus, cavernous sinus, and superior ophthalmic veins, which resolved with ligation.[195] Samaniego et al. described venous congestive encephalopathy and facial swelling, which resolved with ligation, in a patient with innominate occlusion, hypoplastic contralateral transverse sinus, and engorged cerebral veins.[196]

Diagnostic Testing: Duplex ultrasound is recommended for patients with a history of proximal vein cannulation, particularly subclavian lines.[120] However, more proximal subclavian or innominate lesions may be inadequately visualized.[197] KDOQI guidelines mandate venography before the creation of a permanent access in patients with prior subclavian lines.[198] If central venous occlusion is confirmed, placement of AV access in the ipsilateral limb should be avoided.

Duplex is preferred for early-onset edema after autogenous access creation to avoid cannulation of the new access, damage to the thin-walled vein, or bleeding from unincorporated prosthetic graft. However, duplex will not identify central stenoses.[120,199,200] Patients with persistent edema or edema developing after 2 weeks should undergo venography. Venography, while the gold standard,[198] can underestimate the degree of stenosis. Extensive collateral vessels are sometimes the only indication of an underlying lesion. IVUS should be used as an adjunct in those with high clinical suspicion despite absence of an obvious stenosis.

Treatment

Management is controversial. Ligation is well tolerated and provides symptomatic relief but sacrifices a functional access and leaves the ipsilateral extremity unavailable for future access. Given the finite number of access options, attempts at salvage should be made when possible.

Endovascular Intervention: KDOQI recommends percutaneous transluminal angioplasty (PTA) as primary therapy (Fig. 179.6).[201] However, the decision to intervene should not be made lightly and should only be made for symptomatic patients. Histologic analysis demonstrates that recurrent venous lesions have more aggressive neointimal hyperplasia compared with primary lesions.[202] Consequently the natural history of central venous angioplasty and stenting is characterized by frequent restenosis and reintervention. When Renaud et al. implemented a policy of withholding treatment for asymptomatic high-grade (>70%) CVS, they found better patency than with treatment of symptomatic cases without any decrease in access patency.[203]

PTA is the treatment of choice. Immediate success is 82% to 89%,[173,174,204] but long-term outcomes are poor. PP rates drop to 23% to 55% at 6 months, and by 12 months patency is 12% to 43%.[173,174,204,205] With multiple repeat interventions, the APP improves to 64% to 82%.[204,206-208] This results from more elastic recoil in central veins than peripheral veins.[209]

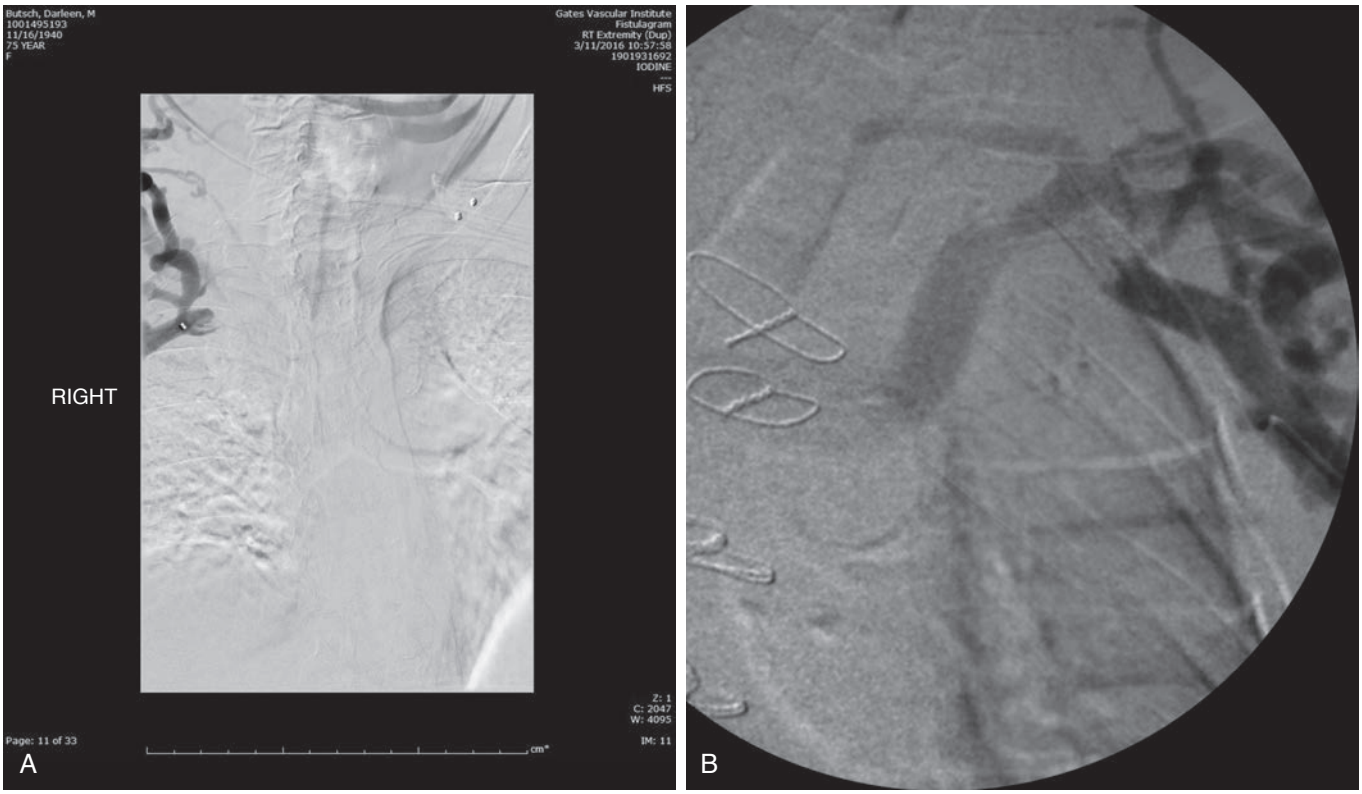

Figure 179.6 Distended collateral veins on physical examination and fistulagram with central occlusion/stenosis.

Kovalik et al. have shown that degree of elastic recoil predicts response to angioplasty. In their series, lesions with greater than 50% recoil had poor long-term patency (2.9 months) but improved with stenting (8.6 months). If recoil was less than 50%, angioplasty results were better (7.6 months) but worse after stenting (4.2 months). They concluded that elastic lesions are more likely to benefit from stenting and that stents should be avoided in nonelastic lesions.[210]

Multiple studies have examined benefits of primary and selective stenting. Stenting increases immediate technical success from 90% to 100%.[171,204,211,212] However, 1-year PP ranges from 11% to 56%, with the majority less than 25%.[171,204,205,207,208,212] Bakken et al. compared PTA with stenting, finding equivalent 1-year PP (29% PTA; 21% stenting) and APP (73% PTA; 46% stenting); therefore their study suggested that stenting does not improve patency.[204] Maya et al. reported 1-year PP 19% for stents ($n = 23$) and 20% for PTA ($n = 32$). Although results were equivalent, the investigators concluded that stents were advantageous in elastic lesions because selective stenting would skew results in favor of PTA.[207]

The most frequent cause of stent failure is intimal hyperplasia, which is particularly robust in the hemodialysis outflow tract.[202] Consequently several groups have proposed stent grafts. Early results are promising, with 12-month PP 40% to 67% and APP 80% to 86%.[213-216] Nevertheless stent grafts should be used with caution in central veins as they have the potential to cover major venous confluences and collaterals. Verstandig et al. reported exclusion of the internal jugular vein in 77%.[214] When considering stent grafts for CVS, the benefit of improved patency must be weighed against potential loss of future dialysis catheter insertion sites.

A few technical points: High-pressure, less-compliant balloons 1 to 2 mm larger than adjacent veins with inflation times greater than 2 minutes should be used. Flexible self-expanding, stents are preferable. Stents should be extended more peripherally than centrally to achieve stability and prevent central displacement. Placement of a guidewire in the IVC prevents stent embolization to the heart or pulmonary artery in the event of undersizing and facilitates removal by snare when necessary. There may be a role for drug-coated balloons (DCBs); however, data are limited. Massmann et al. recently reported a small series with custom-made paclitaxel-coated balloons to treat 10 patients. DCBs demonstrated improved freedom from target lesion revascularization (5 months vs. 10 months, $P = .025$).[217] Stenting remains the best adjunctive therapy for residual stenosis and early (<3 months) recurrence. Although most cases of CVS are due to intrinsic lesions, a subset are due to extrinsic compression.[190,218,219] These will have a poor response to endovascular therapy and are prone to stent fracture and collapse. Therefore it is crucial to maintain a high index of suspicion, particularly for lesions at the costoclavicular junction.[219]

Open Surgical Techniques: Surgical treatment has substantial morbidity and is reserved for patients untreatable with angioplasty/stenting.[201] Open reconstruction provides symptom relief and 1-year patency of 75% to 88%.[220-224] Techniques include direct reconstruction, decompression, and bypass. Bilateral venography is essential to planning. Surgical repair was first described with a spiral saphenous vein graft,[225] later

popularized by Doty et al., with 87.5% patency at 23-year follow-up (mean 10.9 years).[226] In modern series, CVS is most commonly managed via prosthetic bypass, with outflow including right atrium, femoral vein, saphenous vein, ipsilateral internal jugular vein, and contralateral jugular vein.[227] Another option is jugular turndown in which the IJ is divided high in the neck and anastomosed to the ipsilateral subclavian vein.[228] This frequently requires clavicle resection and precludes future use of the IJ for temporary access. In the setting of a high-flow access, banding can be done in addition to improve the inflow-outflow balance.[190,229,230] El-Sabrout and Duncan described prosthetic axillary–right atrial bypass[231] with 89% symptom resolution and 100% graft patency at 1.5 to 52 months (mean 15.4 months). Sottiurai et al. performed brachial or axillary to IJ bypass using 8- to 10-mm PTFE grafts[223] with 100% symptom resolution and 86% graft patency at 31 months (range 10–87). Grimm et al. performed axillary-femoral bypass with 8- to 10-mm ringed PTFE.[230] Upper extremity swelling improved in all; however, three patients developed lower extremity swelling and one required fistula ligation.

Arteriovenous access–related venous hypertension is a particularly challenging problem and is expected to become more common as the dialysis population grows. Angioplasty and stenting remain first-line, but open surgical techniques have an important place in management and should be considered prior to abandoning a functional access.

NEUROPATHY

Approximately two-thirds of patients have preexisting peripheral neuropathy at initiation of dialysis.[232-234] Diabetes is predictive for development of neuropathy after access creation.[235] Specific access-related neuropathy has four grades of severity[2]:

Grade 0: Asymptomatic

Grade 1: Mild—intermittent changes (pain, paresthesia, numbness with sensory deficit)

Grade 2: Moderate—persistent sensory changes

Grade 3: Severe—sensory changes, progressive motor loss (motion, strength, muscle wasting)

Types of Neuropathy and Management

Neuropathy is categorized into three groups in CKD: (1) systemic disease neuropathies, which develop gradually and involve painless, progressive, symmetrical sensorimotor polyneuropathy[168]; (2) mononeuropathies, related to compression, compartment syndromes, and entrapment; and (3) ischemic monomelic neuropathy, which occurs acutely after AV access creation.

Systemic Disease Neuropathy

Diabetic Polyneuropathy: In the United States, 46% of dialysis patients are diabetic (Dialysis Outcomes and Practice Patterns Study [DOPPS]). Diabetic neuropathy with large fiber demyelination typically affects lower extremities with numbness, paresthesias, and pain. Ndip et al. found that 79% of diabetic dialysis patients with foot ulceration have peripheral neuropathy.[236]

Uremic Polyneuropathy: Uremia is the most common cause of neuropathy in dialysis patients; it is present in 50% to 70% and is more common in men.[237,238] It improves with hemodialysis and may resolve with transplantation.[238-241] Axonal degeneration with secondary segmental demyelination is identified and is most severe distally.[237,242-245] Hyperkalemia affects symptom severity.[246] Physical findings include impaired vibratory sensation in the lower extremities, loss of deep tendon reflexes in the Achilles tendon, and loss of distal touch and position sense. It is important to be aware of these neuropathies considering access-related neurologic changes.

Compressive Mononeuropathies

CTS is 10 times more frequent in hemodialysis patients.[247] Warren and Otieno first reported CTS in a hemodialysis patient in 1975,[248] and numerous studies since have shown an increased prevalence, 0.6% to 30%.[249] Time since hemodialysis initiation is associated with CTS, 46% to 50% at 5 years and 50% at 10 years.[250-252] The etiology of increased risk is not understood but thought to be partially due to serum beta$_2$-macroglobulin deposition as amyloid in periarticular tissues, a molecule not cleared by hemodialysis.[249,251,253,254] A more recent study identified 12 patients with early onset CTS after access creation and without amyloid deposition but with venous hypertension.[255] These investigators suggested that venous hypertension with congestion led to median nerve compression and chronic irritation of the carpal ligament with resultant thickening. There are conflicting data as to whether access side impacts on CTS development.[251,256] Systemic factors include uremia, expanded extracellular fluid volume causing irritation of the ligament, and nerve ischemia.[186,187] Pseudoaneurysms and hematomas can also cause nerve compression.[257] Symptoms include tingling dysesthesias in the median nerve distribution, worse at night or during dialysis.[237] Exacerbation with dialysis is related to relative ischemia with venous hypertension and tunnel edema.[251,258] Rapid improvement is expected with early intervention.[259,260] Once motor or sensory deficits develop, symptoms respond more poorly.[261] Ulnar nerve compression at the elbow and wrist is also seen in hemodialysis patients.[249,262-264] Symptoms include pain or sensory changes in the ulnar aspect of the hand, weakness of the adductor pollicis, and weakness with finger adduction and abduction.

Ischemic Monomelic Neuropathy

IMN is rare, occurring in 0.5% of access creations[265-268] and resulting from acute vascular compromise of neurologic structures.[269] Bolton initially described IMN,[270] with Wilbourn coining the term.[271] Delayed recognition/intervention leads to irreversible, profound neurologic deficits in the median, radial, and ulnar nerves.[265] Most cases occur in older diabetics with preexisting peripheral neuropathy, peripheral arterial disease, and brachial-based access. It has never been reported in accesses originating distal to the brachial artery.[269,272,273]

Presentation can be confounded by anesthesia. Within hours of surgery, patients develop acute pain, weakness, or paralysis of the hand and forearm muscles, often with prominent sensory loss and dysesthesias. The hand is warm, with a palpable pulse

or audible signal in distal radial and ulnar arteries.[237,269,272-274] Pain is out of proportion to clinical findings, which differentiates IMN from ARHI. Digital pressure index is higher than 0.3.[275] Diagnosis is frequently delayed, with symptoms attributed to anesthesia, patient positioning, or surgical trauma.[275] Patients with acute limb pain, weakness, and sensory loss in the immediate postoperative period should be assessed for direct nerve injury or compression from hematoma. Most nerve injury from anesthesia occurs more gradually during days to weeks and is more focal with regard to symptoms.[276]

IMN is related to preexisting marginal perfusion to nerves, compromised by additional flow diversion by the access.[275] Prevalence of brachial artery involvement suggests that IMN is due to the inability of this vessel to vasodilate and compensate for increased access demands. The resultant low-level ischemia does not translate to muscle or skin viability issues, nor does it present as ARHI. However, it results in severe irreversible ischemic nerve injury if not promptly treated. The ischemic threshold of peripheral nerves is lower than that of muscle.[266] Dyck et al. found the antecubital area to be a "watershed" for the vasa nervorum of the three nerves of the upper limb. Electrophysiologic studies support the concept of nerve ischemia as the etiology. Nerve conduction studies done 1 hour after AV access creation demonstrate acute, reversible, changes with motor conduction block and conduction slowing due to myelin retraction from the node of Ranvier.[269] Axonal loss of motor and sensory nerves occurs late, consistent with degenerative types of polyneuropathy, and sensory amplitudes are more severely affected.[266] Evidence of denervation is more severe distally, with a proximal gradient.[275] Because IMN is a form of ARHI limited to the nerves, treatment includes access ligation or emergent augmentation of flow. Even with rapid intervention, paralysis and pain may be only partially resolved or may become permanent.[273-277]

CARDIOPULMONARY COMPLICATIONS

Cardiovascular complications, including CHF, pulmonary hypertension (PH), and coronary steal remain the leading causes of morbidity and mortality in patients with ESRD. Patients with CKD also have accelerated atherosclerosis related to comorbidities such as hypertension, diabetes mellitus, uremic dyslipidemia, and increased asymmetric di-methylarginine (ADMA), a nitrous oxide synthase inhibitor. AV access construction itself is associated with an increased risk of cardiovascular death.

Congestive Heart Failure: CHF is present in approximately one-third of new dialysis patients.[278] Associated factors include chronic volume overload, arterial hypertension, cardiovascular calcification, valvular disease, increased arterial stiffness, anemia, inflammation, access flow volumes, and arrhythmias.[279] High access flow (Qa) may predispose to CHF in patients with marginal cardiac function. Left atrial diameter and CO increase within 3 to 14 days of fistula creation.[280] LV mass and left atrial area also increase significantly within 3 months.[281] Abassi et al. found a 40% increase in CO and suggested that a Qa/CO ratio greater than 0.3 increases the risk for high-output cardiac failure.[282] The Qa/CO ratio is significantly higher in patients with upper arm access in comparison with forearm access, and 1 in 10 patients with upper arm access are in the danger zone (Q/CO >0.3) for developing CHF.[283] Not all studies have found a relationship between AV access and CHF. In a review of the U.S. Renal Data System morbidity and mortality data, no association was seen between AV access and CHF or acute coronary syndrome as compared with catheter access.[284]

Treatment includes banding, ligation, or restriction of flow if the access is determined to contribute. Some advocate decreasing access flow to less than 300 mL/min, while NKF-KDOQI provides no guidelines. Ligation leads to complete loss of access, and banding may jeopardize the access. Inflow reduction by distalization for high-flow accesses (>1600 mL/min) was proposed by Chemla, who demonstrated 77% access patency and 100% CHF symptom resolution with a decrease in CO from 8 ± 3.1 to 5.6 ± 1.71 L/min.[285]

Coronary Steal Syndrome

The internal mammary artery (IMA) is frequently utilized in coronary revascularization. However, in patients with ipsilateral AV access, the access may steal from the coronary circulation. Proximal subclavian stenosis predisposes to coronary steal. A high-flow access without inflow stenosis may lead to coronary steal. CTA is recommended to assess the subclavian artery prior to coronary reconstruction and to avoid potential complications. Kato et al. demonstrated retrograde flow in the IMA with a high-flow fistula by angiography.[286] Minami found correctable reversal of flow by fistula compression at coronary revascularization and addressed the situation by using the IMA as a free graft.[287] Feldman et al. compared patients with access ipsilateral and contralateral to IMA bypasses. They found risk of a first cardiac event greater in patients with ipsilateral access (HR 2.92, $P = .008$) and a trend toward higher mortality with ipsilateral access.[288] Cuthbert et al. found that 28% of patients with ipsilateral access developed clinical or physiologic evidence of malperfusion while on hemodialysis and concluded that access ipsilateral to IMA bypass should be avoided.[289] If coronary steal is detected in a limb with ipsilateral AV access and a patent IMA graft, evaluation of the subclavian artery is mandatory, as correction of stenosis may result in symptom resolution without access sacrifice. Flow directionality can also be assessed by duplex ultrasonography prior to IMA harvesting.

Embolization of Stents to Heart and Pulmonary Arteries

Physiologic variations in vein wall diameter, stent undersizing, and lack of adherence of the stent to the wall may lead to embolization. Complications include tricuspid regurgitation, acute myocardial infarction, pulmonary infarction, and cardiogenic shock from embolization to the right atrium, right ventricle, and pulmonary arteries.[290]

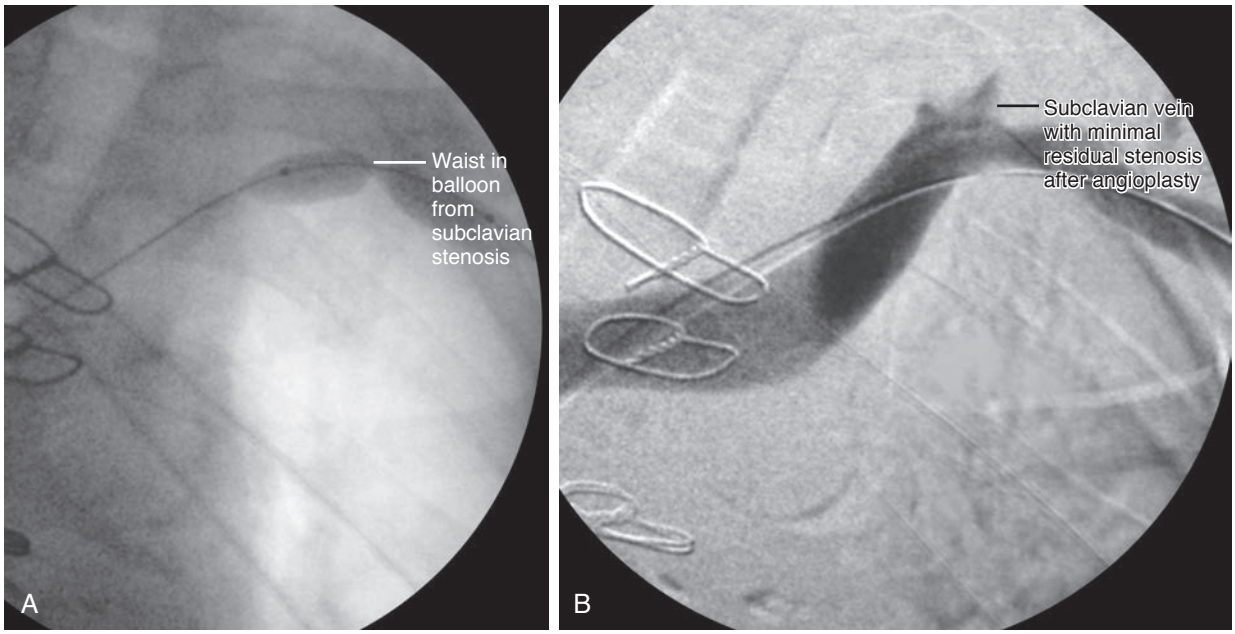

Figure 179.7 (A) Angioplasty of subclavian vein stenosis in a patient with an ipsilateral autogenous AV access and venous hypertension. (B) Completion venogram after subclavian vein angioplasty that demonstrated no residual stenosis.

Pulmonary Hypertension

PH is a progressive, fatal disease with a significant decrease in survival (mortality 30.8% vs. 3.5%) associated with increased CO, which increases in prevalence soon after access creation (40%) and regresses after access closure.[282]

PH is precipitated by volume overload, left ventricular failure, arterial hypertension, increased flow from the access, metabolic changes, and potentially recurrent embolization from the access and from access salvage procedures. Patients with CKD have acquired endothelial cell dysfunction, reducing their ability to tolerate the elevated CO associated with access creation. Nakhoul et al. found elevated endothelin in all dialysis patients, with 48% having PH.[291] Those with PH had greater CO than those without. Temporary access closure resulted in a decrease in CO and systolic pulmonary artery pressure (PAP), suggesting that increased venous return was a factor.

Havlucu et al. found a correlation with systolic PAP and arteriovenous fistula (AVF) flow by Doppler ultrasonography, reversible with AVF compression from 36.8 ± 10.7 to 32.8 ± 10.5 mm Hg.[292] Yigla et al. found PH in 37% of AV access patients, in no peritoneal dialysis patients, and in 1 patient with renal insufficiency. CO was also significantly higher—6.9 L/min versus 5.5 L/min—in patients on hemodialysis. He reported that PAP increased in 66% of patients after beginning hemodialysis and concluded that long-term hemodialysis and AV access creation are associated with PH by affecting pulmonary vascular resistance and CO. Recurrent embolization appears less important[293] Harp evaluated the relationship of access thrombectomy and found PH in 52% of all dialysis patients after at least one thrombectomy versus 26% in patients without ESRD. ESRD was associated with a 2.7-fold increase risk of PH, but thrombectomy itself was not a factor.[294] Hsieh et al. evaluated the impact of repetitive endovascular thrombectomy in a prospective fashion and were unable to demonstrate any correlation.[295]

Treatment includes anticoagulants, diuretics, digoxin, oxygen, and calcium antagonists. Vasodilators and antiproliferative agents may also be utilized. Access ligation or flow reduction should be considered in patients with a poor response to medical management. Alternative modes of dialysis or transplant should be considered. Patients with underlying severe heart failure or preexisting PH should be considered for alternative access or for catheter or peritoneal dialysis rather than AV access creation.

SUMMARY 2363

INTRODUCTION

Vascular injury is a major cause of death and disability in society, with trauma being the principal etiology. Despite the establishment of mature trauma systems to improve delivery of prompt and effective treatment, as well as innumerable technological advances with improved clinical outcomes and expanded application of data collection systems, the burden of traumatic injuries continues to increase in society. Unfortunately, there has been a progressive increase in trauma-related deaths over time, with an overall increase of 21% between 2000 and 2010.[1] In the United States, trauma is the number one cause of death for patients between the ages of 1 and 46, and is the third highest overall cause of mortality across all age groups.[1] As of 2014, traumatic injury by any mechanism was the number one cause of years of potential life lost at 31.7% and accounted for nearly 200,000 deaths overall.[2] Certainly, mortality from trauma is complex, with outcomes predicated on the extent and nature of sustained injuries. Nonetheless, hemorrhage is overwhelmingly the agent of death in most instances. From a military perspective, vascular injury with associated hemorrhage is the leading cause of potentially preventable wartime mortality, despite improved strategies aimed at rapid transport, point-of-injury hemorrhage control, and early operative intervention.[3,4] For both civilian and military environments, long-term disability from limb loss, chronic pain, and posttraumatic stress disorder impact many

victims, adding to the societal burden incurred from vascular trauma.[5]

While our ability to diagnose and treat vascular injuries has substantially improved over time, our overall impact on this incidence and prevalence has been lacking. This dismal reality underscores the complex nature of traumatic injury and the myriad factors that influence its incidence in society. Although applied rigorously to many disease processes that impact public health, an epidemiologic approach to the characterization and management of traumatic vascular injury has not been extensively explored. According to the World Health Organization, epidemiology is defined as the **study** of the **distribution** and **determinants** of **health-related states or events** in **specified populations**, and the **application** of this study to the control of health problems. While traditionally applied to the study of communicable and noncommunicable disease processes, epidemiologic principles can be applied to the study of any process that impacts the health of a population, including vascular injury.

An epidemiologic approach to vascular injury has several potential benefits, particularly as it relates to civilian trauma. At a national level, elucidating the various socioeconomic, geopolitical, and cultural factors influencing trauma can serve as a basis for broad public health initiatives, policy change, and other efforts aimed as mitigating the impact of trauma on at-risk populations. Additionally, the application of epidemiologic principles to vascular injury aims to more accurately classify and risk-stratify various injury patterns through improved data gathering and scoring methodologies, to assess for local and regional differences in terms of volume and case mix, and to track changes over time. Through the recognition of regional differences, these metrics can serve as a vehicle for change at the institution, trauma system, and regional legislative levels.

The purpose of this chapter is to provide a framework for understanding the protean factors that influence vascular injury in society from an epidemiologic standpoint. Providing a historical context, with perspective from the transformative influence of military trauma over the past century, will serve to highlight changes over time affecting the broader delivery of trauma care. Additionally, contemporary efforts employed to characterize the natural history of vascular injury and track outcomes, particularly specific injury patterns, will be explored.

The Origins of Vascular Injury Management

Major vascular trauma commonly manifests with hemorrhage, and, arguably, the initial principles of surgical practice evolved around the control of bleeding. The earliest reported description of vessel injury management came in the 2nd century, where Galen explored techniques of vessel ligation. However, the knowledge was not applied in practice until the 16th century, when a French military surgeon, Ambroise Páre, resurrected this lost knowledge.[6] Beyond this timeframe and for the next 400 years, vascular injury management was limited to major amputation and vessel ligation.

However, beginning in the late 19th and early 20th centuries, novel techniques to directly repair vessel injuries began to emerge. In 1902, a French surgeon named Alexis Carrel popularized techniques for arterial anastomosis, facilitating countless subsequent innovations in multiple surgical disciplines. This work would later earn him the Nobel Prize in Physiology or Medicine in 1912.[6] Additionally, new medical techniques and principles, such as antisepsis, antibiotics, and improved anesthetics, facilitated a widespread revolution in the management of vascular injury. The experiences reported from the major modern conflicts, starting with World War I, provide a highlight of the evolution and key milestones in vascular trauma management. Table 180.1 provides a summary of the reported wartime experiences and outcomes, including the overall and treatment-related amputation rates. Despite growing experience with vascular repair, the techniques for vascular anastomosis and interposition grafting by the turn of the century, widespread application of these techniques was lacking, likely due to insufficient training, equipment, and the high incidence of complications.[6] Additionally, infrastructure to facilitate the timely diagnosis and delivery of definitive treatment was not well established, negating the feasibility of limb salvage efforts (Fig. 180.1A).

Evolution Through Military Conflict

The incidence, nature, and management of vascular injury, and in fact all aspects of trauma, are often described within the framework of major periods of conflict or war. The sheer volume and severity of trauma associated with combat provides a unique opportunity to study the natural history of vascular injury patterns, create novel surgical techniques, and implement systemic change aimed at the mitigation of risk. However, the changing nature of warfare over time inherently influences the incidence, severity, and distribution of vascular injury patterns, requiring ongoing evolution of our techniques and practices. Providing a historical framework for the evolution of wartime vascular injury management allows for the understanding of the contemporary epidemiology, natural history, and management of vascular injury in both modern conflict, as well as within the civilian realm.

A classic paper by DeBakey et al. characterizes the vascular injury burden during World War I and II, noting an incidence of vascular injury during both wars of approximately 1%. Of the 2471 arterial injuries documented during World War II, only 81 underwent attempted repairs, with an amputation rate of 36%. In 40 patients, an attempt was made to repair larger arterial disruptions using vein interposition grafts; unfortunately, the amputation rate was 50% for this cohort. There was overwhelmingly a routine posture toward ligation of vessels in the majority of patients. Although this practice was understood to be less than ideal, it was deemed to be necessary given resource constraints of this era.[7]

The Korean War experience beginning in 1952 resulted in an increased incidence of vascular injuries at approximately 2% of all casualties relative to previous conflicts. This may reflect improved evacuation methods during this conflict utilizing rotary wing aircraft, increasing the number of patients with vascular injuries surviving to definitive surgical therapy. There was a paradigm shift in the management of vascular injuries witnessed during this era, with 88% undergoing an attempt at

TABLE 180.1 Epidemiology of Combat-Related Vascular Injuries, Management, and Amputation Rates

Conflict	No. of Injuries	Incidence (%)	Philosophy	Amputation Rate (%)	Attempted Repair[a]	Method of Repair	Incidence of Repair Type (%)[b]	Post-Repair Amputation Rate (%)
World War I Makins[123]	1202	0.4	Ligate artery and vein (even if uninjured)	19-70[c]	39 (3.2%)	Ligation artery Ligation artery and vein Lateral suture	57 40 3	28 20-90 20
World War II DeBakey et al.[7]	2471	0.96	Repair only minor injuries, no routine vein ligation	49	121 (5%)	Ligation Lateral suture Primary anastomosis Vein graft	66 3 0.6 1.6	50 35 50 58

[a]Excluding injuries managed with initial ligation.
[b]Totals may not equal 100% because of cases that were uncategorized or labeled "other."
[c]The widely reported WWI amputation rate of 19% (Makins) included up to 70% nonacute lesions, and the actual amputation rate based on smaller series appears to be 45%-70%.
[d]Wide use of homografts and reported amputation rates of 33% with arterial graft versus 12% with vein graft.
[e]Among 523 vascular injuries in 497 patients from Dua et al.

primary repair/anastomosis (60%) or interposition graft (27%).[6,8] While early reconstruction strategies employed cadaveric femoral artery as an interposition graft conduit,[9] this was largely abandoned after some time due to an increased failure and amputation rate (33%) compared with vein grafts (12%).[8] Several more comprehensive reports on successful arterial repair performed during the Korean War followed, including classic papers from Colonel Carl Hughes, which gained the attention of the Office of the Army Surgeon General.[10-12] Hughes demonstrated an impressive reduction in the amputation rate among 269 repairs—from 40% in World War II to 13% during the Korean War. While improvements in casualty evacuation during the Korean War were achieved, significant time delays and resuscitation requirements remained the primary Achilles heel of successful vascular injury management.[10] Despite the increased surgical capabilities brought to bear in the management of vascular injury during this time frame, the overall burden of vascular injury and its effect on mortality remained obscure.

The Vietnam War ushered in several significant advances in vascular injury management. Arguably the most important achievement of the era was the creation of the Vietnam Vascular Registry, which provided the ability to characterize injury patterns and outcomes following intervention. Rich et al.[13] published landmark reports of the first 500 and 1000 patients, documenting the preference for attempted repair in the majority (93%) of injuries and describing longer term repair patency and amputation rates. In total, this registry captures nearly 10,000 vascular injuries in over 7500 injured warfighters.[6] Another key accomplishment was the increased emphasis on routine repair of venous injuries as a vital component of limb salvage strategies, albeit controversial.[14,15]

For decades to follow, the vascular injury experience of these previous wars was thought to be unapproachable with regard to the duration of conflict and the number of injuries. With more than 8000 deaths and approximately 50,000 combat-related injuries in more than a decade of modern warfare (http://www.icasualties.org), the Global War on Terror (GWOT) has proved to be a formidable and sustained military campaign. During this conflict, modern advances have allowed a concerted effort to reduce deaths from potentially survivable vascular injuries and to improve the quality of functional extremity salvage (i.e., saving life *and* limb).[16]

The development of the Joint Theater Trauma System has improved surgical care and reduced mortality by implementing clinical practice guidelines and performing outcomes research emerging from the Joint Theater Trauma Registry (JTTR). The GWOT Vascular Initiative is a comprehensive registry designed to study patterns of vessel injury and methods of vascular repair, and to provide more complete long-term analysis of patient outcomes.

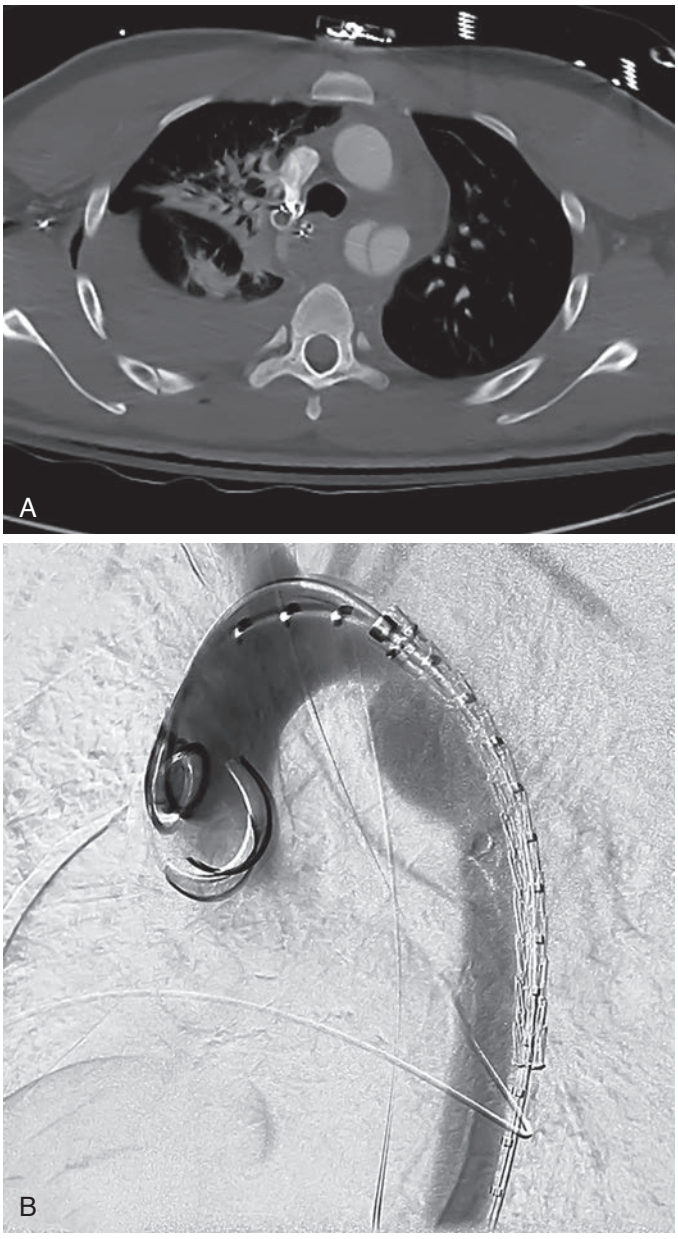

Figure 180.1 Blunt Aortic Injury. (A) Computed tomography angiogram demonstrating type III blunt aortic injury with pseudoaneurysm. (B) Conventional angiography demonstrating an aortic pseudoaneurysm immediately prior to thoracic endovascular aortic repair.

At the beginning of the GWOT, the US Department of Defense implemented a testing, training, and fielding program for battlefield tourniquets.[17-19] Although widespread tourniquet use began with trepidation, the forward deployment of surgical capabilities has provided for limited tourniquet duration, thus increasing the effectiveness of tourniquets and reducing the rate of associated complications. The effectiveness of early tourniquet application observed in Iraq and Afghanistan has led to doctrinal changes that have produced a surge of patients with vascular injuries who, in the past, would not have reached a field hospital alive (see Fig. 180.1B).[20,21] The application of tourniquets for extremity vascular injury is now routine and has been formalized in the Tactical Combat Casualty Care (TCCC) guidelines.[22]

Of interest, the 12% incidence of vascular injuries based on data from the JTTR is the highest ever reported during wartime. Certainly the widespread application of tourniquets contributes to this statistic; however, improved detailed data collection as well as a shift in injury mechanism from conventional weaponry to the improvised explosive devices (IEDs) likely impacts this as well.[23] Additionally, the widespread use of body armor in conjunction with increased exposure to IEDs has led to an epidemiologic shift in injury patterns, with a proportionally higher rate of extremity vascular injury (53%) and a decreased rate of major truncal vascular injury (15%). Interestingly, there has been an increased incidence of vascular ligation (35%) compared to that of the Korean and Vietnam War era, underscoring the devastating nature of many of the extremity wounds in modern warfare, which negate the opportunity for attempts at limb salvage.[23]

Other modern advances include the selective application of surgical adjuncts, such as temporary vascular shunts that facilitate delayed definitive vascular repair in scenarios of polytrauma and the routine performance of fasciotomies to minimize the incidence of undiagnosed compartment syndrome.[24-29] Progress in the management of increasing complex vascular injury patterns and the associated management of complex soft tissue wounds through closed negative pressure wound therapy, has been impressive.[30] Also, the application of endovascular technologies for the diagnosis and treatment of certain types of vascular, pelvic, and solid organ war-related injuries has become more widespread and generally accepted as a mainstay of surgical care.[31-33]

Despite tremendous achievements that have inexorably altered the natural history of vascular injury and its impact on morbidity and mortality, it is challenging to draw definitive comparisons between modern and historical conflicts with regard to "killed in action," "died of wounds," and other outcome measures given the heterogeneity not only due to the technological advancements but also to the changing tactical environment and the subsequent injury patterns. Nonetheless, many warfighters continue to succumb to potentially survivable injuries on the battlefield. In several contemporary studies evaluating combat-related mortalities from Operation Enduring Freedom and Operation Iraqi Freedom, approximately 15% to 25% of casualties were deemed to have potentially survivable injury patterns at the time of autopsy, of which 80% to 87% are attributed to hemorrhage.[3,16,34,35] This not only underscores the lethality of vascular injury and hemorrhage, but also alludes to the fact that viable strategies for more timely intervention remain elusive.

Data Repositories and Registries

One of most important factors in understanding the epidemiology and patterns of vascular injuries and trauma is the collection of large samples with thorough and reliable data. This has traditionally been done by single centers performing chart review analyses during long periods or by the analysis of wartime experience with limited follow-up data. Developments in computerized databases, automated data collection, and the

establishment of trauma systems with dedicated registrars have facilitated the collection and analysis of large and multicenter trauma data. An early example and model for future development was the establishment of the Vietnam Vascular Registry, with subsequent landmark reports on the epidemiology and outcomes of a wide variety of vascular injuries.[13] The recognized importance of the prospective collection of data from wartime experiences led to the establishment of the Joint Theater Trauma System and the JTTR, which continue to collect critical information from combat operations in Iraq and Afghanistan. The past decade has also seen the establishment of the National Trauma Data Bank (NTDB) by the American College of Surgeons. The NTDB is the largest trauma registry ever assembled, and as of the 2015 annual report, it contains more than 6 million records from 746 trauma centers in North America, of which nearly 500 are level I or level II centers. This rich data source has allowed detailed descriptive data and adequately powered statistical analysis of a wide variety of vascular injuries and related traumatic disease. The NTDB data are subject to extensive auditing, with an edit check program that aims to ensure data quality and accuracy. Submission data are also rigorously standardized. A data dictionary—the National Trauma Data Standard—commissioned by the federal government and established by the ACSCOT Subcommittee on Trauma Registry Programs, allows for uniform data collection across institutions and serves as the standard for data submission to the NTDB.

While robust in its breadth and depth, the NTDB does possess certain limitations that influence its ability to accurately characterize the epidemiology of traumatic injury, particularly certain vascular injury patterns. One limitation is that nonadmitted patients are uniformly not captured in this database. This is of particular importance in the context of vascular injury, as patients that die without transport to a treatment facility are not captured. Thus, major vascular injuries where exsanguination results in rapid demise are likely underrepresented in the NTDB. This creates an inherent selection bias for more stable, less severely injuried patients, confounding analyses aimed to characterize the epidemiology and natural history of vascular injury, particularly truncal injury patterns. The NTDB is also not a true population-based data set, as the data set only reflects experience at participating institutions, which inherently are biased in favor of large-volume, urban trauma centers. Hence, the experience of nonparticipating facilities, likely smaller community and rural hospitals capable of locally treating less severe injury patterns, will not be reflected in the NTDB data set. While capturing certain in-hospital complications, the database does not fully characterize the outcomes following vascular injury and is limited to in-hospital outcomes and complications.

The PROspective Vascular Injury Treatment (PROOVIT) registry, supported by the American Association for the Surgery of Trauma, has been established to address key limitations of the NTDB, in an effort to better characterize the natural history and outcomes of civilian vascular injury patterns. The initial publication of this data set included 542 patients from 14 centers from March 2013 to February 2014, in whom 484 sustained arterial injuries and 71 experience isolated venous injuries. The additional strengths of this database include the capture of key elements of prehospital care, such as the application of tourniquets, which was seen in 20% of patients within this series.[36]

Vascular Injury Classification and Scoring

The ideal vascular injury classification and scoring system has yet to be developed, probably because of the wide variation in traumatic vascular disease and the associated outcomes. Standard injury scoring systems, such as the Injury Severity Score (ISS), the Revised Trauma Score (RTS), and the Trauma and Injury Severity Score (TRISS), fail to accurately and reliably capture the impact of major vascular injury on morbidity and mortality.[37,38] Beyond this, the myriad factors that influence mortality—independent of the injury itself—cannot be effectively captured using ISS, specifically. In a study by Markov, mortality rates for patients with ISS >15 following civilian versus military-related vascular trauma with similar injury patterns was 40% and 10%, respectively, further underscoring the limitations of ISS to characterize vascular injury outcomes.

For battlefield or combat-related vascular trauma, it is probably most useful to categorize injuries according to a three-tiered system based on the wound location and the ability to achieve hemorrhage control. This system also can be easily applied to civilian vascular trauma. Peripheral or extremity wounds (tier 1) are located distal to the axillary artery or vein (upper) or the common femoral artery or vein (lower), and are responsible for the smallest percentage (14%) of modern battlefield deaths due to bleeding.[39] This has largely been attributed to the widespread distribution and use of tourniquets or pressure packing, which is performed in 56% of combat casualties. Proximal groin or axillary wounds (tier 2) are now categorized as junctional wounds and are often not amenable to either direct pressure or tourniquets. This has led to the development and wide deployment of advanced hemostatic dressings and the search for junctional hemorrhage control devices.[39] The third category (tier 3) is intracavitary wounds to the thorax or abdomen and pelvis, resulting in noncompressible truncal hemorrhage (NCTH). This has been identified as the most difficult and deadly source of hemorrhage on the battlefield, and NCTH has been identified as the etiology in 67% of battlefield deaths from hemorrhage.[39] This categorization scheme is most useful for penetrating or battlefield trauma, but it can be applied to any vascular trauma with associated hemorrhage.

The American Association for the Surgery of Trauma Organ Injury Scaling (AAST-OIS) system is the most widely used grading system for traumatic injuries and is well validated for predicting the outcomes and the need for intervention in solid organ injuries. AAST-OIS tables are currently also available for traumatic vascular injuries, including cervical, thoracic, abdominal, and peripheral. This grading system is organized primarily around the exact identity of the vessel rather than the severity of the vascular injury or the degree of hemorrhage or ischemia, and thus provides little additional information about treatment or outcomes. Additional classification systems have been developed to better characterize the natural history, to guide

treatment, and to predict outcomes for specific injury patterns, such as blunt carotid and aortic injuries.[40,41]

For major extremity fractures and soft tissue injury, several scoring systems have been developed to characterize the "mangled extremity." The most commonly described include the Mangled Extremity Severity Score, the Mangled Extremity Syndrome Index, the Predictive Salvage Index, and the Limb Salvage Index.[42] Although they contain different components, the presence of vascular injury and limb ischemia is a universal key variable. In addition to providing an objective classification system for epidemiologic purposes, these scores have been studied for their ability to predict the need for extremity amputation in both civilian and military settings.[42,43] Although they have been correlated with the need for amputation, prospective trials have found that they lack adequate predictive ability to be used for individual patients and did not correlate with limb salvage when arterial reconstruction was performed.[43]

Contemporary Civilian Vascular Injury

Violence in Society

The epidemic of urban violence is a scourge on society and largely contributes to the burden of vascular injuries seen at treatment facilities. Homicide rates clearly reflect the overall violence in society and are loosely linked to the incidence of vascular injury; therefore, they reflect on global and regional trends, which provides a framework for understanding the impact on local trauma systems. Table 180.2 shows the rates of homicide for select nations over time. In the United States, the homicide rate in 2013 was 3.8 per 100,000 in the population. In comparison, the rates in Honduras, the United Kingdom and Japan were 84, 1, and 0.3 per 100,000, respectively, which underscores the wide variation in different nation states.[44] Regional variations are even more pronounced. According to FBI statistics for 2015, the homicide rate in St. Louis was a staggering 50 per 100,000, which is greater than 10 times the national average. In the United States, gun violence is the principal agent of death in 60% of cases (Table 180.3), compared to 11% for bladed weaponry. This contrasts strikingly with the United Kingdom, where firearm-related homicide is a low 7%, reflecting strict gun control policies.

Epidemiologic Patterns and Trends

The exact incidence and distribution of vascular injury mechanisms may vary widely between centers, depending on the setting (urban vs. rural) and population served. According to a recent

NTDB analysis of all trauma admissions, the incidence of vascular trauma is 1.6% for adults and 0.6% for pediatric patients, which is significantly lower than the 6% to 12% incidence among combat casualties.[23,28] However, the reported incidence of major vascular injury is likely to be an underestimate, as mentioned previously, and does not include patients who die at the trauma scene. In one analysis of autopsy reports of 552 trauma deaths identified, penetrating injury was the reported mechanism in 42% of patients, with approximately 80% dying from hemorrhage. Of the patients who had vital signs in the field, 26% were identified has having major vessel disruption.[45] The majority of prehospital or immediate deaths from vessel disruption were due to aortic injury (55%), and most (78%) were associated with death within 15 minutes of injury.

While blunt trauma accounts for approximately half of trauma deaths, vascular injury due to blunt trauma is relatively uncommon, with death from blunt vascular injury being relatively rare.[45] The most lethal blunt vascular injury pattern involves laceration or transection of the thoracic aorta, accounting for approximately 10% of all trauma-related prehospital deaths.[46] While many patients will succumb to this injury pattern immediately, those who survive to undergo definitive care fare well, with an injury-specific mortality rate of 12%.[47]

Major vascular disruption or bleeding continues to be associated with approximately 25% of early trauma deaths, and some important modern epidemiologic trends have been identified. The average age of all trauma patients and those with vascular injury is steadily increasing, with a 10-year increase in the average age of trauma patients between 1996 and 2004.[48] Thus, the classically described "young and healthy" trauma patient is being replaced with more elderly patients who have a higher incidence of preexisting vascular disease that may increase the risk for vessel injury and may alter treatment options.

Factors Influencing the Natural History of Vascular Injury

Most vascular injury patterns mandate prompt treatment in order to optimize outcomes. That treatment may come in the form of definitive treatment or temporizing measures aimed at facilitating a safe delay in care. The most significant improvements in vascular injury management over the past century have addressed these key factors. The development of a robust network of emergency medical services that can provide rapid transport and basic or advanced life support measures are an essential component of modern trauma care. One study from the United Kingdom demonstrated a decreased ratio of prehospital to in-hospital deaths over an 8-year period (1996 to 2004) from 1.5 to 0.75, underscoring the improved efficiency of prehospital EMS.[48] Gunst et al. reported consistent findings where decreased transport times and advances in prehospital care resulted in more critically injured patients surviving until arrival at a hospital, particularly those with nonsurvivable injury patterns. This led to a temporal shift in early in-hospital trauma deaths toward an earlier time point. When these early deaths were scrutinized, 76% were deemed nonsurvivable.[49] While these statistics do not support the claim that decreased transport times lead to increased survival, at a minimum it does confirm the ability of prehospital EMS to provide for the potential salvage of critically injured patients that would have otherwise died in the prehospital setting.

For severely injured patients, damage control techniques, including abbreviated surgery, the application of endovascular techniques, balanced resuscitation, and temporary intravascular shunts (both arterial and venous) have been associated with major reductions in both mortality and limb loss.[50-52] These innovations have altered the classic trimodal distribution of trauma-related mortality toward more of a bimodal distribution,

with a significantly decreased incidence of late deaths beyond 24 hours.[49]

Arguably the most significant development in modern vascular surgery is the emergence of endovascular techniques for managing vascular disease, and these techniques are now being extended to traumatic injuries. Although initially applied to injuries for which open repair was highly morbid (thoracic aorta) or provided limited exposure (distal carotid, subclavian artery), endovascular techniques for temporizing acute control of hemorrhage, or as definitive management, can be applied to a wide array of arterial and venous injury patterns.[33,53-55] A national analysis demonstrated a 27-fold increase in the use of endovascular therapy, and this was associated with a decrease in morbidity, hospital stay, and mortality.[52] Endovascular techniques have, even now, been extended to the combat setting, and include vena cava filter placement, embolization (58% of nonfilter treatment procedures), and stent placement (30%). Technical success of these procedures is 90% to 100% and provides a definitive, minimally invasive treatment option.[56]

Impact of Age and Gender on Vascular Injury

One of the largest determinants of risk for traumatic injury is age, with the overwhelming burden impacting young adults. According the 2015 NTDB report, traumatic injury progressively increases beginning at age 14, peaking at approximately age 21, and progressively declining thereafter. The majority of overall traumatic injuries are due to motorized vehicles between patient ages of 14 and 49, with falls as the dominant injury mechanism in all other age groups. While penetrating injury due to firearms accounts for less than onethird of injuries in the peak age demographic, the case fatality rate is nearly 4 times greater at approximately 15%. More than 70% of traumatic injuries in the peak age group occur in males, with up to 90% for penetrating extremity wounds.[57]

The overall incidence of vascular injury in the pediatric population (age <16) is 0.6%, compared to 1.6% in adults, based on a recent NTDB analysis.[58] Injuries to vessels in the thorax were approximately 7 times lower in children compared to adults. Penetrating injury patterns were less common in children (41.8%) compared to adults (51.2%).[58] However, a smaller single institution series reported a higher proportion of penetrating injuries in children at 67%, likely reflecting regional variation and low sample size.[59] Unfortunately, firearm and stab wounds accounted for the majority of penetrating injuries in children, with a mortality rate of 20% for those injured by a gun.[58]

The upper extremity was the most common location of pediatric vascular injury (37.9%), with most injuries involving either the radial or ulnar arteries (22%). The upper extremity is also the most common site of penetrating vascular injury for both adults and children. With regard to blunt injury patterns, the upper extremity (33%) and chest (33%) are the most common sites of blunt vascular injury in children and adults, respectively.[58] The amputation rates for both children and adults were similar.

The incidence of vascular injury in the geriatric population (mean age 70 years) is similar to that of the pediatric population, at 0.7%. There is still a gender bias toward injury in males at 60%, albeit less pronounced than in the younger adult population. Blunt mechanisms (MVC and falls) account for the overwhelming majority of injuries (84%), with blunt thoracic aortic injury being most frequent (39%). Crude mortality rates were significantly higher in the geriatric population compared to younger adults (44% vs. 22%), with injury to the thorax carrying a high mortality rate of 66%. With respect to penetrating injuries, the forearm vessels are most commonly injured (31.5%). Amputation rates following extremity vascular injury were similar in both the geriatric and younger adult populations.[60]

Ethnicity and Socioeconomic Factors

Disparity in healthcare outcomes has been extensively documented for multiple disease processes, with traumatic injury being no exception. Beyond outcomes, there is also a disparate distribution in the burden of traumatic injury within society, based on race and socioeconomic status. The effect of race and insurance status has been explored in multiple studies, with most indicating pronounced effects.[57,61-65] However, there appears to be a lack of uniformity across various injury patterns.

In a large review of the NTDB from the years of 2001 to 2005, Haider et al. demonstrated marked differences in the incidence of penetrating trauma as a function of both race and insurance status. The overall incidence of penetrating injury in this sample was 8.7%. For insured patients, the incidence by race was as follows: white = 3.1%, black = 18.3%, and Hispanic = 11.7%. For uninsured patients, a similar distribution was seen: white = 7.4%, black 31%, and Hispanic = 21.8%. Unadjusted mortality rates were statistically different for white, black, and Hispanic patients at 5.7%, 8.2%, and 9.1%, respectively. When stratified by insurance status these findings persisted, with mortality rates for uninsured white, black, and Hispanic patients at 7.9%, 11.4%, and 11.3%, respectively. These findings continued to persist despite adjustment for injury severity and demographic variables.[61]

Several authors point to heterogeneity within the trauma population as a potentially confounding factor in explaining outcomes based on race and insurance status. In an effort to control for this, Crandall et al. analyzed the outcomes in a more homogeneous population involving patients who sustained isolated lower extremity vascular injury. Mortality rates were higher for uninsured patients (31.7% vs. 21.5%); however, when stratified by mechanism, only penetrating injury remained significant. In a risk-adjusted model, race remained a predictor of increased mortality following penetrating lower extremity vascular injury in blacks (odds ratio [OR] 1.45, P = .03).[57] In another study evaluating outcomes of pedestrians struck by motor vehicles, Maybury demonstrated that blacks (OR 1.22) and Hispanics (OR 1.33) had a significantly higher mortality rate than whites utilizing a multivariate risk-adjusted model, with uninsured status also as an independent predictor of increased mortality.[65] The explanation for these outcome disparities prove challenging and may, in part, reflect physiologic and environmental variables that are not appropriately captured within the NTDB. Nonetheless, these findings highlight the

need for further investigation, and support the development of outreach programs aimed at minimizing the impact of traumatic injury on at-risk populations.

Mechanisms of Injury, Ballistics, and Biomechanics

The clinical presentation, pattern of associated injuries, need for intervention, and outcomes after traumatic vascular injury will be highly dependent on the mechanism of injury and the specific characteristics of that mechanism. For blunt injury, this mainly involves the velocity or forces of impact, the use of restraints or protective devices, and the primary anatomic areas that sustain the brunt of the kinetic forces. In addition, patients sustaining blunt trauma may suffer penetrating-type vascular injury from impalements, cuts from glass or sharp debris, and punctures by fractured bone fragments. The most common blunt mechanism associated with major vascular injury is motor vehicle collision, and injury to the vessel typically results from stretching and shearing forces, or from vascular avulsion (usually due to rapid deceleration).[66] Several additional etiologic factors have been proposed, including the generation of a sudden spike in intravascular pressure, creating wall stress, tear, or rupture, as well as forward inertial deceleration of blood impacting the anterior vessel wall ("water-hammer" effect).[66,67]

For penetrating trauma, the wounds can be primarily classified as due to stab/puncture or from missiles/projectiles that are typically firearms related. Stab and puncture wounds result in direct vascular injury without significant transmission of kinetic energy or damage to surrounding tissues. Missiles may injure vascular structures by direct laceration or by the transfer of energy due to proximity, with an impact kinetic energy (iKE) related to the mass (M) and velocity (V) of the projectile ($iKE = \frac{1}{2} MV^2$). Rarely, missiles or fragments can enter the lumen of the arterial or venous system and embolize, resulting in luminal occlusion and distal ischemia. Terms such as "high velocity" are often used, but are frequently poorly defined or misunderstood, and there are multiple projectile characteristics, such as shape, deformity, fragmentation, pitch, and yaw, that are of equal importance to, or more important than, the velocity.[68] Additional injury to surrounding tissue has been attributed to both the "sonic wave" and the stretching of tissue due to the pressure wave ("temporary cavity"), which are considerations that have been used to justify excessive tissue debridement or vessel resection. However, subsequent study has found that the effect of the sonic wave is negligible, and the size of the temporary cavity is smaller (11× the diameter of the missile) than previously described (up to 30× diameter).[68] Jahnke et al. examined the arteries from vascular wounds in the Korean War and excised the injured segment as well as a 1-cm margin of grossly normal vessel.[11] They demonstrated histologic evidence of injury that extended through the 1 cm of normal-appearing vessel. Similarly, histologic vessel injury was demonstrated in samples from the Vietnam War, but showed no correlation with the outcome of repair. Excessive debridement of grossly normal vessel or surrounding tissues is not required, even with the ballistics of so-called high-velocity wounds. Finally, particular mention should be made of shotgun injuries. Although shotguns are classified as low velocity, the resultant tissue injury due to diffuse tearing, contusion, and devascularization from multiple pellets can be significantly greater than even that of high-velocity gunshots.[69,70] Although less common than stab or gunshot mechanisms, they have been associated with vascular injury in up to 25% of wounds, and the degree of injury is highly correlated with the type of pellet and the effective weapon–victim range.[69] Shotgun pellets are notorious for creating vessel micropunctures that are difficult to diagnose even by examination or imaging studies.[71]

Blast injury, such as that seen with improvised explosive devices in the wars in Iraq and Afghanistan, has its own unique wounding pattern and mechanisms. The overall mechanism is a combination of blunt force trauma, penetrating fragment injuries, and potentially thermal injury. Blast injuries in modern combat series now outnumber standard gunshot wounds and account for 73% of vascular injuries among wounded soldiers. Blast effects are classified as primary (direct blast pressure), secondary (penetrating fragments), tertiary (collision with objects or vehicles), and quaternary (thermal injury). The relative distribution of each varies by the type of explosive, enclosed versus outdoors, and the presence of protective equipment. The majority of vascular and other injuries are due to secondary and tertiary blast effect (81%). Blast-induced extremity vascular injury with coexisting fracture is associated with a 50% amputation rate with attempts at limb salvage and a 77% amputation rate overall.[72] Blast injuries may also occur with civilian incidents, such as terrorist bombings, and vascular injuries have been identified in up to 10% of victims.

EPIDEMIOLOGY AND NATURAL HISTORY OF SPECIFIC VASCULAR INJURIES

The epidemiology for major traumatic vascular injuries will vary widely by injury location, mechanism, and the specific blood vessel involved. Similarly, the natural history and outcomes of these injuries will vary widely by these factors as well as by the specific size and degree of injury to the vessel. As many of these injuries are rapidly fatal or are immediately managed by either ligation or repair, the evolution and long-term outcome of untreated vascular injury is inherently poorly understood. Currently available clinical data on their natural history mainly come from the experience with nonoperative management of blunt internal carotid artery injuries and asymptomatic extremity artery injuries.[73,74] Also, there are limited data from several animal models on the development and progression of traumatic vascular injuries.[67] Table 180.4 shows a summary of the known natural history and potential life- or limb-threatening complications that may develop after either blunt or penetrating major vascular trauma. Clinically, occult injuries, such as narrowing/vasospasm, small intimal flap or pseudoaneurysm, and minor arteriovenous fistulae may resolve without operation in up to 86% of cases, and only 2% overall require operative intervention.[70,74] More significant injuries will frequently progress and

TABLE 180.4 Natural History of Various Types of Vascular Injuries and Potential Future Complications

Injury Type	Natural History[a]	Complications
Penetrating or Iatrogenic		
Laceration	Pseudoaneurysm or thrombosis	Ischemia, rupture, embolization
Contusion	Stenosis, thrombosis	Ischemia, embolization
Arteriovenous fistula	Increase in size and flow	"Steal" syndromes, heart failure
Blunt		
Intimal dissection or thrombosis (<25%)	Spontaneous resolution	None unless progression
Intimal dissection or thrombosis (>25%)	Pseudoaneurysm, thrombosis	Rupture, ischemia
Pseudoaneurysm	Increase in size	Rupture, embolization
Thrombosis	Occlusion, recanalization	Ischemia, stenosis
Arteriovenous fistula	Increase in size and flow	"Steal" syndromes, pseudoaneurysm
Transection	Thrombosis, pseudoaneurysm	Ischemia, compartment syndrome

[a]Natural history without intervention and assuming initial hemorrhage control.

may present with life- or limb-threatening disease without initial definitive treatment.

Neck

The incidence of vascular injury in the neck is 20% with penetrating trauma and approximately 1% in blunt trauma in civilian series, with the majority of injuries involving the carotid artery.[40,75] However, there is marked difference in the epidemiology and treatment paradigms of blunt versus penetrating carotid artery injuries. The overall incidence of diagnosed carotid artery injury is 0.2%, with 41% due to penetrating trauma versus 59% from blunt mechanisms.[76] Interestingly, a series examining missed arterial injuries identified the carotid as the most common site (39%).[77] Based on a review of the NTDB, the majority of carotid artery injuries are located in the internal carotid (37%) and less commonly the common carotid (20%), with mixed injuries the least common (10%). However, unspecified injuries accounted for 33% of documented carotid injuries.[76]

The majority of blunt carotid artery injuries are due to stretch from hyperflexion/extension with rotation and are located in the distal internal carotid artery.[75,76] Bilateral carotid artery injury or associated vertebral artery injury is present in 20% to 50% of cases. This injury pattern is usually associated with high-velocity motor vehicle crashes and multisystem injury (79%), including a 50% incidence of severe brain injury.[76,78] The increased utilization of routine computed tomography (CT) angiography for trauma has resulted in a surge of blunt carotid artery injury diagnoses.[40] The primary predictors of outcome are the grade of injury, the degree of associated injuries, and the development of neurologic symptoms. Mortality of up to 50% has been reported, but the injury-associated mortality is 15%, and the incidence of severe neurologic deficits among survivors is 16%.[39,75,78]

Vertebral artery injury is relatively uncommon, accounting for 1% to 7% of penetrating neck injuries and 1% of blunt injuries.[40,79] While mortality from isolated vertebral artery injury is approximately 10% to 20%, the mortality increases to 50% when combined carotid–vertebral artery injury is present. The majority of vertebral artery injuries (78%) have an associated cervical spine fracture, and the incidence of vertebral artery injury is up to 40% when a cervical spine fracture is present.[40,78] The incidence of posterior circulation stroke with blunt vertebral artery injury has been reported to be as high as 24%, with an 8% attributed mortality rate. However, aggressive screening with early diagnosis by CT angiography was associated with a reduction in the stroke risk from 14% to 0%.[80]

Truncal Injury

Noncompressible Truncal Hemorrhage

Injuries to named vessels of the thorax or abdomen from either blunt or penetrating mechanisms are highly morbid, with a large percentage of patients dying before they reach a hospital. A study of 1203 battlefield casualties in Iraq and Afghanistan found no survivors among those with injury to a named abdominal or thoracic vessel.[81] Even for pediatric patients, who are typically more tolerant to injury and hemorrhage, mortality approaches 100% with thoracic vascular injuries and hemodynamic instability at presentation. However, exsanguinating hemorrhage may not necessarily involve injury to named vascular structures. NCTH, irrespective of injury pattern carries a high associated mortality, accounting for 60% to 70% of potentially preventable mortality in the civilian setting.[82] From experience during Operation Enduring and Iraqi Freedom, 24% of deaths were deemed survivable, of which 42% were due to NCTH, accounting for 10% of all combat-related deaths.[16,34] Unlike peripheral or junctional vascular trauma, these injuries are not amenable to direct compression or simple inflow occlusion (tourniquet) in the prehospital or emergency department phase; therefore, they have been the focus of great interest and innovation. Critical concepts or interventions for patients with NCTH are (1) minimizing delays in transfer from the emergency department to the operating room; (2) permissive hypotension until vascular control is obtained; (3) balanced or "hemostatic" resuscitation with the early use of plasma; (4) procoagulant adjuncts, such as tranexamic acid; and (5) the use of damage control surgery techniques and intravascular shunts when indicated.[50,83]

In an effort to alter the natural history of this highly lethal injury pattern, novel strategies are being developed, which are particularly aimed at the prehospital phase of care. Resuscitative endovascular balloon occlusion of the aorta has emerged as a viable adjunct in the management of patients with NCTH.[33,53]

This intervention is minimally invasive, potentially obviating the need for heroic intervention, such as open aortic cross-clamping, and can be applied in the prehospital arena. Experience with this technique is increasing, with the development of new technologies and devices to increase safety and feasibility. The AAST Aortic Occlusion for Resuscitation in Trauma and Acute Care Surgery (AORTA) Registry was established in 2013 to prospectively track outcomes of patients undergoing any form of aortic occlusion including REBOA.[84]

Thorax

Thoracic Aorta

The majority of thoracic vascular injury (90%) is due to penetrating trauma, with 28% of penetrating aortic injuries in the thoracic portion.[85] In a landmark study of 5760 vascular injuries, Mattox et al found that 14% involved the thoracic aorta, of which 86% were due to penetrating mechanisms.[86] Thoracic aortic injuries can be classified into several groups, including intrapericardial/ascending (8% to 27%), aortic arch (8% to 18%), and descending thoracic (11% to 21%).[87]

Blunt trauma of the descending thoracic aorta is the most frequently diagnosed and encountered blunt thoracic vascular injury with 98% of these injuries occurring at the ligamentum arteriosum or just distal to the origin of the left subclavian artery (Fig. 180.2).[88] The most common mechanisms of injury are motor vehicle accidents (driver's chest decelerates against the steering wheel), falls from a height with impact on a hard surface, and impact from a large mass. Additionally, blunt aortic injury is identified in up to 30% of airplane crash victims.[89] Injuries are classified as follows: intimal tear (grade I), large intimal flap or intramural hematoma (grade II), pseudoaneurysm (grade III), and rupture (grade IV).[41,90]

Blunt trauma to the ascending aorta occurs from sudden displacement of the intact sternum or displacement of the fractured or dislocated sternum onto the anterior surface of the ascending aorta. Several injuries can occur: a subadventitial hematoma, a subintimal hematoma or tear, or a complete tear with pseudoaneurysm formation or free rupture.[46] Another injury to the ascending aorta from blunt trauma is a torsion tear caused by the sudden rotation of the heart apex posteriorly with a spiral tear starting above the aortic valve. Most (98%) of these die at the scene from pericardial tamponade or exsanguination and, thus, rarely survive to hospital diagnosis or repair.[46,91]

In contemporary practice, blunt thoracic aortic injuries are managed primarily with thoracic endovascular aortic repair (TEVAR). A landmark multicenter study by Fabian et al (AAST-1) in 1997 characterized the traditional approach to blunt thoracic aortic injuries, with 35% undergoing clamp and sew repair, and 65% having repair with cardiopulmonary bypass.[75] Mortality was 31%, and the paraplegia rate was 9%. In a recent multi-center experience, TEVAR was utilized in 76% of cases, with overall and aortic-related mortality rates of 8.6% and 2.5%, respectively, and paraplegia in a mere 0.5%.[92] Additionally, the literature supports delayed repair of stable injuries (grade I to III), particularly in the presence of significant associated injuries.[47,92] Endovascular repair has also been extended to patients with acute penetrating thoracic injury or delayed complications, such as pseudoaneurysm or arteriovenous fistula.[56] Finally, nonoperative management of select patients with low-risk injuries (grade I/II) or with prohibitive surgical risk is becoming more widely accepted.[47,92,93]

Great Vessels

Injury to the great vessels (innominate, brachiocephalic, proximal subclavian) is frequently fatal (90% occur within 30 minutes) due to hemorrhage or associated injury to the airway, heart, or aortic arch.[87] Additionally, mortality rates of 70% to 80% have been reported for isolated subclavian artery injuries.[55,94,95] The incidence of great vessel injury is approximately 5% with gunshot wounds, and 2% with stab wounds; it is extremely uncommon (<1%) in blunt trauma.[60,87] In a large autopsy study of trauma deaths, 12.7% of deaths were due to injury to the aorta or great vessels, and no patient with a penetrating wound survived to hospital arrival compared with 5% of blunt injuries.[46] Many patients will have multiple-vessel injury (65%), and the majority (77%) present with clear signs of hemorrhage or a large and expanding hematoma.[96] Operative approaches are dependent on individual surgeon and institution preferences, but typically involve a median sternotomy or left thoracotomy. High patency rates (>90%) have been described with both vein and prosthetic repairs, with no significant incidence of prosthetic graft infection reported.[94,96] Ligation of the subclavian arteries may be performed in select cases and is frequently well tolerated because of collateral circulation.[95,68] Experience with TEVAR for blunt thoracic aortic injury involving routine coverage of the left subclavian artery supports this claim, with only a 4% to 5% incidence of left arm ischemic symptoms. Long-term functional deficits among survivors are attributed to the central nervous or brachial plexus injuries more than to the vascular injury.[94]

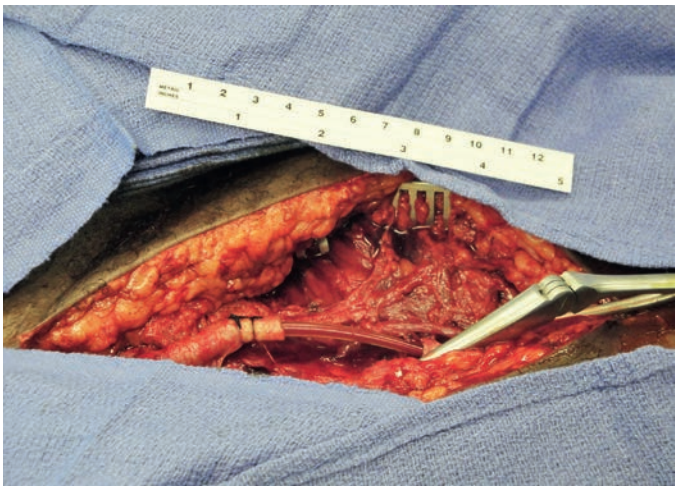

Figure 180.2 Temporary Vascular Shunt. Injury to the superficial femoral artery from a gunshot wound. Due to concomitant injury, temporary shunting was performed using an Argyle shunt to maintain limb viability while more life-threatening injuries were managed.

Axillosubclavian Vessels

Although the proximal subclavian vessels are primarily mediastinal structures, the distal subclavian and proximal axillary vessels cross anatomic zones including the chest, neck, and extremity. Proximal subclavian injuries adhere to the principles described before for great vessels, but axillosubclavian injuries often have a different presentation and complicating factors. Among modern combat casualties, the incidence of upper extremity vascular injury is 1.7%, and 23% of these involve the axillary or subclavian vessels.[97] The majority of civilian injuries are due to penetrating trauma (55% to 75%) and are most common in shotgun wounds (18%), followed by gunshots (10%) and stab wounds (9%).[70] Concomitant vein injury is present in onethird of patients.[98] Blunt axillosubclavian injuries are rare and are due to either shear forces or clavicle fracture with nearly universal presence of nerve injury or fracture.[99] Limb function is often severely impaired, but this is primarily due to the high incidence (40% to 100%) of associated brachial plexus injury.[98] Amputation is ultimately required in 3% to 15% and mortality is up to 25%, with worse outcomes among the blunt injuries patterns.[99]

There is increasing interest in, and successful reports of, endovascular management of these injuries, particularly for pseudoaneurysms and arteriovenous fistulae. A series of 57 patients with long-term follow-up demonstrated stenosis in 20% and occlusion in 12%; all were managed percutaneously with no limb ischemia or loss.[55] Additionally, these techniques have been shown to decrease hospital length of stay and have a high degree of technical success approaching 100%.[55] These techniques may also be extended to so-called unstable patients and, in fact, may achieve faster hemorrhage control in systems that are prepared for emergent endovascular intervention.[56]

Abdomen

In a large series of 5760 vascular injuries, 34% involved abdominal vasculature and 24% involved multiple vessels.[86] The majority of abdominal vascular injuries were due to penetrating mechanisms (89%), with 36% of patients having multiple vessel injury.[100,101] Hemodynamic instability or complete arrest requiring emergency department thoracotomy has been reported in up to 15% of patients.[102] There appears to be a relatively equal distribution of the type of vessel injured, with vein injuries in 53% versus arterial injuries in 47%.[102] Approximately half (53%) of patients had two or more abdominal vessels injured, with mortality increasing from 45% with one vessel to 60% and 73% with two and three vessels injured, respectively.[102] The most commonly injured major vessels were the inferior vena cava (IVC) and branches (52%), the aorta and branches (35%), the superior mesenteric artery (SMA) and branches (45%), and the portal or hepatic venous system (22%).[100,101] The reported high mortality rates of 30% to 60% highlight the need for early diagnosis and intervention, with 70% to 89% of deaths attributed to bleeding.[100] Hypotension was present in 25% of patients and is one of the strongest independent predictors of death (OR, 4.5 to 18).[100]

The major abdominal vasculature is located in the retroperitoneum; therefore, injuries may present with contained retroperitoneal hematomas rather than free bleeding. A four-zone anatomic classification for retroperitoneal hematomas based on the vasculature is commonly used: zone 1 (central) contains the aorta and vena cava, zone 2 (lateral) contains the renal vessels, zone 3 (pelvic) contains the iliac vessels, and zone 4 (hepatoportal) contains the portal vein and retrohepatic vena cava. Zone 3 predominates in blunt trauma (70%), whereas zone 2 is most commonly seen in penetrating injury (50%).[103] Retroperitoneal hematomas are associated with morbidity of up to 60%, and with mortality from 13% to 40%.[103]

Abdominal Aorta (Zone 1)

Blunt injury to the abdominal aorta is rarely seen, and the majority of these injuries probably result in prehospital death from bleeding or severe associated injuries. Injury to the abdominal aorta represents only 5% of aortic injuries and was identified in 9% of all fatal aortic injuries from vehicular trauma.[104] More than half (56%) of the fatalities involved transection of the aorta and have been associated with the deceleration and hyperflexion with lap belt restraints.[104] Only 25% of patients will have abdominal wall bruising or injury, and the most common early signs are arterial insufficiency (81%), acute abdomen (55%), and weakness or paralysis (47%).[104] These injuries are virtually always in the infrarenal aorta, most commonly at the junction with the inferior mesenteric artery or the iliac bifurcation.[66,104] An intimal flap with distal dissection is the most common pathologic lesion (57%), followed by thrombosis (40%) and pseudoaneurysm (15%).[104] Mortality is 20% to 40% and increases to 83% with advanced age (>65 years).[102,104]

Penetrating abdominal aortic injury is most frequently due to gunshot wounds (78%) and carries an overall survival of less than 50%.[102] Approximately 30% will present in extremis with no measurable blood pressure, and up to 21% may require emergency department thoracotomy.[85] The location of injury is most commonly infrarenal (45%), followed by suprarenal (37%) and subdiaphragmatic (18%).[105] Injury to the suprarenal aorta is particularly difficult and highly morbid, although Mattox et al reported survival in 10 of 28 (36%) patients.[106] Overall mortality rates of 33% to 81% have been reported.[85,106] Although modern trauma management principles have been found to have no impact on the high mortality of these injuries, a study from San Diego found that mortality decreased from 78% to 40% when the patient was brought directly to the operating room (bypassing the emergency department) for resuscitation.[85,105]

Inferior Vena Cava (Zone 1)

Although the IVC is part of the lower pressure venous system, injuries cause rapid exsanguination unless they are contained or immediately controlled. Excluding mesenteric vessels, the IVC is the most commonly injured major abdominal vessel, representing 6.7% of all penetrating vascular injuries and 3.4% of blunt injuries.[60] The majority of injuries (>90%) are due to penetrating mechanisms and are located in the infrarenal cava

(85%). Approximately half of patients will present with hypotension.[107] Associated visceral injuries are present in 90% of patients and include injury to the duodenum (31%), liver (29%), and pancreas (26%).[107]

Mortality with isolated IVC injury is reported as high as 70% and increases to 78% in combination with another venous injury.[102] However, survival of up to 96% is reported among patients with an isolated infrarenal IVC injury and no hemodynamic instability.[107] Data from combat injuries of the IVC in Vietnam found that the majority underwent surgical repair (72%) versus ligation (19%), with a 23% mortality rate. IVC injury in the wars in Iraq and Afghanistan accounts for 1.4% of all vascular injuries, with approximately 50% undergoing ligation versus shunting with delayed repair or immediate repair in the remainder.[23]

Celiac and Mesenteric Vessels (Zone 1)

Traumatic injuries to the celiac trunk, SMA, or superior mesenteric vein are extremely uncommon and represent only 0.01% to 0.1% of all vascular injuries.[108] Similarly, low incidences have been reported from recent large series of battlefield injuries (0.19% celiac, 0.83% SMA).[23] A much higher incidence of 6.3% was demonstrated in a large NTDB series, but this probably includes branch vessels and more distal mesenteric injuries.[60] The majority of visceral artery injuries are due to penetrating trauma, representing 90% to 95% of celiac artery and 52% to 77% of SMA injuries.[108,109] Associated injuries are the rule, with a mean of 4.2 injuries per patient and with 35% of patients having a coexisting superior mesenteric vein injury.[108] The clinical presentation is typically either hemodynamic instability or peritonitis, with a mean estimated blood loss of 8.5 liters.[109] Mortality is 20% to 40%, with most deaths due to intraoperative or early postoperative bleeding (71%), and later postoperative complications (29%).[100,108] Mortality is directly correlated to both the injury severity and the number of coexisting vessel injuries.[85,100]

Renal Vessels (Zone 2)

Although renal injuries are relatively common with both blunt and penetrating trauma, true renovascular injury is much less common. For blunt mechanisms (incidence of 0.08%), a distinction should be made between renal parenchymal injury involving the segmental vessels or renal avulsion (AAST-OIS grade 4 to 5 injuries) and primary renovascular injury that is usually due to stretching and subsequent dissection or thrombosis. The injury mechanism is equally distributed between blunt (49%) and penetrating (51%).[110] Associated abdominal injuries are present in 77%. Nephrectomy was required in 51% of penetrating injury, with a mortality of 30%.[111]

Iliac Vessels (Zone 3)

Iliac vascular injury is uncommon, with an overall incidence of less than 1% representing 14% of civilian penetrating arterial injuries and 2% of combat vascular injuries.[112,113] Iliac artery and vein injuries are a particular challenge because of the difficulties of exposure and obtaining distal control in the deep pelvis. Injuries to the main vessels are predominantly due to gunshot wounds (86% to 95%), and 56% will have multiple iliac injuries.[113] The majority (68%) of injuries that survive to hospital admission are to the common or external iliac vein, and 32% involve the iliac arteries. Mortality with iliac vessel injury is 28% to 49%, and appears to be decreased with the use of damage control techniques including intravascular shunts.[50] Injuries to branch vessels or the internal iliac vessels are most commonly due to blunt trauma with an associated pelvic fracture. Injury to the main iliac or femoral vessels with pelvic fracture is exceedingly rare (0 of 429 patients in one series). Several series have identified the control of pelvic hemorrhage as the most frequent preventable cause of death from bleeding, and surgical intervention with packing or iliac artery ligation may be required.

Hepatoportal Vessels (Zone 4)

Injuries to the hepatoportal system are highly morbid because of common factors including massive hemorrhage, associated pancreaticoduodenal injury, difficult surgical exposure, and surgeon inexperience with these uncommon injuries. Injury to the hepatic veins or retrohepatic vena cava occurred in 9% and portal vein in 5% of abdominal vascular injuries; and 94% are due to penetrating trauma.[100] Among patients with injury to the IVC, there is a 19% incidence of combined injury with the portal vein.[107] Portal vein injuries are 92% fatal in association with other portal triad injuries, and 100% fatal with hepatic artery injury. Injuries of the retrohepatic vena cava have an associated mortality of 70% to 100% even with various shunt or exclusion techniques.[107] Injury of the retrohepatic vena cava (88%) and injury of the portal vein (69%) represent two of the top three causes of death from abdominal vascular trauma.[100]

Extremity

Extremity trauma is extremely common in all settings from both blunt and penetrating mechanisms, accounting for approximately 1% to 2% of all civilian trauma.[60] Vascular injury is more common in the lower extremities (66%) versus upper (34%).[28] In contrast, approximately 50% of modern combat injuries involve the extremities, with 75% due to blast mechanisms.[114] Although blunt mechanisms account for the large majority of overall extremity injuries, penetrating trauma mechanisms cause most (60% to 80%) extremity vascular injuries.[115]

Prehospital management of extremity vascular injury in military conflict has evolved significantly during OEF/OIF, with the widespread use of tourniquets beginning in 2005 as well as commonplace use of hemostatic dressings. Tourniquet use resulted in a staggering reduction in the prehospital death rate from 23.3 deaths per year to 3.5 deaths per year, for an overall reduction in potentially survivable death of 85%.[39] Currently, extremity vascular injury accounts for 13.5% of potentially survivable vascular injuries in modern conflicts.[39]

Isolated civilian extremity trauma with vascular injury carries a 10% risk of mortality or limb loss, and this risk is higher for penetrating mechanism and more proximal vessel injury.[116] Blunt extremity vascular injury is associated with an 18% amputation

rate and a 10% mortality rate.[115] With adjustment for other variables, lower extremity vascular injury is independently associated with an increased amputation rate (OR, 4.3) and higher mortality (OR, 2.2).[117]

Temporary intravascular shunt use is increasingly applied in the context of polytrauma, with contemporary series reporting its use in 9% of civilian vascular injuries and up to 24% of combat extremity vascular injuries (see Fig. 180.2).[28,118] In the largest published combat series of temporary intravascular shunts, patency varied widely from 86% for proximal injuries to 12% for distal vessels.[28] Despite the varied patency rates, early limb salvage in this population was 88% for distal shunts and 95% for proximal shunt placement (P = not significant) and is comparable to the reported limb salvage rates of 75% to 100% in civilian series.[118]

Upper Extremity

A recent analysis of the NTDB found that the upper extremities were the site of 27% of all civilian vascular injuries. Approximately 25% of blunt extremity vascular injuries are in the arm, with 50% located in the brachial artery. Among patients who required upper extremity amputation, the most commonly injured vessel was the brachial artery (12% of patients).[60] Compartment syndrome is present or may develop in 21% and is associated with multiple vessel injuries and open fractures. Mangled extremity predictive scoring systems have been found to be less predictive of outcomes for upper extremity injury, and limb salvage has been demonstrated in 90% of patients. Blunt injury is associated with a significantly higher amputation rate (20%) and mortality compared with penetrating mechanisms.[115]

Contemporary military experience reveals an overall incidence of upper extremity arterial injury in 30% to 34% of patients, with 11% proximal (brachial artery) and 19% distal (radial or ulnar).[23,97] Associated injuries to the ulnar or median nerve are present in up to 50%, and functional outcomes are mainly related to the associated nerve injuries rather than to the vascular trauma.[119] Associated injuries to the ulnar or median nerve are present in up to 50%, and functional outcomes are mainly related to the associated nerve injuries rather than to the vascular trauma.[119]

The majority of upper extremity vascular injuries in both civilian and military trauma are to the forearm vessels, including the radial and ulnar arteries.[60,97,117] Penetrating trauma is the cause of up to 81% of injuries, but stab wounds are more common than gunshot injury (opposite of the lower extremity).[117] Blunt radial or ulnar injury is almost always seen with a coexisting fracture of the forearm or elbow dislocation (95%) and is associated with higher mortality and limb loss.[115] Injury to forearm nerves and bone or soft tissue is the primary determinant of the ultimate functional outcome.[119]

Lower Extremity

Femoropopliteal Vessels

The majority of penetrating extremity wounds are to the lower extremity (71%) and have a 10% incidence of vascular injury versus 1% for blunt trauma.[70,73,115] Most femoral artery injuries are due to penetrating trauma, but blunt trauma is now the predominant cause (61%) of popliteal injury.[120] Knee dislocations are particularly high risk, with up to a 30% incidence of popliteal artery injury.[121] Femoral artery injuries represent 14% of all lower extremity vascular injuries from blunt trauma and 42% from penetrating.[60,115] An NTDB analysis of 651 patients demonstrated injury to the common femoral artery (CFA) in 18%, the superficial femoral artery (SFA) in 28%, and the popliteal in 36%.[116] The most feared complications vary by injury site, with bleeding of greater concern in more proximal injuries (CFA and SFA) and limb loss due to ischemia of greatest concern with popliteal injuries. Up to 46% of CFA and SFA injuries have an associated injury to the femoral vein, and 40% to 50% of popliteal injuries are combined.[120] Between 7% and 25% of patients will have an associated nerve injury, and long-term function is related to the nerve and soft tissue injuries more than to the vascular trauma. An analysis of almost 30,000 patients with vascular injury from the NTDB found that among patients who required lower extremity amputation, the popliteal artery was the most commonly injured vessel (28% of patients).[60] The majority of deaths due to extremity hemorrhage in both the civilian and military populations are from injuries to the femoral vessels. After adjustment for confounding factors, femoral or popliteal vascular injury is associated with increased mortality (OR, 2.2) and limb loss (OR, 4.3).[117]

Tibioperoneal Vessels

The true incidence of tibioperoneal vessel injury is unknown as the majority are likely to be clinically silent. Tibioperoneal vessels represent the majority (63%) of blunt lower extremity vascular injuries, 10% of penetrating leg trauma, and 44% among combat casualties.[23,60,115] Among patients with isolated lower extremity trauma with vascular injury, the posterior tibial artery is injured in 13% and the anterior tibial artery is injured in 8.6% (combined injury in 1.1%).[116] Whereas observation or ligation for isolated single-vessel injury is universally well tolerated, up to 50% of multivessel injuries develop symptoms of limb ischemia and are associated with an OR of 5.2 for amputation.[116,122] Associated injuries include tibial or fibular fractures in 64%, severe soft tissue injury in 32%, and nerve injury in 36%.[122] Amputation is required in approximately 10% of patients and is twice as frequent with blunt trauma as with penetrating trauma. The overall mortality is less than 5% and is 3 times less common than in more proximal arterial injuries.[122]

SUMMARY

Vascular injury remains a common source of morbidity and mortality in both military and civilian settings. While significant progress is evident, the overall blight of traumatic injury remains a scourge on society. The greatest opportunity to influence outcomes does not stem from improvements in prehospital care, innovation in technique and therapeutics, or surgical capabilities, but rather from efforts targeting injury prevention. An epidemiologic approach to trauma and vascular injury serves

to identify the complex factors that influence the incidence and prevalence in society. This establishes the foundation for public health and legislative initiatives aimed at mitigating the impact on at-risk populations. Improved data gathering through registries and databases—using standardized metrics and outcomes measures—is important to accurately characterize injury across the spectrum of care. Overall, a more systematic and comprehensive approach is warranted to minimize impact on the individual, on society, and on our healthcare system as a whole.

Cervical vascular injuries are notoriously difficult to evaluate and to manage, mostly secondary to complex anatomy confined to a relatively narrow anatomic space. The initial evaluation of these patients is often obscured by associated injuries to the head, chest, or abdomen. In addition, signs of cerebral ischemia, cranial nerve deficits, or cervical nerve compression may not be present on initial evaluation. The evaluation and appropriate management of this injury pattern have been controversial and continue to evolve. Advances in noninvasive imaging (primarily computed tomography [CT]) have revolutionized the evaluation of stable patients with cervical vascular injuries, aerodigestive injuries, and associated fractures. In addition, endovascular surgery has added another facet to the care of these trauma patients. Injuries to the distal internal carotid artery, proximal common carotid artery, subclavian artery, or vertebral arteries are now amenable to endovascular methods to arrest hemorrhage, to exclude dissections and pseudoaneurysms, or to assist with open repair. This chapter addresses the presentation, evaluation, and treatment of cervical vascular injuries.

CAROTID ARTERIES

Penetrating Injury

After penetrating cervical trauma, cervical blood vessels are the most commonly injured structures in the neck and account for a 7% to 27% stroke rate and a 7% to 50% mortality.[1] In this population, 80% of deaths are stroke related.

Abstract

Cervical vascular injuries are notoriously difficult to evaluate and to manage, mostly secondary to complex anatomy confined to a relatively narrow anatomic space. The initial evaluation of these patients is often obscured by associated injuries to the head, chest, or abdomen. In addition, signs of cerebral ischemia, cranial nerve deficits, or cervical nerve compression may not be present on initial evaluation. The evaluation and appropriate management of this injury pattern have been controversial and continue to evolve. Advances in noninvasive imaging (primarily computed tomography [CT]) have revolutionized the evaluation of stable patients with cervical vascular injuries, aerodigestive injuries, and associated fractures. In addition, endovascular surgery has added another facet to the care of these trauma patients. Injuries to the distal internal carotid artery, proximal common carotid artery, subclavian artery, or vertebral arteries are now amenable to endovascular methods to arrest hemorrhage, to exclude dissections and pseudoaneurysms, or to assist with open repair. This chapter addresses the presentation, evaluation, and treatment of cervical vascular injuries.

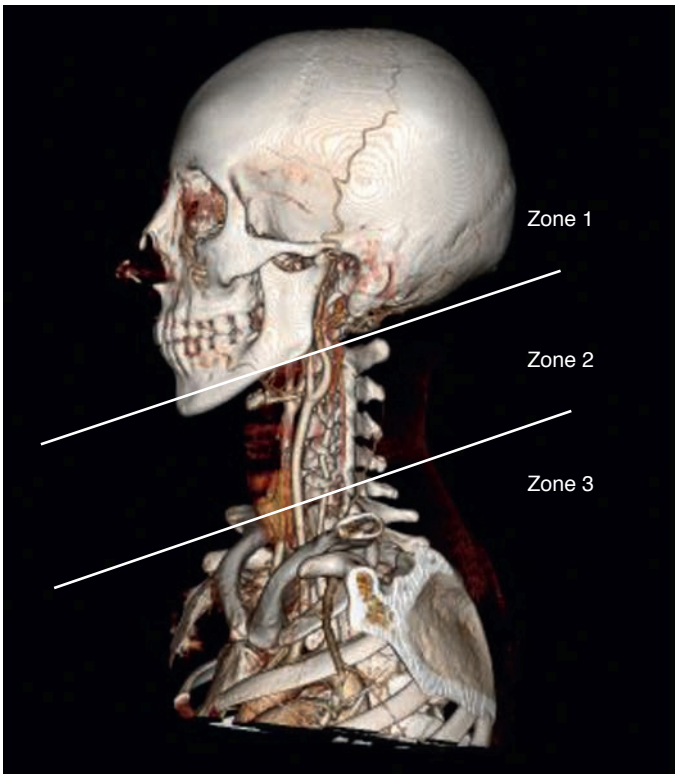

Figure 181.1 Anatomic zones of the neck for penetrating neck injuries.

Clinical Presentation

The neck has classically been divided into three zones that dictate diagnostic evaluation and treatment[2] (Fig. 181.1):

- Zone I: below the cricoid cartilage—proximal control obtained in the chest.
- Zone II: between the cricoid cartilage and the angle of the mandible—proximal and distal control obtained in the neck.
- Zone III: above the angle of the mandible—distal control difficult to obtain.

Zone II is the most commonly injured (47%), followed by zone III (19%) and zone I (18%). It is not uncommon for the injury to traverse two zones of the neck.[3] In addition to location, the physical examination triages patients on the basis of "hard signs" of vascular injury (mandating exploration) and "soft signs" of vascular injury (observation vs. further diagnostic evaluation). Hard signs include shock, refractory hypotension, pulsatile bleeding, bruit, enlarging hematoma, and loss of pulse with stable or evolving neurologic deficit. Soft signs include history of bleeding at the scene of injury, stable hematoma, nerve injury, proximity of injury track, and unequal upper extremity blood pressure measurements. Ninety-seven percent of patients with hard signs have a vascular injury as opposed to only 3% with soft signs.[3]

On the basis of mechanism of injury, gunshot wounds are more likely to cause a large neck hematoma and vascular injury (27%) compared with stab wounds (15%).[3] Shotgun wounds, blast injuries, and transcervical (crossing midline) gunshot wounds have a higher rate of vascular injury and should be approached with a high index of suspicion. Associated injuries to the tracheobronchial tree, esophagus, and spinal cord are present in 1% to 7% of patients.[3] In addition to hard signs of a vascular injury, patients may present with hard signs of a tracheobronchial injury (respiratory distress or air bubbling from the wound), mandating operative exploration. Other soft signs of cervical neck injury include painful swallowing, subcutaneous emphysema, hematemesis, and signs of nerve injury (cranial nerves IX, X, XI, and XII) or brachial plexus injury (axillary, musculocutaneous, radial, median, and ulnar nerves). A focused and detailed clinical evaluation reliably identifies patients with vascular injuries that require treatment. A physical examination with normal findings has a negative predictive value of 90% to 100% for vascular injuries.[4]

Special consideration should be given to patients who present with coma, a dense hemispheric stroke, or documented carotid thrombosis. The treatment of this specific injury pattern has come full circle from revascularization in the 1950s, to routine ligation in the 1970s, followed by revascularization as the current mainstay of treatment. In the 1970s, authors reported only a few patients with dense hemispheric stroke who developed hemorrhagic stroke after revascularization, leading to the recommendation of internal carotid artery ligation distal to the thrombus.[5-7] Follow-up studies demonstrated that the extent of anoxic brain injury (not hemorrhagic conversion of the injury), development of reperfusion injury, cerebral edema, and resultant uncal herniation accounted for patients with worsening neurologic status and death.[8,9] However, to date, there is no preoperative marker other than time (>24 hours from time of injury) that predicts those patients unlikely to benefit from revascularization. Early revascularization has consistently demonstrated improvement or stabilization of neurologic symptoms in patients with dense hemispheric strokes (100%), even in patients who present obtunded (50%).[1,10]

Diagnostic Evaluation

Patients with hard signs of a vascular injury should proceed to the operative suite. All patients should have plain radiographs of the neck and chest to determine the track of the injury and to diagnose occult hemothoraces or pneumothoraces. There have been several advances in the treatment of penetrating neck injuries, and data are now sufficient to support selective exploration in hemodynamically stable patients who do not have hard signs of a vascular or tracheobronchial injury. Exploration of cervical injuries based on platysma muscle penetration carries an unacceptably high negative exploration rate of 50% to 90%.[11]

CT is the modern workhorse for trauma evaluation and should be the initial diagnostic step in evaluating patients with penetrating neck injuries who do not have hard signs of vascular or aerodigestive injury. Contrasted axial imaging with reformatting software allows exact determination of the injury track, vascular injuries, proximity to the esophagus and trachea, spinal fractures and cord involvement, and extension into the head or chest (Fig. 181.2). In the setting of penetrating cervical injuries, computed tomographic angiography (CTA) has a 90% sensitivity and 100% specificity for vascular injuries that require treatment.[12,13] CTA may be limited secondary to missile fragments (especially shotgun injuries) or bone fragments obscuring

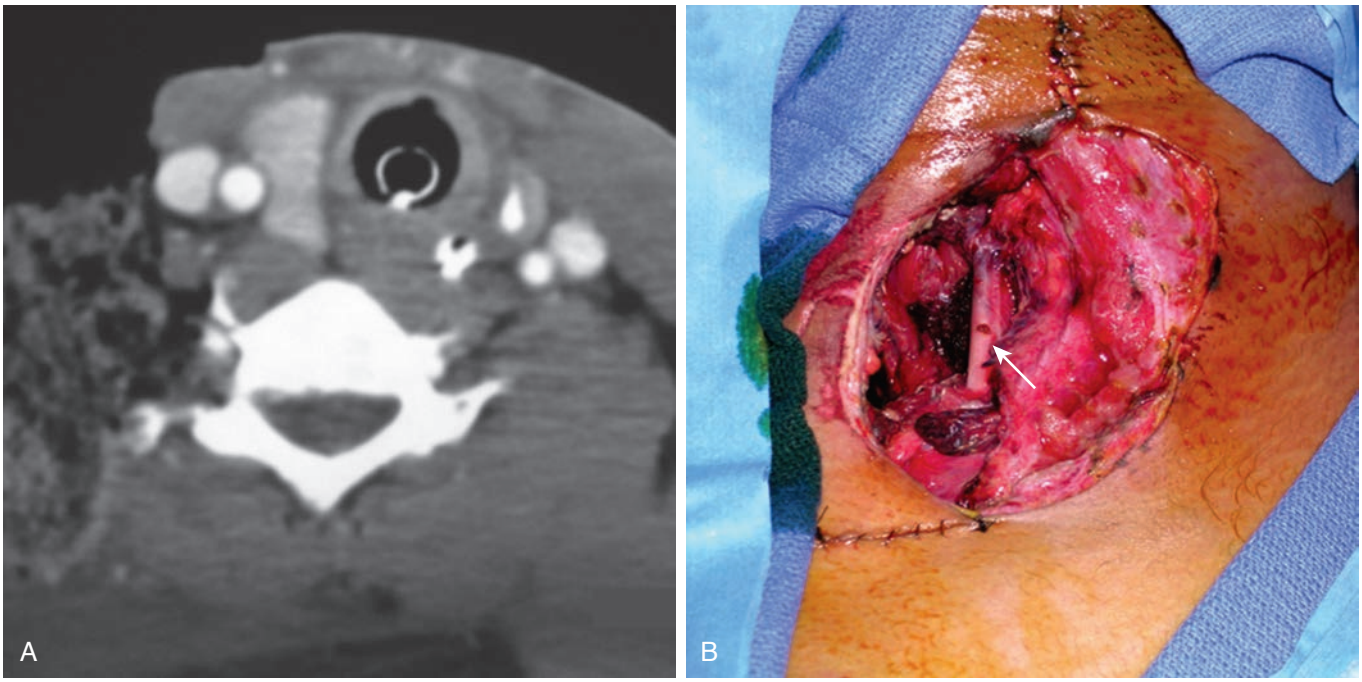

Figure 181.2 This patient sustained a high-velocity gunshot wound to zone I of the neck. On initial evaluation, he did not have hard signs of a vascular injury. (A) Computed tomographic angiography demonstrates no injury to the internal jugular vein or common carotid artery. In addition, there is no injury to the aerodigestive tract. (B) The patient's wound was débrided in the operative suite; the *arrow* marks the cords of the brachial plexus.

the cervical vasculature; arteriography should be used for these patients as a confirmatory study. Ultrasonography has been used for penetrating neck trauma, but its utility is limited to zone II neck injuries.[14] In addition, subcutaneous air, fragments, and hematomas make ultrasound less reliable.

Medical Treatment (Nonoperative Management)

Occult injuries (intimal flaps, dissections, and pseudoaneurysms) identified during evaluation for penetrating cervical injury should be managed just as those caused by blunt trauma (detailed later). Isolated intimal flaps are rare in penetrating trauma, and dissections occur in only 2% of cases. Pseudoaneurysms are the most common occult injury identified. Large pseudoaneurysms should be considered for early intervention, whereas small pseudoaneurysms should be treated with antithrombotic therapy and early follow-up imaging. The natural history of these lesions is not known; however, patients should be closely monitored for development of embolic symptoms.

Endovascular Treatment

An endoluminal approach to neck injuries may avoid the morbidity of median sternotomy, a high thoracic incision, or difficult dissection at the base of the skull. Another benefit is that endoluminal therapy can be performed under local anesthesia, allowing the provider direct assessment of the patient's neurologic status. For zone I and zone III injuries, endovascular exclusion of a pseudoaneurysm, partial transection, or arteriovenous fistula remains a viable option based on the location of injury and the patient's clinical status. Self-expanding covered stents can be safely delivered to these locations with limited morbidity.[15-18] Zone II injuries should be approached with operative repair.

Surgical Treatment

Proximal and Distal Control in the Neck

Obtaining control of the injury in each zone presents unique challenges. All patients should have their proximal thighs (potential vein conduit) and chest (potential proximal control) prepared into the operative field. Zone I injuries that are manifested with hard signs may be approached through a cervical incision, but a median sternotomy or high anterolateral thoracotomy will be required to obtain proximal control. If the patient is in shock, endovascular attempts at proximal control should not delay performing a median sternotomy. Depending on the patient's hemodynamics and the location of injury, proximal control of the great vessels may be performed from a femoral approach in the operative suite with balloon occlusion (a large 33-mm compliant balloon catheter). Alternatively, if the proximal vessel can be visualized from a cervical approach but not secured with a vascular clamp, a compliant balloon or Fogarty catheter can be passed retrograde for temporary proximal control. After the vessel is properly exposed, the balloon can be replaced with a vascular clamp.

An overt injury in zone II can be readily approached through a cervical incision and repair performed under direct visualization. The most common vessel injured by penetrating mechanisms is the internal jugular vein, followed by the common carotid artery. The operative feasibility, ability to examine the aerodigestive tract, and relatively low risk to exploration in this region

favor open exploration over endovascular techniques in emergent situations.

Hemorrhage from a zone III injury can be devastating, and an immediate operative exploration through a cervical incision can be used first to control inflow and to assess the injury pattern. Even after subluxation of the mandible and division of the posterior belly of the digastric muscle, the distal extent of the injury may not be visualized. If the vessel is transected with inadequate length for clamp application, distal control can be obtained by placing a Fogarty balloon (No. 3-4) within the vessel lumen. If the vessel is lacerated, a sheath can be placed in the common carotid artery and a Fogarty catheter can be passed antegrade through the injury to control backbleeding. After the Fogarty balloon is inflated, arteriography can be performed through the side arm of the sheath to delineate the injury with respect to the skull base and further guide operative exposure. After hemorrhage is arrested, the surgeon must decide whether to proceed with operative repair, embolization of the carotid artery, endoluminal stenting, or temporary shunting or to return the patient to the intensive care unit for resuscitation, imaging of the brain, and delayed repair. If a damage control approach is used, the patient should have serial imaging to evaluate evolving cerebral edema, and cerebral perfusion pressures should guide further resuscitative maneuvers.

Surgical Repair of Cervical Vessels

After the injury has been delineated and controlled, the surgeon must decide whether to ligate, repair, or temporarily shunt the vessel. The internal jugular vein and external carotid artery may be ligated with limited morbidity. Ligation of the internal carotid artery results in a 45% mortality,[1] and it should be reserved only for injuries at the base of the skull that are not amenable to reconstruction. Clean-based lacerations caused by stab wounds may be repaired primarily; however, gunshot wounds, fragmentation wounds, and shotgun injuries typically require reconstruction of the common carotid or internal carotid artery. Shunts should be used in patients who are already at risk of cerebral hypoperfusion secondary to shock and to all injuries of the internal carotid artery. If the distal clamp can be placed below the carotid bulb, the internal carotid artery will receive adequate backbleeding through the external carotid artery. Heparin (50 units/kg) should be given before clamps are placed.

The greater saphenous vein has good size match with the internal carotid artery and, when used as an interposition graft, has demonstrated excellent patency and limited infectious risk. The external carotid artery can also be transposed to the internal carotid artery for injuries in the proximal internal carotid. In addition, superficial femoral artery can be used in the common or internal carotid artery but requires an additional reconstruction in the lower extremity with polytetrafluoroethylene (PTFE).[19] PTFE or Dacron typically has a better size match than the greater saphenous vein in the common carotid artery, and in this location, there is no difference in patency rates between the conduits. In the setting of associated aerodigestive injuries, autogenous conduits should be used, the esophageal repair should be drained away from the vascular repair, and a muscle pedicle (cervical strap muscles, omohyoid muscle, digastric muscle, or sternal head of the sternocleidomastoid) should be placed between the two repairs.

After repair of the vascular injury, all patients must be monitored for signs of cerebral edema and intracranial hypertension. If a clinical neurologic examination cannot be performed, direct intracerebral pressure monitoring or serial head imaging should be obtained.

Blunt Cerebrovascular Injuries

The overall incidence of blunt cerebrovascular injury (BCVI) has been universally reported as less than 1% of all trauma admissions for blunt trauma, but this relatively small population of patients has stroke rates ranging from 25% to 58% and mortality rates of 31% to 59%.[20-22] The variability in incidence of BCVI is 0.19% to 0.67% for unscreened populations compared with 0.6% to 1.07% for screened populations.[20]

Clinical Presentation

The recognition and treatment of BCVI have dramatically evolved during the past 2 decades. As imaging technology has improved with respect to both image quality and acquisition times, its use has become a fundamental diagnostic tool in blunt trauma evaluation. Paralleling advances in noninvasive imaging, a heightened awareness of BCVI has emerged. Through aggressive screening, these injuries have increasingly been recognized before devastating neurologic ischemia results.

Mechanism of Blunt Cerebrovascular Injury

Three basic mechanisms of injury are encountered: (1) extreme hyperextension and rotation, (2) a direct blow to the vessel, and (3) vessel laceration by adjacent bone fractures.[23] The most common mechanism causing blunt carotid injury is hyperextension of the carotid vessels over the lateral articular processes of C1-3 at the base of the skull, which is typically a result of high-speed automobile crashes. There are also scattered case reports of chiropractic manipulation[24] and rapid head turning with exercise causing BCVI.[25] A direct blow to the artery typically occurs in the setting of a misplaced seat belt across the neck during a motor vehicle crash or in the setting of hanging. This injury pattern typically occurs in the proximal internal carotid artery as opposed to the distal aspect. Basilar skull fractures involving the petrous or sphenoid portions of the carotid canal can injure the vessel at this location.

Common mechanisms of injury associated with BCVI include motor vehicle crash (41% to 70%), direct cervical blow (10% to 20%), automobile versus pedestrian (12% to 18%), fall from height (5% to 15%), and hanging events (5%).[20,22] Most common associated injuries at the time of diagnosis include closed head injuries (50% to 65%), facial fractures (60%), cervical spine fractures (50%), and thoracic injuries (40% to 51%).[20,22]

Signs and Symptoms of Blunt Cerebrovascular Injury

Case reports, as early as 1967, described BCVI with recognized symptoms of cerebral ischemia, and all patients were symptomatic

at the time of diagnosis.[26] Carotid injuries typically are manifested with a contralateral sensory or motor deficit, decreased mental status, or neurologic deficits not explained by closed head injury. A carotid-cavernous fistula may be manifested with orbital pain, proptosis, hyperemia, cerebral swelling, or seizure. Depending on whether the vessel is occluded or whether the resultant injury is a nidus for embolic events, the symptoms may be variable. Patients typically have coexisting traumatic brain injuries that may mask signs and symptoms of BCVI.

Patients may present to the trauma center with obvious signs of BCVI; however, many patients are initially asymptomatic and subsequently develop symptoms after a latent period. Several authors have reported times from 1 hour to several weeks after injury before the development of symptoms.[27-30] Evaluating an unscreened trauma population, Berne et al. found a median time to diagnosis of 12.5 hours for survivors of BCVI and 19.5 hours for nonsurvivors, suggesting a sufficient window of opportunity for diagnosis and treatment.[22] Neither admission Glasgow Coma Scale score nor baseline neurologic examination correlates with subsequent development of symptoms attributed to BCVI.

Screening for Blunt Cerebrovascular Injury

Although there is no consensus on the ideal screening protocol, several authors have found associations with signs, symptoms, and risk factors identified on admission. The first and most comprehensive screening protocol was initiated at the Denver Health Medical Center. The criteria are listed in Table 181.1.[20,31] With this screening protocol, the authors reported an overall BCVI incidence of 0.86%. Exactly 4.8% of all trauma patients were screened on the basis of defined risk criteria, and 18% of screened patients were found to have an injury. Fifty-two percent of these screened patients were asymptomatic. Neurologic morbidity was 16%, and BCVI-associated mortality was 15%.[20] Using the Memphis criteria (see Table 181.1), they found an incidence of 1.03%; 3.5% of all blunt trauma patients were screened, and 29% of screened patients were found to have an injury.[32] Both screening regimens mandated four-vessel cerebral angiography if the patient met at least one of the screening criteria.

Several authors have evaluated a more restricted screening protocol in an effort to reduce the cost of screening and to limit the number of examinations with normal findings. A cervical seat belt sign has been evaluated in several prospective studies and has not been found to be predictive of BCVI.[20,33] Biffl et al. performed a multivariate analysis on a prospectively screened population and found four independent risk factors for BCVI, listed in Table 181.1.[34] Patients with one factor had a 41% risk of BCVI; two factors, 56% to 74%; three factors, 80% to 88%; and all four factors, 93%. However, 20% of patients with BCVI did not have any of the four risk factors. The bulk of the available literature supports an appropriate screening protocol for BCVI, and all major trauma centers should have predetermined screening criteria for BCVI.

Diagnostic Evaluation

Duplex Ultrasound

Duplex scanning has been evaluated in multiple trauma centers for diagnosis of BCVI. In the evaluation of carotid artery stenosis, duplex ultrasound is limited when lesions of less than 60% stenosis are evaluated; likewise, duplex ultrasound will not often

TABLE 181.1 Screening Criteria for Blunt Cerebrovascular Injury

	Denver Criteria[a]	Memphis Criteria[b]	Modified Criteria[c] (Odds Ratio)
Signs and symptoms	Arterial hemorrhage or expanding hematoma	Neurologic examination findings not explained by brain imaging	GCS score <6 (1.98)
	Cervical bruit	Horner syndrome	
	Neurologic examination findings inconsistent with head CT findings	Neck soft tissue injury (seat belt sign, hanging, or hematoma)	
	Stroke on follow-up head CT		
	Focal neurologic deficit		
Risk factors	Le Fort II or III fracture pattern	Le Fort II or III fracture pattern	Le Fort II or III fracture pattern (3.7)
	Basilar skull fracture with involvement of the carotid canal	Basilar skull fracture with involvement of the carotid canal	Petrous fracture (2.64)
	Diffuse axonal injury with GCS score <6	Cervical spine fracture	Diffuse axonal injury (3.09)
	Cervical spine fracture		
	Near-hanging with anoxic brain injury

identify small intimal tears or nonocclusive dissections. It is often difficult to obtain adequate visualization of the internal carotid artery at the base of the skull, where the majority of these injuries occur. The sensitivity of duplex ultrasound for detection of BCVI ranges from 38% to 86%[29,35]; therefore, it should not be used as a screening modality.

Digital Subtraction Angiography

Selective digital subtraction angiography (DSA) has, in the past, been considered the diagnostic "gold standard" for screening patients with suspected BCVI. The Denver group proposed an angiographic grading system for BCVI (Table 181.2), which has become the standard for reporting BCVI.[36] Most important, the grading scale held prognostic value for patients' future risk of subsequent stroke.

There are several limitations of DSA that make it a difficult diagnostic tool. First and foremost, it is an invasive procedure with technical limitations and a complication profile that carries a risk of stroke (<1.0%).[20] Performing screening DSA on all patients at risk of BCVI may impose a large economic and workload burden on the angiography suite; some institutions cannot support this type of demand.

Computed Tomographic Angiography

Helical CTA offers several potential advantages over conventional DSA and should now be considered the gold standard diagnostic modality. It is a noninvasive study that can be obtained in less than 5 minutes, and, as opposed to cerebral angiography, CTA obtains three-dimensional images of the vessel wall (Fig. 181.3). In addition, the workup of blunt trauma patients will inevitably involve CT imaging of the head, chest, abdomen, or all of these. CTA of the carotid-vertebral circulation can easily be obtained during this examination, sacrificing little in time (60 seconds per scan), contrast burden (approximately 100 mL), or radiation exposure.

The ability to use CTA for screening depends on the quality of the scanner at the host institution. Using early-generation single-slice and four-slice CT scanners, two prospective comparative studies (performed by the Denver and Memphis groups) found CTA to have a sensitivity of 47% to 68% and specificity of 67% to 99% compared with DSA.[32,37] CTA missed 55% of grade I, 14% of grade II, and 13% of grade III injuries.[37] CTA technology rapidly improved during the ensuing years, such that the number of detectors progressively increased and postimaging processing became readily available. Bub et al. prospectively compared multidetector CTA (four- and eight-slice scanners) with DSA and found a sensitivity of 83%to 92% and a specificity of 88% to 98% from three different radiologists.[38] The interobserver reliability was also higher for CTA than for DSA.

In 2005 Biffl et al. reported their experience using 16-slice CTA for the diagnosis of BCVI, and contrary to the prior study in Denver disqualifying early-generation CT scanners, DSA was not used as the gold standard.[39] During an 11-month period, 331 patients were screened, and 5.4% were diagnosed with BCVI. In this final study, CTA scans with normal findings were followed with clinical observation, and no patients developed neurologic symptoms consistent with delayed presentation of missed BCVI. All abnormal examination findings were confirmed with DSA. Of the 18 injuries identified by CTA, 17 were correctly graded, whereas one patient was upstaged to grade III on DSA (a small pseudoaneurysm was not identified on CTA; false-positive rate of 1.2%).[39] In 2006 a prospective comparative study validated 16-slice CTA as a primary screening modality for BCVI.[40] In this report, CTA was performed in addition to DSA in 162 consecutive patients; 20 carotid and

Figure 181.3 This three-dimensional computed tomographic angiography reconstruction with bone subtraction demonstrates occlusion of the right internal carotid artery. This patient presented with a zone II neck hematoma and a seat belt mark across the right side of the neck after an automobile crash. The *arrow* marks the occlusion at the origin of the internal carotid artery.

26 vertebral injuries were diagnosed. In that population, this resulted in an incidence of 1.25% and a screening yield of 28%, which is comparable with historic controls. CTA and DSA were 100% concordant for blunt carotid injuries, resulting in a sensitivity of 100% and a specificity of 100%.[40] This is the only study comparing conventional 16-slice CTA directly with DSA and demonstrating equivalence. On the basis of these findings, a minimum of 16-slice CTA should be considered the primary screening modality for BCVI. However, many authorities still remain passionate that DSA should be the primary screening test of choice for patients with BCVI.[41]

In 2009 the initiation of a CTA-based screening and diagnostic program at one institution, along with interdisciplinary standardized treatment guidelines, reduced the time to diagnosis of BCVI 12-fold and the institutional stroke rate due to BCVI 4fold. The authors concluded that this effect may be due to earlier diagnosis and initiation of definitive therapy.[42]

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is an attractive noninvasive modality because of the resolution of images obtained in this anatomic region, the infinite number of projections of the vessel, and the ability to assess the intracranial architecture for signs of stroke.[43,44] Limitations include availability and the time required for image acquisition. This modality is thus impractical in a trauma patient with multiple competing injuries. In comparative studies of DSA versus MRA, MRA performs poorly, with sensitivities of 50% to 95%.[32,45] The latest report is from 2002, and improved technology may therefore change the role of MRA in BCVI.

Medical Treatment

The mainstay for treatment for BCVI is antithrombotic therapy; however, there are no randomized controlled trials to support this recommendation. Fabian et al. reported the first prospective observational study demonstrating improved neurologic outcome associated with early use of antithrombotic therapy.[21] Their analysis revealed the benefit of heparin therapy for decreasing the rate of neurologic deterioration after symptoms developed and decreasing the rate of new neurologic events. Heparin therapy was associated with a dramatic reduction in neurologic morbidity (29%) compared with no treatment (73%). Biffl et al. confirmed that patients benefited from early anticoagulation, documenting the greatest benefit to patients who were asymptomatic at the time of heparinization.[20] In the asymptomatic group, only one patient developed subsequent stroke. On analysis of the symptomatic cohort, 93% of patients had improvement in their neurologic deficits with anticoagulation compared with only 67% without anticoagulation. On the basis of these two studies, anticoagulation became the first line of treatment of BCVI.

Complications associated with anticoagulation range from 25% to 54% in the trauma population.[20] Most concerning is intracranial hemorrhage, but more common are gastrointestinal bleeds, retroperitoneal hemorrhage, blunt solid organ injury with hemorrhage, and rebleeding from surgical wounds. Eachempati et al. noted that few patients were able to receive heparin therapy at the time of BCVI diagnosis (14%), and they found a complication rate of 16% among those who received heparin therapy.[46] Because of the complication profile of full anticoagulation therapy, several authors have focused on antiplatelet therapy as an alternative to traditional anticoagulation.

A prospective comparison of antiplatelet therapy with anticoagulation for BCVI does not exist. There is one study by Biffl et al. that reported anticoagulation (heparin with transition to Coumadin) to be superior to antiplatelet therapy (aspirin or clopidogrel), with stroke rates of 1% versus 9%.[20] Several follow-up studies have failed to confirm this result. Miller et al. found that resultant stroke rates after BCVI treated with heparin therapy and antiplatelet therapy (5% and 3%, respectively) were similar.[47] Follow-up studies further demonstrated no difference in stroke rates for those patients treated with heparin (5% to 8%) compared with those treated with antiplatelet therapy (3% to 7%).[31,32,48]

Either heparin or antiplatelet therapy can be used with similar results. If the patient has no contraindications to anticoagulation, a prudent protocol would be heparin therapy (goal activated partial thromboplastin time of 50 to 60 seconds) and transition to Coumadin (goal international normalized ratio of 2.0) for 3 months. Antiplatelet therapy should be used for the same time period.

All patients who are medically treated should undergo serial CTA or DSA at 1-week and 3-month follow-up. At 3-month follow-up, one can expect 72% of grade I injuries to completely heal.[49] Grade II injuries are fairly evenly distributed: 33% improve, 33% are stable, and 33% progress to pseudoaneurysms.[49] Grade III injuries tend either to remain unchanged (50%) or to enlarge (40%). Grade IV injuries universally did not improve and probably do not warrant follow-up imaging after discharge.[49]

Endovascular Treatment

Endovascular therapy has primarily been reserved for evolving dissections that are surgically inaccessible, pseudoaneurysms that persist or enlarge after antithrombotic treatment, or patients with worsening neurologic symptoms on medical therapy. When patients develop a symptomatic injury, a pseudoaneurysm, or a chronic dissection, endoluminal treatment with either a bare or covered stent is an alternative to open repair.[50,51] Balloon-expandable and self-expanding stents have been used in this location, and in all cases, apposition of the dissection to the wall was achieved with no neurologic events reported.[51,52]

Follow-up imaging of BCVI treated with antithrombotic therapy is imperative. Pseudoaneurysms are unlikely to resolve with medical management,[53] and 33% of acute nonocclusive dissections treated with anticoagulation develop pseudoaneurysms on follow-up arteriography.[21] These lesions have a low risk of rupture, but they tend to be the source of chronic embolic events or thrombosis.[54,55]

Because of the potential for embolic stroke and their failure to resolve with antithrombotic therapy, pseudoaneurysms that fail to resolve, enlarge, or result in ischemic complications should be excluded from the cerebral circulation. Based on the location of these injuries in the distal internal carotid artery, endovascular therapy offers several advantages over open repair. Self-expanding

covered stents can be safely delivered to these locations with limited morbidity.[15-18]

Initial reports from Parodi et al. relied on balloon-expandable bare Palmaz stents (Cordis Johnson & Johnson, Miami Lakes, Florida) to cover the orifice of the pseudoaneurysm.[56] Covering the orifice will typically promote thrombosis of the pseudoaneurysm, but if the sac fails to thrombose, an option has been to coil embolize the sac through the interstices of the bare stent.[57] In these series the mean follow-up was 3.5 years without neurologic sequelae, but thrombosis and embolic potential, as well as the potential for restenosis, remain a concern after endovascular placement of devices in the carotid artery.[58] Although thromboembolic complications are most common immediately after stent placement, patients should be committed to lifelong follow-up for unforeseen complications, such as stent fracture.[59] Post-stent therapy is variable, but on extrapolation of data from carotid artery stenting for atherosclerotic disease, a regimen of dual antiplatelet therapy (aspirin and clopidogrel) appears adequate to prevent stent thrombosis and embolic ischemic events.[60] If antiplatelet therapy is discontinued, stent thrombosis and resultant stroke are inherent risks.[16]

The enthusiasm for carotid stenting for BCVI paralleled advances in carotid stenting platforms used for carotid artery stenosis. There are several positive case reports followed by sporadic case series in the literature. However, Cothren et al. provided a sobering report highlighting the risk of stent thrombosis. They evaluated blunt carotid pseudoaneurysms (grade III) persisting 7 to 10 days after injury in 46 patients; 92% were asymptomatic. Twenty-three patients were excluded with carotid Wall stents, and 23 patients were treated with either antiplatelet or anticoagulation therapy.[61] Three (13%) periprocedural ischemic complications occurred. Eight (45%) in the carotid stent group experienced carotid artery occlusion during follow-up, and only 1 (4%) in the medical treatment group experienced carotid artery occlusion.[61] This is the highest rate of carotid stent occlusion published, and it demonstrates the challenges of stenting a dissected artery at the skull base.

As opposed to the experience of Cothren et al., Edwards et al. placed 22 carotid stents for BCVI; 18 patients had pseudoaneurysms, and 4 patients were treated for extensive dissections. They experienced no periprocedural complications. Twelve patients were treated with postprocedural antiplatelet therapy, and eight received anticoagulation. With a mean angiographic follow-up of 7 months, none were occluded (100% patency).[49] The variance in outcomes can be explained by the challenges of treating this injury pattern.

Follow-up for this patient cohort is imperative, and further prospective studies with long-term follow-up are needed to determine the risks and efficacy of carotid stents for BCVI. Compliance with medications and follow-up surveillance should be considered in planning appropriate therapy for trauma patients.

Surgical Treatment

The indications for surgical intervention parallel those for endovascular intervention.[21,62] Patients with evolving dissections, pseudoaneurysms that persist or enlarge after antithrombotic treatment, or patients with worsening neurologic symptoms should undergo repair. Whether an open repair or endovascular repair is used should be based on the patient's associated injuries, the location of the injury, the ability to comply with the antiplatelet regimen, and the ability to achieve long-term follow-up.

Schievink et al. have addressed blunt carotid pseudoaneurysms with operative repair in 22 patients.[63] To exclude the lesions, 5 patients required carotid ligation, 13 underwent resection with reconstruction, and 4 required cervical to intracranial carotid bypass. In their series, two patients experienced ischemic stroke, and the most common complication was cranial nerve neurapraxia secondary to high surgical exposure. This series illustrates the difficulty of treating these lesions at the base of the skull and the resultant morbidity.

If the injury is located at the base of the skull, the only option for treatment may be endovascular exclusion. When the lesion is located in the proximal internal carotid or common carotid artery, the vessel should be approached by an anterior exposure. The vessel may be repaired primarily or, more commonly, by patch angioplasty with either greater saphenous vein or prosthetic material.

VERTEBRAL ARTERIES

Vertebral artery injuries are rare occurrences, with an incidence of 0.20% to 0.77% of all trauma admissions.[20,21] Although injuries to the first portion (V1) of the vertebral artery are readily accessible, those to the second portion (V2, within the bony foramen of the cervical canal), the third portion (V3, as the vessel exits the bony foramen and enters the base of the skull), and the fourth portion (V4, intracranial segment to the basilar artery) can be extremely difficult to control.

Clinical Presentation

Penetrating injuries are most commonly due to gunshot wounds and stab wounds.[64] Life-threatening hemorrhage is rare from an isolated vertebral injury (mortality, 4%); however, penetrating injuries frequently involve the common carotid artery, subclavian artery, internal jugular vein, and subclavian vein, which may be life threatening. Patients typically are asymptomatic or complain of associated neurologic injury secondary to either compression from hematoma or direct injury.[64]

The most common mechanism for blunt vertebral artery injury is fracture of the transverse foramen through which the vessel courses (vertebrae C2-6).[65] The vertebral vessels are relatively fixed throughout the vertebral canal, making the V2 segment susceptible to hyperextension and stretch injuries. Because of the rich collateral circulation in the neck, unilateral vertebral artery injuries are often asymptomatic in 80% of cases. With regard to dissections, patients may complain of subtle neck pain or posterior headache. Vertebrobasilar ischemia may be manifested with protean symptoms, including dizziness, vertigo, nausea, tinnitus, dysarthria, dysphagia, ataxia, visual deficits, and hoarseness. The degree of ischemia is determined by the extent of distal propagation into the basilar or posterior

inferior cerebellar arteries. Patients with bilateral vertebral artery injuries may present with more severe symptoms: coma, fixed pupils, and loss of respiratory drive. Approximately 25% of patients will have bilateral blunt vertebral artery injuries, and 33% will have an associated blunt carotid injury.[66]

Diagnostic Evaluation

Vertebral artery injury typically is manifested with penetrating neck injury. If the patient presents with refractory shock, with hard signs of a vascular injury, or with hard signs of a tracheal injury (continuous air bubbling from the wound), the management is straightforward, and the injury should be diagnosed in the operating room. Plain films in the emergency department are useful for determining the track of the missile and any foreign bodies within the wound. Hemodynamically stable patients with a normal Glasgow Coma Scale score who do not have hard signs of a vascular injury should undergo CTA of the neck. The provider should also include the head and chest in the evaluation of the injury to fully evaluate associated injuries and to identify the track of the missile or knife. This mechanism of injury should also prompt a high suspicion for aerodigestive injuries, which may require additional evaluation (bronchoscopy, rigid esophagoscopy, or upper gastrointestinal swallow studies).

Blunt vertebral artery injuries were originally diagnosed by DSA, and the same grading criteria (see Table 181.2) were applied to the vertebral artery as for the carotid artery. In contrast to blunt carotid injuries, grade of blunt vertebral artery injuries does not correlate with increasing risk of stroke. The stroke risk of blunt vertebral artery injuries is 20% irrespective of grade.[66] The same controversy about screening and imaging surrounds the evaluation of blunt vertebral artery injuries. The same screening criteria used for blunt carotid trauma (see Table 181.1) are applied to blunt vertebral artery injuries; however, cervical spine fracture is the only factor that is independently associated with blunt vertebral artery injuries (odds ratio, 14.5).[34]

All imaging modalities are less accurate for diagnosis of blunt vertebral artery injuries compared with carotid injuries. Duplex evaluation of the vertebral vessels is extremely limited; however, with color-flow imaging, the operator can assess for vessel patency. MRA has the previously stated limitations in the setting of trauma. In the evaluation of blunt vertebral artery injuries, CTA has a sensitivity and specificity of 40% to 60% and 90% to 97%, respectively.[38] If there is a high index of suspicion based on cervical fracture, a confirmatory study should be obtained. MRA is an acceptable option when it is available; however, if concern persists, DSA should be performed.

Medical Treatment

Medical management has no role for penetrating injuries, but it does have a role for blunt injuries identified during the diagnostic evaluation. The posterior circulation stroke rate attributed to blunt vertebral artery injury is 24%, with an associated mortality of 8%.[66] Symptomatic patients should be treated with heparin and monitored for hemorrhagic conversion with serial neurologic examinations. Heparin therapy was first evaluated in asymptomatic patients and found to reduce neurologic events in the posterior circulation from 20% to 35% (no anticoagulation) to 0% to 14% (heparin therapy).[47,66] In patients who could not tolerate anticoagulation, the efficacy of heparin was similar to that of aspirin. Follow-up studies increasingly used aspirin secondary to the bleeding complications associated with heparin therapy. Miller et al. treated 43 vertebral artery injuries; 32 patients received aspirin or clopidogrel, and only 8 patients received heparin therapy.[47] None of the patients developed stroke. Symptomatic patients or those patients without contraindications to anticoagulation should be treated with 3 to 6 months of anticoagulation with radiographic follow-up. Asymptomatic patients should be treated with either 3 to 6 months of anticoagulation or dual antiplatelet therapy; data are insufficient for one treatment to be recommended at this time.

Endovascular Treatment

Endovascular treatment of the vertebral artery is used for uncontrolled hemorrhage not controlled with surgery, backbleeding from the V3 segment, pseudoaneurysm, and symptomatic patients who cannot tolerate anticoagulation (Fig. 181.4). The endovascular technique of crossing the vertebral artery confluence at the basilar artery is technically challenging, but when possible, both proximal and distal ends of the transected or lacerated vessel should be treated with embolization. If the vessel is intact, the injury may be crossed from an antegrade approach, allowing embolization of both the outflow and inflow (trap-door technique). In nearly half of vertebral artery injuries evaluated with endovascular techniques, the vessel was thrombosed and required no treatment at all.[67] Preservation of the vertebral artery may be a concern when other extracranial blood supply has also been compromised. In these complex cases, endovascular stenting of the vertebral artery has been performed as a salvage procedure.[47] There are no data to support routine stenting for blunt vertebral artery injuries.

Surgical Treatment

Operative management is reserved for patients with active bleeding from the vertebral artery at the time of neck exploration. In a review of the largest series of penetrating vertebral artery injuries, 50% of patients who underwent open exploration required postoperative endoluminal embolization to arrest bleeding or to control arteriovenous fistulas.[67] Controlling the vertebral artery can be challenging for even the most experienced trauma or vascular surgeon. Unilateral surgical ligation results in a stroke rate of 3% to 5%.[68]

The approach is the same as that described previously for exploration of the carotid artery. Once the sternocleidomastoid muscle has been retracted laterally, the V1 segment can be visualized by transecting the sternocleidomastoid muscle from the sternum and clavicle. Next, the internal jugular vein is identified, and laterally, the scalene fat pad is divided vertically, with care taken to identify and protect the phrenic nerve coursing lateral to medial across the anterior scalene muscle. Division

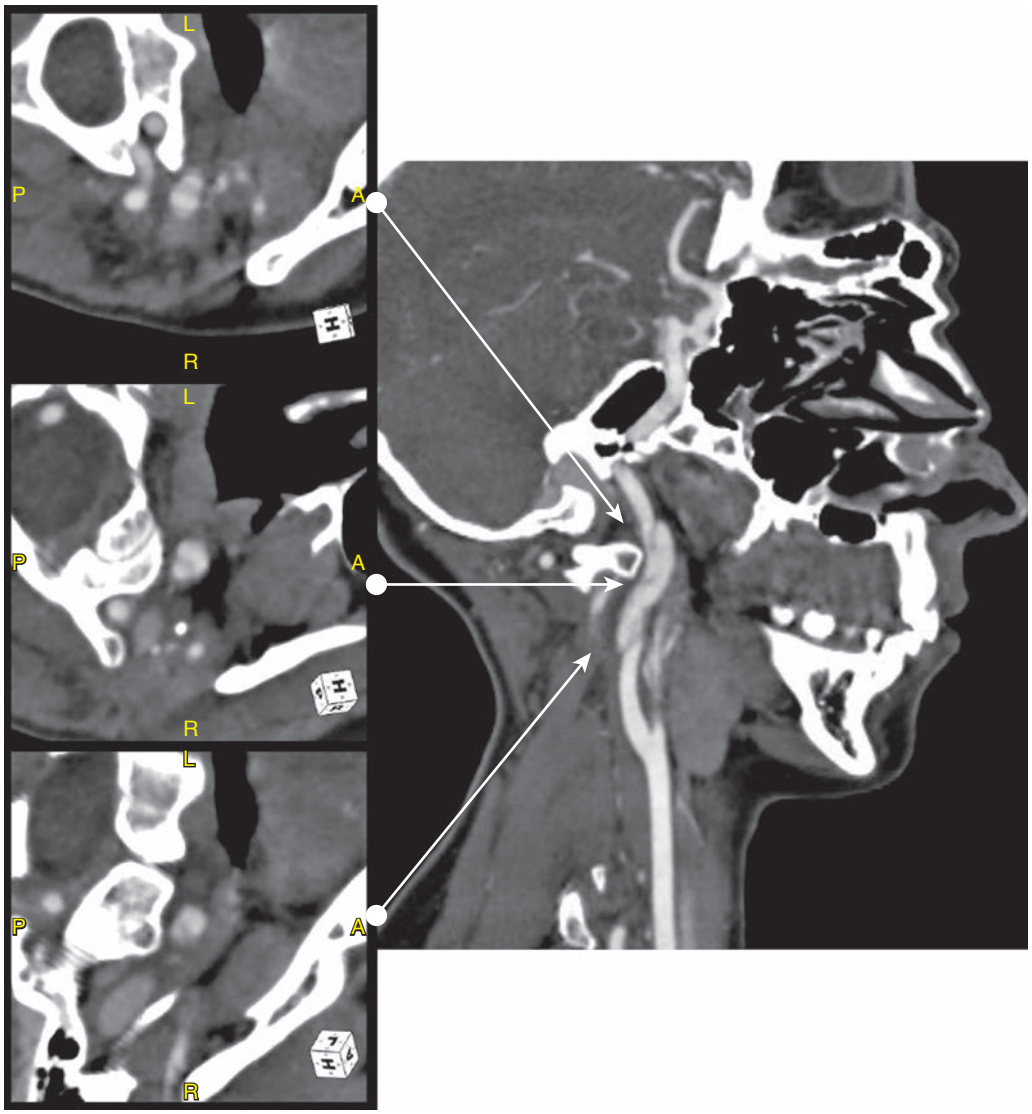

Figure 181.4 Patient suffered a high-speed motor vehicle accident with resultant bilateral internal carotid artery dissections. She was treated with antiplatelet therapy, and then repeat axial imaging on hospital day 7 demonstrated a complex right internal carotid artery dissection which extends up to C1. The dissection measures 3.8 cm in length, and the axial images at three separate locations demonstrate a patent flow lumen.

of the anterior scalene muscle from the first rib allows visualization of the first portion of the subclavian artery and the origin of the vertebral artery, thyrocervical trunk, and internal mammary artery. On the right side, the recurrent laryngeal nerve should be protected, and care should be taken on the left side to avoid injury to the thoracic duct. Partial manubrium and clavicle resection can gain exposure in this location.

The V2 segment is more challenging to control, and most surgeons should simply ligate the proximal V1 segment as repair of the vertebral artery is futile and exposure of the V2 segment is fraught with venous bleeding. Exposure of V2 involves retracting the sternocleidomastoid muscle laterally, dividing the omohyoid muscle, and retracting the carotid sheath medially. Identification of the cervical spinal bodies and the associated prevertebral fascia is mandatory. The sympathetic chain ganglia should be protected as they course through this region. Longitudinal opening of the anterior longitudinal ligament and paraspinous muscles allows identification of the transverse process of the spinal bodies. Removal of the anterior aspect of the transverse processes by use of a handheld rongeur allows exposure of the vertebral artery. Posterior to the vessel lie the cervical nerve roots. Hemorrhage in this location should be controlled with proximal ligation of V1. Bone wax can be packed into the bony canal, and postoperative embolization of the distal vertebral artery may be performed if needed.

Most vascular and trauma surgeons are unfamiliar with the V3 segment at the base of the skull. Rather than a timely dissection, the patient may be better served by proximal ligation of the V1 segment, packing of the wound (with bone wax, gauze, or balloon occlusion), and then endoluminal embolization. To expose the V3 segment for ligation, the incision is extended posteriorly behind the ear onto the mastoid process.[69] The

sternocleidomastoid muscle is retracted medially and may be divided from the skull base. During this step, the spinal accessory nerve should be identified and preserved. The transverse process of C1 is identified anterior and below the mastoid process. The muscle attachments to C1 and C2 are cleared with a periosteal elevator, and then, after resection of the lateral process of C1, the vertebral artery is exposed.

SUBCLAVIAN ARTERY

Injuries to the thoracic outlet are extremely lethal. Prehospital mortality is 50% to 80%, and of those who survive transport, 15% die during treatment.[70]

Clinical Presentation

Blunt injuries to the subclavian vessels are extremely rare, but when they occur, patients typically have associated clavicular fractures, mediastinal injuries, and pulmonary contusions. Penetrating injuries account for the majority of trauma to the subclavian vessels; in one US trauma center, gunshot wounds accounted for 74% and stab wounds accounted for 26% of injuries.[71] These patients often present to the emergency department in cardiac arrest, and consideration for resuscitative thoracotomy must be based on time from injury and signs of life. Those patients who survive transport may present with hard signs of vascular injury as described earlier, which mandate immediate operative exploration. All other patients with soft signs of a vascular injury should have further diagnostic evaluation. A normal radial pulse does not reliably exclude an upper extremity vascular injury. Concomitant cervical and thoracic injuries are common in 70% of patients.

The upper extremities rarely suffer from ischemia because of the intense collateral circulation; the long-term morbidity of these injuries is secondary to brachial plexus injuries. Brachial plexus injuries can be caused by penetrating injuries that directly transect nerve roots; blunt injuries that result in shear or traction forces; and operative exposure, which can result in iatrogenic injury. Blunt injury to the brachial plexus is typically secondary to stretch injuries to the upper extremity or bone fractures.

Diagnostic Evaluation

In the unstable patient, there are few options other than immediate exploration, but because of the fibrous attachments surrounding the subclavian vessels, injuries will frequently result in a contained extrapleural hematoma that may extend into the supraclavicular fossa. If time allows, CTA can be invaluable to identify the location of injury and to evaluate the mediastinum. Hemodynamically stable patients with asymmetrical pulses or neurologic deficits should undergo evaluation with CTA, including the chest, neck, and upper extremity. Injury to the axillary vessels can range from intimal disruption to pseudoaneurysms, dissection, and even thrombosis. In addition, axial imaging will appropriately evaluate the mediastinum, cervical vasculature, and associated bone fractures.

Medical Treatment

Intimal disruptions and dissections that are not flow limiting should be treated with clinical observation. Anticoagulation or antiplatelet therapy may be added at the discretion of the surgeon. If the patient develops embolic symptoms, antithrombotic therapy should be instituted with arteriography of the injury.

Endovascular Treatment

Endovascular treatment in this area can obviate the need for an extensive dissection at the base of the neck. Covered stent-grafts have been increasingly used in this location, with several authors reporting immediate technical success for treatment of pseudoaneurysms, lacerations, arteriovenous fistulas, and even complete transections (Fig. 181.5).[72-74] Approximately 42% to 50% of patients are candidates for endovascular treatment.

These injuries may be approached from a transfemoral, transbrachial, or combined technique. Acute thromboses in patients with malperfusion symptoms can be treated through a retrograde brachial approach, and after flow is restored, a covered stent can be used to treat the injury. Most transected vessels can be crossed with a hydrophilic wire. Undoubtedly, endovascular techniques reduce the morbidity of operative exposure and potential nerve injury in a blood-stained field. There are relatively few contraindications to this approach. The patient must be hemodynamically stable. Some consider a large supraclavicular hematoma with brachial plexus compression a relative contraindication; however, the injury may be treated with a covered stent followed by hematoma evacuation in a controlled field.

The mobility and compression between the first rib and clavicle raise concern about long-term patency in the young trauma population; it is imperative to observe these patients for late sequelae. In addition, endovascular repair does not preclude stent explantation with formal open repair; this approach would ideally reduce the potential for iatrogenic nerve injury in the acute setting. In one of the largest reported series, three early stent thromboses were encountered in 56 patients.[72] All three were opened with a secondary intervention, and no patient experienced upper extremity ischemia.[72] Endovascular therapy in the thoracic outlet offers a less invasive, rapid treatment and has the added benefit of avoiding injury to the brachial plexus, which has long-term implications for a functional recovery.

Surgical Treatment

Injuries to the thoracic outlet can be difficult to expose in an acute setting; it is important to prepare the neck, chest, and groin into the surgical field. Proximal control requires either a median sternotomy for the innominate and right subclavian arteries or a high left anterolateral thoracotomy with potential clavicular resection for the left subclavian artery. Rather than direct exploration of the hematoma, a remote occlusion balloon can be placed either from the groin or retrograde from the brachial artery. In doing so, the surgeon can perform arteriography, and with

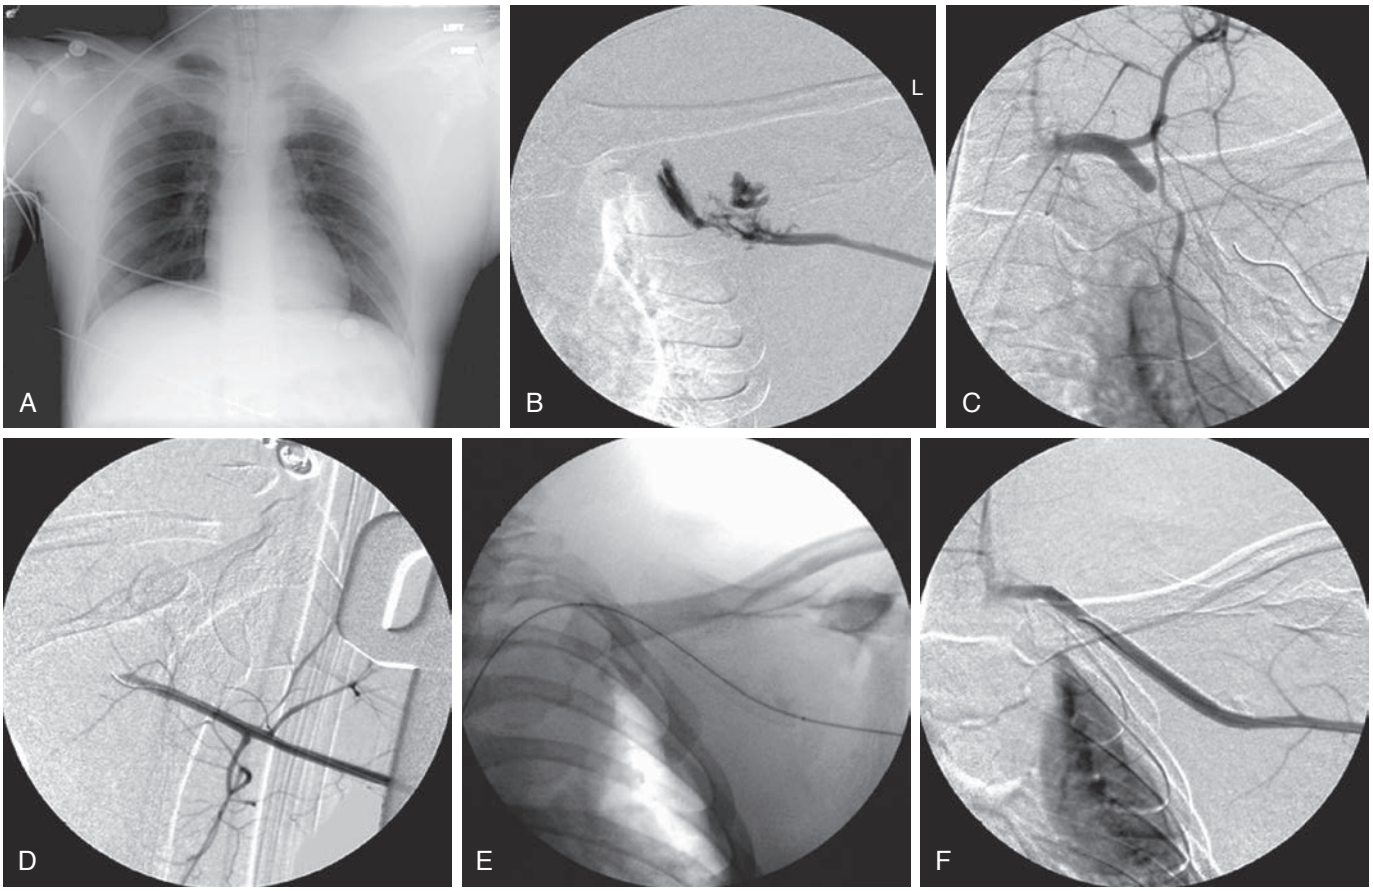

Figure 181.5 Blunt subclavian artery transection. (A) The patient presented with a large stable hematoma in the supraclavicular fossa extending into the axilla after a high-speed motorcycle crash. The chest radiograph demonstrates the soft tissue density over the left clavicle. (B) From the left brachial approach, there is extravasation at the level of the subclavian to axillary artery junction. (C) From the right groin, left subclavian artery selective angiography was performed. (D) A curved Glidewire was used to cross the transection. (E) Once the transection was crossed, the brachial wire was snared within the hematoma, obtaining femoral-brachial wire access. The transection was treated with a covered stent. (F) Completion angiogram demonstrates complete exclusion of the transected segment and no residual extravasation.

proximal control, the operative tempo changes from emergent to semiurgent. Either an endovascular treatment can ensue, or the surgeon can proceed with a meticulous dissection at the base of the neck and avoid either a sternotomy or thoracic incision.

If the patient is in extremis, subclavian artery ligation rarely results in upper extremity ischemia. When the vessel is repaired, the injury typically requires an interposition graft. PTFE works well in this location and has excellent patency.[75,76] If the field is grossly contaminated, saphenous vein, internal jugular vein, and superficial femoral artery have all been used in this location. Nearly 50% of penetrating subclavian injuries will have an associated subclavian vein injury in addition to the arterial injury.[75]

CERVICAL VENOUS INJURIES

Venous injuries to the neck and thoracic outlet are invariably due to penetrating injuries. Blunt venous injuries are extremely rare and should be considered with sternal and clavicle fractures. Venous injuries to the internal jugular vein occur in 20% of penetrating neck trauma, and subclavian vein injuries occur in 50% of penetrating subclavian injuries.[76,77]

Clinical Presentation

When patients present in extremis, the venous injury is typically identified in the operative suite. Isolated venous injuries are manifested with hard or soft signs of a vascular injury, but patients are rarely hypotensive.[78]

Diagnostic Evaluation

The diagnostic evaluation should parallel the evaluation described before for each arterial anatomic region. If the patient undergoes CTA for a suspected vascular injury, delayed acquisition (ranging from 30 seconds to 3 minutes) will provide improved imaging of the venous anatomy once the contrast material has cleared the associated arterial anatomy.

Endovascular Treatment

Endovascular stents have increasingly been used in the central venous system for subclavian and superior vena cava chronic thromboses. The efficacy of covered stents for venous trauma has been described only in case reports, with good technical results.[79,80] This technology will be increasingly used for isolated venous injuries in hemodynamically stable patients.

Surgical Treatment

The surgical approach to each vein is identical to the arterial exposure described earlier. If the patient has hard signs of a vascular injury and is in extremis, the neck and subclavian veins can be ligated with limited morbidity. If the internal jugular vein is ligated, the patient should be monitored for cerebral edema, but this is a rare occurrence even with bilateral internal jugular vein ligation. Internal jugular vein reconstructions (with either spiral vein grafts or externally reinforced PTFE) in the setting of bilateral neck dissections have an 18-month patency of 64%; elevated stump pressures (>30 mm Hg) may improve patency.[81] When the subclavian vein is ligated, the upper extremity should be elevated and placed in compression; transient edema typically resolves during the course of 7 to 10 days, and long-term venous stasis is rare.[77] Simple lacerations of the vein can be repaired with lateral venorrhaphy if less than 50% of the wall is involved.[77] All repairs are at risk of eventual thrombosis; mechanical and chemical thromboprophylaxis should be considered. Extensive vein repairs (end to end, venous interposition, or spiral/panel grafts) typically do not have a role in penetrating neck injuries (as opposed to lower extremity injuries) when time is critical.

INTRODUCTION

Thoracic injuries are common sequelae of both blunt and penetrating trauma, with blunt thoracic injuries proving responsible for approximately 8% of all trauma admissions in the United States, with motor vehicle crashes being the most common mechanism.[1-4] Penetrating injuries are also commonly encountered, with one report from a high-volume, urban trauma center[3] identifying penetrating chest trauma among 7% of all trauma admissions and 16% of all penetrating trauma admissions overall.

Despite the prevalence of thoracic injury following trauma, the majority of patients presenting with these injuries will not require thoracic operative intervention. Appropriate utilization of tube thoracostomy and comprehensive inpatient management will prove definitive treatment for the majority of patients with these injuries. Even among penetrating mechanisms, only 14% of stab wounds and 15% to 20% of gunshot wounds to the chest require operative intervention for thoracic injury.[3]

It is important to note, however, that vascular injury occurring within the thoracic region continues to be associated with high mortality,[1-4] with many patients likely not surviving to reach a facility capable of providing care.[5-7] Among those who do present to trauma centers, however, the continued evolution of imaging capabilities and improved approaches for nonoperative and operative management continue to improve the care of these patients.[5-8] Significant progress has been made over the last two decades in the diagnosis and treatment of thoracic vascular injuries. This paradigm shift includes the widespread use of computed tomography angiography (CTA) for diagnosis, aggressive blood pressure control, delayed repair for stable patients, adoption of endovascular repair as the treatment modality of choice for anatomically suitable candidates, and medical management of minimal aortic injuries. These advances have significantly improved the outcomes of patients with thoracic vascular trauma. Nevertheless, the effective treatment of these injuries requires careful consideration of treatment dilemmas, thoughtful decision-making, a comprehensive appreciation of

Abstract

Blunt thoracic aortic injury (BTAI) and major thoracic vascular injuries remain serious events following trauma. Considerable advances have been made in the diagnosis, medical management, and operative repair of these injuries. In particular, endovascular adjuncts have emerged as critical tools in appropriate selected patients.

anatomic relationships within the thoracic cavity, and prompt operative intervention when indicated. This chapter summarizes the current diagnosis and management of thoracic vascular injuries.

Presentation and Evaluation

Any patient with significant blunt chest trauma or penetrating injury around the thoracic cavity is at risk for vascular injury. The patient may provide useful history, but often this information is provided by prehospital personnel. The mechanism of injury, time from injury, vital signs, and neurologic status at the scene, as well as any changes during transport, are critical. With blunt injury specifics, such as prolonged extrication, the location and degree of occupant compartment vehicle deformation may provide useful information. With penetrating trauma, the specific details are typically vague and often unreliable.

Evaluation proceeds according to the Advanced Trauma Life Support guidelines, and potentially life-threatening conditions are immediately treated. As with any trauma patient, thorax trauma may necessitate intubation for airway control. While these patients require evaluation and imaging for potential neurologic, intraabdominal, or extremity trauma, the discussion herein will focus largely on the diagnosis and characterization of thoracic vascular injuries. Physical examination, which should be performed both rapidly and thoroughly, has been shown to be reliable and can often help make the diagnosis. The presence of distended neck veins, tracheal deviation, subcutaneous emphysema, chest wall instability, absent breath sounds, or muffled heart sounds may all provide crucial information. Likewise, the absence of an upper extremity pulse suggests a proximal arterial injury. Vital signs should be frequently monitored with careful observation of the work of breathing and arterial saturation. Overall, the most common thoracic injuries are hemothorax and/or pneumothorax. However, rapid diagnosis of vascular injury is likely paramount to success in most instances.

Penetrating thoracic trauma in a hemodynamically unstable patient warrants operative intervention. The decision regarding surgical exposure may be problematic, especially if there is concomitant abdominal injury. Clinical judgment is paramount in this situation. The hemodynamically stable patient may benefit from additional imaging, especially chest computed tomography, which provides more detailed and organ-specific information.[9]

IMAGING

Plain radiography of the chest remains the most commonly utilized initial radiographic imaging following thoracic trauma. An adequate plain film should make the diagnosis of any large hemothorax or pneumothorax. Since screening chest x-rays (CXRs) are usually performed supine, however, hemothorax can be somewhat difficult to adequately diagnose. Haziness of one hemithorax, when compared with the other, may be the only real radiographic sign. If this is of any substance, a chest tube should be placed.

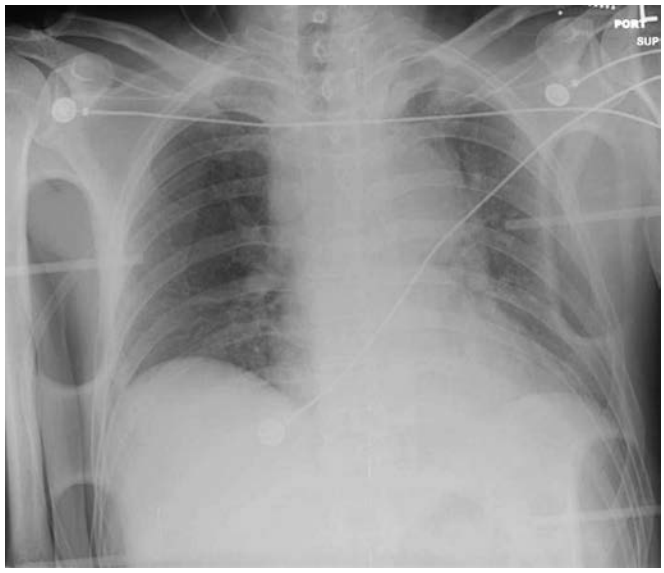

Figure 182.1 Chest radiograph of a patient with blunt thoracic aortic injury showing a widened mediastinum and obliteration of the aortic knob.

A CXR may also allow the clinician to evaluate the mediastinum for the possibility of a blunt traumatic aortic injury (BTAI; Fig. 182.1). A variety of clinical findings may prove suggestive of BTAI, including widened mediastinum, apical capping, or loss of normal radiographic cardiac or aortic arch silhouette. It is important to note, however, that plain chest radiography in this setting is neither specific nor sensitive for the presence of BTAI. A recent study by Gutierrez and colleagues[10] at Los Angeles County Hospital found that among 3728 trauma patients admitted to their facility over 2 years, 200 patients (5.4%) had an abnormal CXR on arrival. From the same overall group, 17 BTAIs were identified by CTA. Only seven of the CTA-confirmed BTAI patients had any mediastinal abnormality on CXR, for a sensitivity of CXR of only 41%. These findings highlight an improved understanding that CXR alone is not a reliable screening modality for BTAI. They also emphasize the need for careful consideration of other factors—including mechanism of injury—in determining those who need subsequent CTA imaging after trauma.

In the modern era, CTA has become a tool of trauma evaluation that is liberally employed. Computed tomography (CT) protocols that utilize angiographic contrast are ubiquitous to initial evaluation protocol of most major trauma centers, and have specific benefits with regard to the diagnosis and characterization of vascular injury. This imaging modality, particularly with the advent of advanced multi-slice imaging capabilities, affords both precise evaluation of the aorta and other vascular structures of the chest. Postimaging processing can also rapidly and effectively provide good resolution—three-dimensional evaluation of the thoracic vascular structures.[11-13] CTA of a patient with BTAI is shown in (Fig. 182.2). Intravascular ultrasound (IVUS) provides real-time, 360-degree imaging of the aorta using a high-frequency (10 MHz), miniature ultrasound probe placed through a femoral arterial sheath (Fig. 182.3).[14] IVUS is a useful tool for evaluation of traumatic aortic injury,

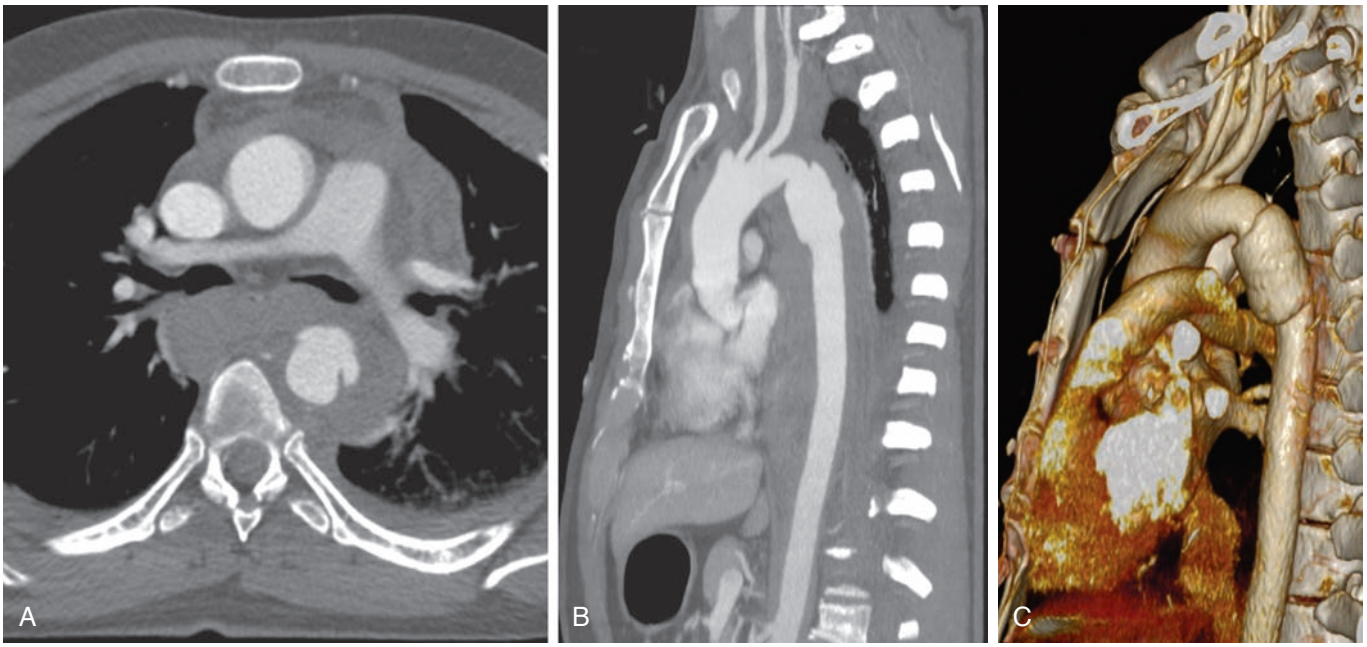

Figure 182.2 Computed tomography angiography of a patient with blunt thoracic aortic injury. (A) Axial view demonstrating the injury and periaortic hematoma. (B) Sagittal view demonstrating the typical location of the injury at the isthmus distal to the left subclavian artery. (C) Three-dimensional computed tomography reconstruction.

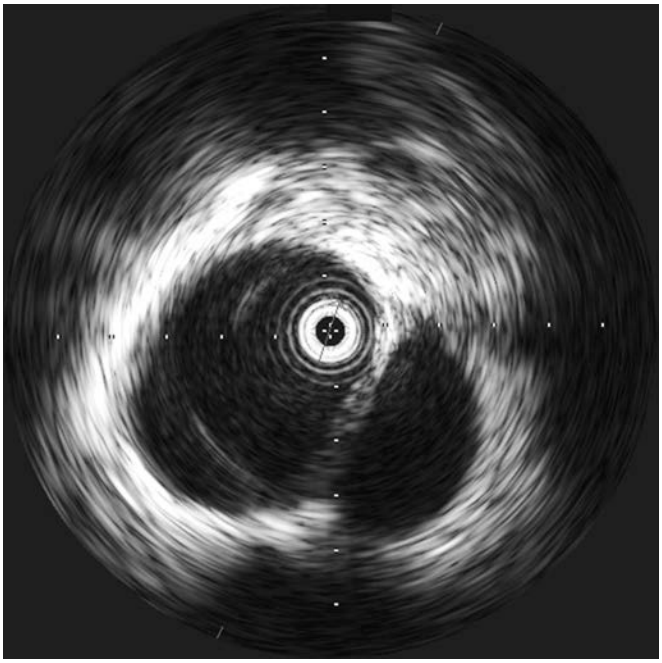

Figure 182.3 Intravascular ultrasound image of a patient with blunt thoracic aortic injury demonstrates a pseudoaneurysm.

especially in cases with equivocal CTA, or in cases of periaortic hematomas in the absence of a direct sign of aortic injury.[15] IVUS does not require contrast or radiation and can be performed concurrently using the same femoral puncture as angiography. The disadvantages of IVUS are additional cost (capital equipment and disposable catheter), larger sheath, and operating room time.[16]

Angiography, once considered the "gold standard" for diagnosis, remains a valuable imaging modality in the management of patients with thoracic vascular trauma. However, it has taken on a therapeutic, rather than purely diagnostic, role, given the wide utilization of CTA. Today, angiograms are more commonly performed in the operating room at the time of definitive repair. Disadvantages include invasive nature, cost, use of intravenous contrast, access site complications, and the need to transport the patient to an angiography suite or operating room (CTAs are commonly performed in the emergency center). There is a small incidence of false-positive angiograms from known anatomic abnormalities, such as ductus diverticulum and aberrant brachiocephalic arteries.[17,18]

Indications for Emergent Operation

While the vast majority of traumatic thoracic injuries can be managed nonoperatively, surgery may be indicated emergently, urgently, or in a delayed fashion. Indications for emergent operation thoracic exploration include shock with a penetrating chest injury, initial chest tube output of 1500 cc, or persistent chest tube output of 250 cc/h for 3 hours. There is likely a linear relationship between the total amount of thoracic hemorrhage and mortality, necessitating a familiarity of the treating surgeon with the most common exposures that will be required in an emergent setting. The patient's overall clinical condition and astute surgical judgment are of paramount importance when deciding to operate and what type of surgical exposure or approach to utilize.

Open Surgical Exposure/Incisions

There are several surgical approaches to the thorax, each with advantages and disadvantages for emergent trauma applications.

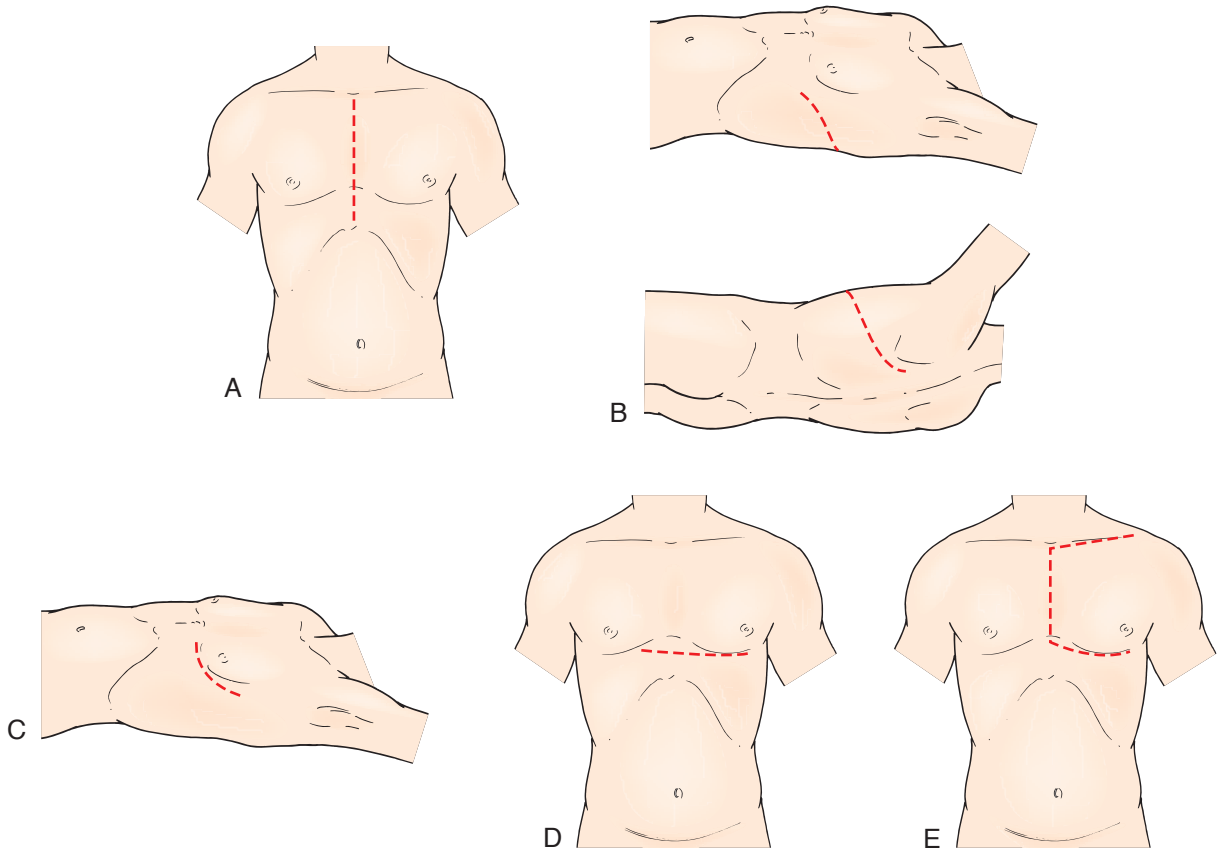

Figure 182.4 Incisions for thoracic trauma. (A) Median sternotomy with right or left neck extensions can be used to treat injuries to the heart, proximal aorta, innominate, and left carotid arteries. (B) Left posterolateral thoracotomy for repair of descending thoracic aortic injuries. (C) Left anterolateral thoracotomy for patients in extremis (ED thoracotomy); also provides access to the left subclavian artery. (D) Extension of the anterolateral thoracotomy to the opposite chest as a "clamshell" incision. (E) "Book" thoracotomy.

The surgeon should be familiar will all of them, and the clinical situation should determine the choice of incision. Hemodynamically unstable patients may not tolerate lateral positioning, as it may exacerbate hypotension. In addition, in the emergent exploration of the unstable trauma patient, the only imaging is likely to be portable chest radiograph. In this scenario, the surgeon will have limited knowledge of potential mediastinal involvement, the projectile's path, or additional cavitary involvement. With penetrating thoracic trauma, there is the possibility of injury to adjacent body regions, such as the abdomen and neck. Therefore, a thoracic incision must prove versatile in accommodating flexibility in the conduct of operation. In this setting, incision selection requires careful consideration of the appropriate extensions that can be made to best optimize exposure and control options.

In the stable patient, additional imaging data is more likely to have been obtained. Armed with better understanding of the location and nature of injury, a better decision regarding optimal therapy can be formulated. In the modern endovascular age, this information may facilitate the effective utilization of less-invasive adjuncts. However, knowledge of open surgical options and defaults remain paramount. If open exploration or repair is selected, the choice of incision should be guided by the CT findings.[19]

Commonly employed open operative approaches include anterolateral thoracotomy, posterolateral thoracotomy, and even bilateral thoracotomy (or "clamshell thoracotomy") and median sternotomy (Fig. 182.4). The anterolateral approach is perhaps the most expedient—and extending it across the midline affords excellent exposure to both pleural spaces, the anterior mediastinum and nearly the full complement of thoracic vascular structures. Likewise, the incision can be continued as a celiotomy for abdominal exploration and is preferred over the posterolateral approach in the patient in shock. The main disadvantage of the anterolateral approach is exposure of posterior thoracic structures. By extending the ipsilateral arm and placing a bump to elevate the thorax approximately 20 degrees, the incision can be carried to the axilla—a maneuver that will improve posterior exposure. The posterolateral thoracotomy affords optimal exposure of the hemithorax, especially the posterior structures, and is the standard incision for most elective thorax operations. Its lack of versatility limits the usefulness in trauma, but is the preferred approach to repair any injury pattern that also involves intrathoracic tracheoesophageal injuries. Sternotomy provides excellent access to the heart, proximal great vessels, and anterior mediastinum. This particular incision is versatile—and can be extended as an abdominal, periclavicular, or neck

incision. The "trap door" incision is rarely used, since left-sided thoracic vessels can be approached via sternotomy with extension.[20]

Operative Techniques

Thoracic vascular injuries after significant trauma rarely occur in isolation, particularly after penetrating mechanisms. Therefore, it is useful to appreciate a few key nonvascular operative techniques that may be required during emergent operative exploration. Among patients requiring emergent thoracic exploration, between 20% and 30% will need a pulmonary resection, which ranges from wedge resections to major anatomic resections.[21,22] Pneumonorrhaphy, wedge resection, tractotomy, and formal anatomic resection are all techniques that can be utilized to manage pulmonary parenchymal injury. The trauma surgeon should be facile with all of these techniques, and the choice of a particular one is driven by the patient's clinical condition and the extent and location of the pulmonary injury. The widespread adoption of a variety of surgical staplers has facilitated tractotomy and pulmonary resections. Pneumonorrhaphy is the simplest technique and is applicable to superficial pulmonary lacerations. These can be closed with a running simple or mattress suture. Injuries near the lung periphery can be excised by a stapled wedge resection. The lung is mobilized, any adhesions are lysed, and the inferior pulmonary ligament may need to be divided to improve lower lobe exposure. A stapled wedge resection is performed by grasping the parenchyma with a lung clamp and firing the stapler to excise the peripheral tissue. Tractotomy is rapid and ideal for through-and-through parenchymal injuries.[23] Placing the jaws of the stapler through the tract and firing it will open the tissue. Bleeding vessels or air leaks can then be individually ligated. Tissue thickness will determine the appropriate size staples, and at times, the staple line needs to be over sewn with a running suture.

More centrally located injuries, especially those close to the hilum, require special consideration. Precise understanding of the pulmonary vasculature and hilar anatomy are necessary to safely perform a stapled resection for centrally located injuries. If a nonanatomic resection is precluded, as with extensively damaged lung parenchyma, a formal lobectomy is necessary. Hilar injuries present a significant challenge. Hemorrhagic shock is invariably present, and the injury necessitates pneumonectomy, which carries a prohibitive mortality. Several techniques can be used to obtain hilar control, including lung torsion, manual compression, and application of a vascular clamp. Manual compression followed by clamping is the most widely used. Very proximal hilar injures are particularly problematic, and opening the pericardium will occasionally allow vascular control.

MANAGEMENT OF SPECIFIC THORACIC VASCULAR INJURIES

Blunt Thoracic Aortic Injury

BTAI remains the second-most frequent cause of mortality after blunt force.[24,25] A recent autopsy study conducted by Teixeira and colleagues at Los Angeles County Hospital identified thoracic aortic injury (TAI) as a contributor in onethird of automobile accident deaths. National Vital Statistics data suggest that the majority of deaths due to BTAI after these blunt mechanisms occur prior to the arrival to a hospital facility.[26]

Among patients who survive to receive care, continued medical advances have improved the ability to expediently diagnose and effectively treat TAI. Thoracic endovascular aortic repair (TEVAR) has emerged as the primary treatment modality utilized for TAI among amenable patients, gradually replacing traditional open repair (OR) as the dominant surgical treatment modality.[13,27-41] Among patients with severe BTAI, the subsequent use of TEVAR has been associated with improved morbidity and mortality compared with traditional OR approaches.[13,27-30] Given these results, and following a 2011 analysis of the accumulated literature, the Clinical Practice Guidelines from the Society for Vascular Surgery (SVS) suggested that "endovascular repair be performed preferentially over open surgical repair or nonoperative management."[38]

Diagnosis

The clinical presentation of TAI can vary considerably. On arrival to a treating facility, patients may be asymptomatic or complain of pain in the chest or radiating to the neck, back, or shoulder. Hemodynamics may range from normotensive to frank shock, with hypotension being a common sign.[42]

The initial diagnostic test of choice is the plain CXR, which has a number of findings that are suggestive—but not confirmatory—of the diagnosis. On initial plain radiography, a widened or otherwise abnormal appearing mediastinum may be seen in up to 93% of patients with TAI.[43,44] Various definitions have been utilized to define pathologic widening of the mediastinum on plain radiography. These have included an 8 cm wide mediastinum at the level of the aortic knob, or a width at the same level that exceeds 25% of the total chest width.[43,44] It is imperative, however, that any visualized abnormality undergo advanced imaging, particularly in the context of suspicious mechanisms of injury. It is also important to appreciate that a normal plain chest radiograph does not exclude TAI and—as previously discussed—has a low sensitivity for this purpose.[10]

Over the last decade, CTA of the chest has emerged as the most commonly employed initial imaging tool for the diagnosis of or evaluation for BTAI, with a high documented sensitivity (95% to 100%) and concomitant high negative predictive value (99% to 100%) following trauma.[45-47] False positives do occur, however, particularly among lower grade injuries. In an examination of patients undergoing traditional angiogram after CTA, Bruckner and colleagues noted that CTA had an appreciably low specificity of 40% and a positive predictive value of only 15%.[47] Despite these findings, the majority of studies have validated the utilization of CTA after trauma due to the high sensitivity and ability to exclude blunt TAI with very high negative predictive value when CTA is utilized in this setting.[45-47]

Classification/Grading

BTAIs represent a spectrum of lesions that range from intimal tears to free rupture. The mechanism often involves rapid deceleration, where the greatest point of strain is at the aortic isthmus (Fig. 182.5). Classification is based on the extent of injury to the anatomic layers of the aortic wall. Based on imaging, BTAI is classified into four grades: intimal tears (grade 1); intramural hematoma (grade 2); pseudoaneurysm (grade 3); and rupture (grade 4; Fig. 182.6).[30,38] Grade 1 injuries do not cause an external aortic contour abnormality and are best visualized on CTA or IVUS. Angiograms in grade 1 patients can be interpreted as normal. Injuries involving the media, such as intramural hematomas or dissections, are considered grade 2. Grade 2 injuries cause an abnormality in the aortic contour and can be visualized on CTA, IVUS, or angiography. Pseudoaneurysms and ruptures (grade 3 and 4) are easily visualized with all imaging modalities. Additional classification systems based on contemporary imaging have also been proposed.[30,48-52] Accurate diagnosis (grade) of BTAI is critical because it affects management decisions and is an important tool in evaluating outcomes.

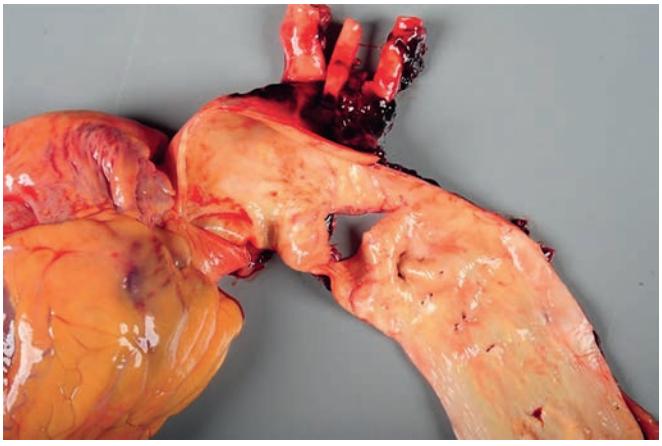

Figure 182.5 Postmortem aorta with injury in the descending aorta at the isthmus.

Blunt Thoracic Aortic Injury Treatment—Medical Therapy

Immediate management of all BTAI injuries, either as definitive therapy or during preparation for repair, includes aggressive blood pressure control. Effective pharmacologic suppression of aortic pressure fluctuations is utilized to reduce the stress on the injured aortic wall. These efforts have been shown to potentially reduce the risk of aortic rupture after BTAI diagnosis from 12% to 1.5%.[53] For grade 1 injuries, medical management alone is the mainstay of definitive therapy. For grade 2, 3, and 4 injuries, the SVS guidelines suggest medical management be utilized as a bridge to subsequent repair.

The optimal blood pressure goal and control regimen has not been well established, with different institutions having proposed various approaches. Fabian et al.[54] suggested the use of an intravenous beta-blocker to keep blood pressure at or below a recommended figure of 100 mm Hg or a mean below 80 mm Hg. The group also proposed the addition of an intravenous vasodilator if the beta-blocker was adequate on its own, as a monotherapy to control blood pressure. At our institution, we utilize a target goal of less than 120 mm Hg systolic blood pressure, most commonly achieved with titrated continuous beta-blockade infusion as tolerated.

It is important to consider that specific patterns of associated traumatic injury may affect the ability to employ medical therapy for BTAI. Specifically, patients with traumatic brain injury requiring optimization of cerebral perfusion pressure (CPP) may require elevation of blood pressure to optimize neurologic outcome. This required elevation is counter to the medical management of BTAI and may necessitate earlier intervention for aortic injury to facilitate optimal brain injury outcome. Given the common complexity of severely injured trauma patients, it is advisable that all discussions about the appropriateness of medical therapy and timing of potential BTAI repair be undertaken in a collaborative fashion by the key stakeholders in care.

The managing team must also remain vigilant for other indications to abort medical therapy, including obvious signs of malperfusion or possible early progression of BTAI while undergoing medical management. In the largest retrospective, multicenter series of BTAI patients to date, the Aortic Trauma

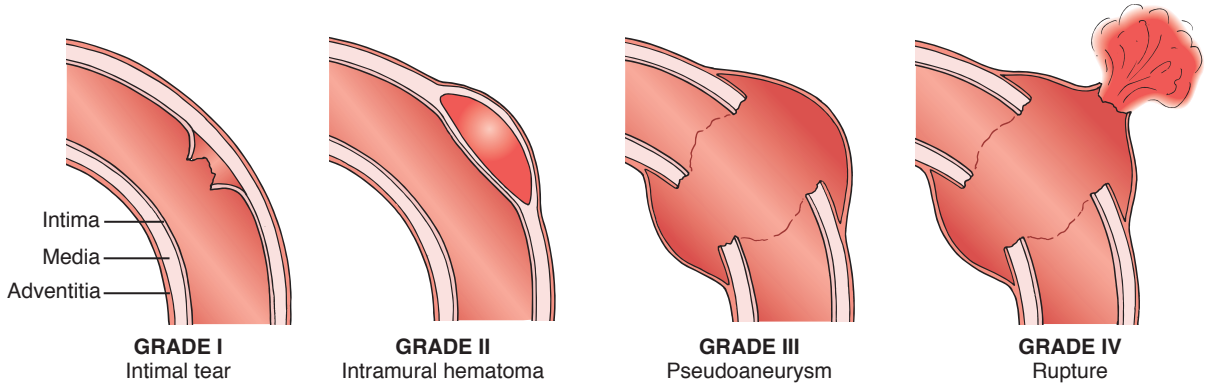

Figure 182.6 Classification of traumatic aortic injury.

Foundation (ATF) study group noted that medical therapy alone was selected for 32.2% of patients. Only two in-hospital failures of medical therapy were noted in the population studied, both undergoing subsequent endovascular salvage repair without complication.[13]

Blunt Thoracic Aortic Injury Repair

While prompt repair of BTAI is preferred, existing data suggest that selective delayed repair may result in optimal outcomes.[31] This approach is commonly required among trauma patients, requiring treatment of more immediately life-threatening injuries, such as laparotomy or emergent craniotomy—a common occurrence among the severely injured cohort.[5,13] Until definitive intervention for BTAI is undertaken, medical management of blood pressure control is performed in an appropriate intensive care. The subsequent timing of definitive repair is then individualized for the specific patient through a multidisciplinary, decision-making process.

Once the optimal timing of intervention for the individual patient has been established, endovascular repair has emerged as the mainstay of subsequent definitive BTAI treatment in the modern era. The evolution in endovascular technologies occurring over the last decade or more has afforded that TEVAR can be safely and effectively performed in the majority of patients with BTAI. In the largest multicenter retrospective BTAI examination to date, conducted by the ATF between 2008 and 2013,[13] TEVAR was the treatment utilized for 76.4% of the 382 BTAI patients studied, with only 23.6% requiring OR.

Documented improved outcomes following TEVAR for the treatment of BTAI are due both to increased experience with endovascular approaches to treatment and device advances. The first endovascular device approved by the US Food and Drug Administration (FDA) for the treatment of thoracic aortic aneurysms was the Thoracic Aortic Graft (TAG; W.L. Gore & Associates, Flagstaff, Arizona) in 2005. This device was initially used for TEVAR in patients with BTAI in an off-label indication. Subsequent introduction of a variety of on-label FDA approved devices in 2008 has increased the tools available for definitive treatment of these injuries by effective endovascular means.

The technique utilized for endovascular repair at our institution has been described previously.[28] In summary, all endovascular procedures are performed under general anesthesia in a hybrid operating room equipped with fixed imaging equipment (Axiom, Siemens Medical, Malvern, Pennsylvania). Intraoperatively, the abdomen and bilateral groins are prepped in standard fashion. An arch aortogram is performed through femoral access, and the location of the injury is confirmed. The cerebrovascular anatomy is evaluated based on the arch angiogram, especially if left subclavian artery coverage is planned. IVUS is used selectively based on the discretion of the attending surgeon. The patient is anticoagulated using a weight-based heparin protocol if there are no contraindications. Otherwise, a smaller dose of heparin (3000 to 5000 units) is administered.

The thoracic device is selected based on CT images according to the manufacturer's sizing recommendations. Measurements are made based on two-dimensional, thin-cut axial CT scans with IV contrast. The device is delivered and deployed using a standard technique without any pharmacologic adjunct; extension pieces may be deployed as indicated. The subclavian artery is covered, as needed, to obtain a proximal landing zone or gain better apposition with the lesser curvature of the aortic arch. We maintain a policy of selective delayed subclavian artery revascularization for such cases.[55] Postdeployment balloon angioplasty is performed selectively when incomplete apposition of the graft at the proximal landing zone is noted. The heparin is then reversed with protamine. Postoperatively, patients are returned to the surgical-trauma intensive care unit and discharged following stabilization of their other injuries**.** A diagnostic and completion angiogram of a patient with a grade III BTAI is shown (Fig. 182.7). A follow-up CTA shows successful exclusion of the aneurysm.

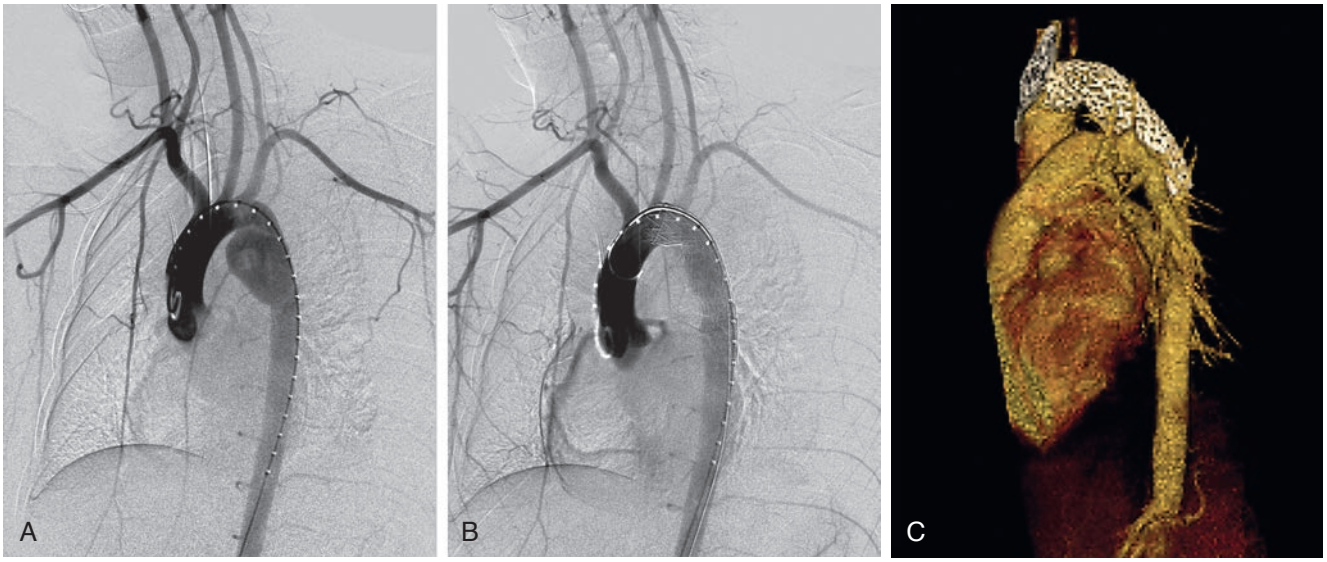

Figure 182.7 (A) Diagnostic and (B) completion angiography of a patient with a grade III blunt thoracic aortic injury. (C) Follow-up computed tomography angiography shows successful exclusion of the aneurysm.

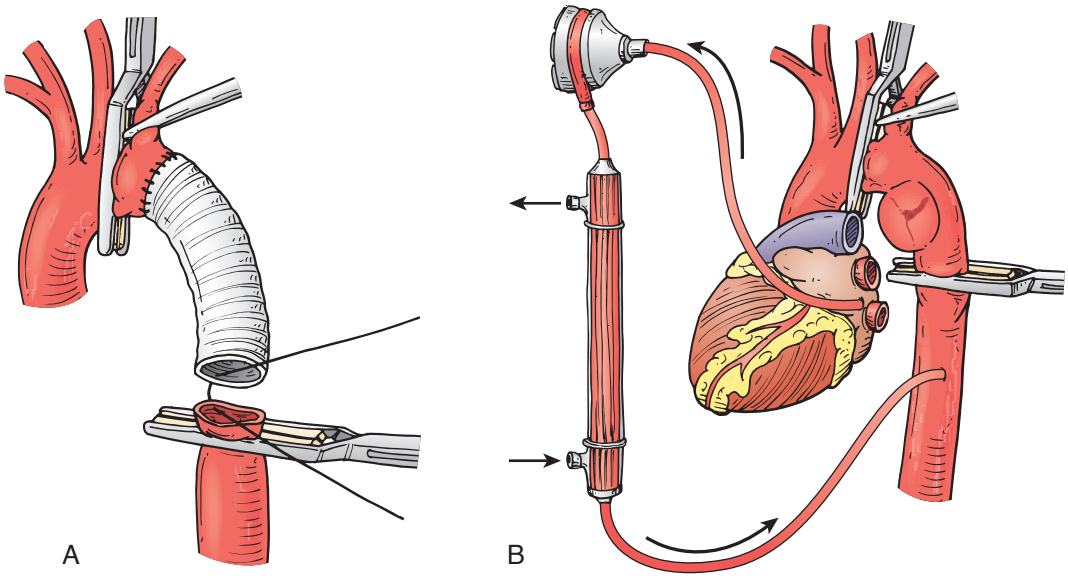

Figure 182.8 Open repair of blunt thoracic aortic injury can be performed using a (A) clamp and sew technique or (B) distal aortic perfusion.

Select patients with unsuitable anatomy or other confounding factors may continue to require open surgical repair. In the modern era, OR is reserved for specific scenarios. Among patients showing signs of hemodynamic compromise and the need for emergent repair, not all facilities will have the capability to martial endovascular resources in the required time frame to optimize outcome. While rapid mobilization of endovascular resources is inherent to many modern trauma centers, local capabilities must be considered.

Other considerations in selecting OR include the consideration of patients anatomically unfavorable for TEVAR. The foremost criteria determining the need for OR is the absence of an adequate proximal landing zone to allow for proper "seal" of the site of injury by the device. In approximately 40% of BTAI patients, left subclavian artery coverage is required to achieve this objective.[13] Available data suggest that the majority of trauma patients requiring left subclavian artery coverage in this setting will have good short- and mid-term outcomes without the need for subsequent bypass.[13,55] Other anatomical criteria that may preclude the ability to safely conduct TEVAR for BTAI include small or diseased iliofemoral vessels, with diameters of these vessels less than 7 mm being a risk factor for access site complications, including dissection, rupture, and hematoma formation.

When OR is required, a number of approaches can be considered to facilitate BTAI treatment, depending on the site and length of the descending thoracic aorta involved. Given that the most commonly encountered location of BTAI is in the region of the isthmus, a left posterolateral thoracotomy to enter the chest through the fourth space is usually the most expedient and optimal incision choice. Once the chest is opened, the initial objective is to acquire proximal and distal control around the area of injured thoracic aorta. The proximal clamp is typically applied between the left common carotid and left subclavian arteries, while the distal clamp is placed at some point on the distal descending thoracic aorta distal to the zone of injury (Fig. 182.8A).

Depending on the clinical scenario and patient condition, a distal aortic perfusion strategy should be expediently developed. The most expeditious technique is "left-heart bypass," which can be performed through cannulation of the left inferior pulmonary vein and distal thoracic aorta (see Fig. 182.8B). Rarely, the proximal clamp positioning is untenable. In this scenario, full cardiopulmonary bypass (CPB) is advisable, commonly through a femoral artery and a femoral vein cannulation. If total circulatory arrest is warranted, then careful venting of the left ventricle during times of cooling and rewarming is crucial.

One of the caveats, which is often problematic for the polytrauma patient, is the need for systemic anticoagulation with the use of bypass. For left-heart bypass, this is achieved through administration of intravenous heparin at a dose of 1 mg/kg to achieve an activated clotting time (ACT) of more than 200 seconds. In cases where full bypass is required, heparin is used at a dose of 4 mg/kg to achieve an ACT of greater than 480 seconds. Once the patient is on bypass and the perfusion circuit is satisfactory, the periaortic hematoma is incised, the extent of injury explored, and the ensuing aortic repair undertaken. It is paramount that the aortic adventitia is incorporated into the subsequent suture lines, as this layer provides the majority of the tensile strength of the aorta. The patient is gradually rewarmed during the latter phase of the anastomosis to facilitate removal of the clamps at a moderate degree of hypothermia (32°C to 34°C). Once the clamps are off, the patient is weaned off the bypass until adequate hemostasis is achieved and the wound is closed in its respective layers.

A significant consideration when undertaking open BTAI repair is spinal cord protection and the importance of distal aortic perfusion in minimizing the risk of postoperative

paraplegia.[56] Several potential strategies designed to mitigate the risk of postoperative paraplegia have previously been described in the literature.[57-61] Perhaps the most significant contributor to spinal cord ischemia occurs as a result of aortic clamping and subsequent occlusion of critical segmental spinal cord arterial branches. Important factors in determining the incidence of immediate onset or delayed paraplegia following aortic repair include duration of cross-clamping, level and length of aortic segment excluded by clamping, duration of systemic hypotension, cerebrospinal fluid pressure, distal aortic pressure, and the number of intercostals ligated during repair.[62] Multiple adjuncts have helped lower the incidence of paraplegia following aortic repair for BTAI, including cerebrospinal fluid drainage, administration of steroids, generalized and localized hypothermia, as well as reattachment of key intercostal arteries during the conduct of repair.[59-62]

Postoperative Management

The hemodynamic state of the patient is closely monitored following the procedure, and meticulous care is provided for any other trauma they have experienced. Significant vigilance must be maintained for any of the common complications that can arise following aortic trauma, including bleeding, infection, and neurologic changes. Long-term data on durability and major complications is limited to less than 10 years, as widespread adoption of TEVAR did not occur until the mid-2000s. Knowledge of optimal follow-up practice is, subsequently, limited. At present, the follow-up surveillance strategy utilized at our center includes clinical examination and CT at 1, 6, and 12 months, and yearly thereafter.

Potential Complications of Thoracic Endovascular Aortic Repair

Current data suggest that in comparison to OR, TEVAR may reduce early death, paraplegia, renal insufficiency, transfusions, reoperation for bleeding, cardiac complications, pneumonia, and length of hospital stay.[13,30-32] In their landmark 2008 report, Demetriades and colleagues of the AAST BTAI study group[32] documented significant improvements in BTAI care associated with the transition from open to TEVAR. In their examination of 193 patients with BTAI, they found that TEVAR was associated with significantly decreased transfusion requirements and lower mortality compared with OR. The more contemporary findings from the ATF study group experience support these findings, with a significantly lower PRBC requirement (mean 5.9 vs. 3.1 units, $P < .002$) in the first 24 hours and a lower overall mortality (8.6% vs. 19.7%, $P = .021$) and aortic-related mortality (13.1% vs. 2.5%, $P = .003$) among TEVAR treated patients compared with open counterparts.[13]

The common concerns for paralysis and stroke that have been associated with OR appear to also be mitigated with the increasing use of TEVAR. In the aforementioned ATF multicenter study of 382 BTAI patients,[13] only 1 paralysis following TEVAR was noted, occurring in an 81-year-old male requiring 20-cm device coverage of the thoracic aorta. Likewise, stroke was a very rare occurrence, identified in only two patients, ages 62 and 85, respectively. Both required coverage of the left subclavian artery to facilitate TEVAR. These findings support the safety profile for TEVAR in the setting of BTAI, but suggest that older patients with possible native atherosclerotic burden and BTAI patterns requiring more extensive endograft coverage may increase risk of ischemic complications.

Access- and device-related complications also appear to be rare complications of TEVAR in contemporary practice. This improvement in safety profile has emerged as a benefit of increased experience and improvements in device technology. In the older 2008 report of the AAST BTAI study group, the investigators noted a significant rate of specific TEVAR-related complications.[32] Demetriades and his group found that 18.4% of patients undergoing TEVAR had some form of stent graft-specific complication, most notably endoleak at 13.6%. The continued advancement of endovascular technologies since this report, including the increasing utilization of FDA-approved devices specific to aortic trauma, has improved the ability to avoid these adverse events following TEVAR. In the more contemporary published experience of the ATF Study Group, which captured the treatment of 382 BTAI patients, a significantly decreased risk of TEVAR-related complications was documented.[13] This group noted six malpositions of the endograft at initial TEVAR occurred (3.0%) and a post-TEVAR endoleak rate of 2.5%. Only one delayed stent migration was noted. In addition, just two access site complications (one pseudoaneurysm, one persistent bleeding requiring intervention) were identified. Among the six defined TEVAR treatment failures encountered in this large series, all underwent subsequent salvage with reintervention (two repeat TEVAR, four OR). The ATF study group identified only one patient treated with repeat TEVAR who suffered aortic-related mortality. No other mortalities were observed among the TEVAR failures.

Although increasingly rare in the modern era, it is important to note that complications during or after TEVAR remain possible in specific settings. Excessive oversizing or undersizing of endografts can lead to propagation of aortic injury or failure to achieve adequate seal. Patient-specific anatomical issues may also contribute, including the presence of a tight curvature of the aortic arch, native atherosclerotic burden and the aforementioned diameter limitations of iliac access vessels.

Outcomes After Blunt Thoracic Aortic Injury Management

The largest multicenter retrospective study of BTAI outcomes conducted to date included 382 patients from nine American College of Surgeons verified Level I trauma centers in North America.[13] This study, a collaborative effort conducted under the auspices of the ATF, captured a distribution of BTAI grades of injury (94 grade 1 injuries [24.6%], 68 grade 2 [17.8%], 192 grade 3 [50.3%], and 28 grade 4 [7.3%]). Overall in-hospital mortality for all patients with BTAI was 18.8% (nonoperative management 34.4%, OR 19.7%, TEVAR 8.6%), with an aortic-related mortality of 6.5% (nonoperative management 9.8%, OR 13.1%, TEVAR 2.5%).

Among the ATF BTAI study patients, the majority of aortic-related deaths (18/25) occurred prior to the opportunity for completion of OR or TEVAR. Of the seven patients who died after OR (3) or TEVAR (4), all had an Injury Severity Score (ISS) in excess of 25, consistent with severe polytrauma. Using multivariate logistic regression, the investigators found that the independent predictors of aortic-related mortality included higher overall ISS and higher grade of BTAI injury. On multivariate regression, TEVAR utilization proved the only variable protective against aortic-related mortality.

Remaining Controversies and Future Directions

The current SVS guidelines for BTAI management[38] provide an evidence-based, consensus-derived grading system and suggested course of treatment. These guidelines represent the most comprehensive effort in BTAI care optimization yet conducted by a major medical organization. The SVS guidelines do, however, have some limitations—including the fact that they are specific to the aortic lesion alone. Potential future improvements include further refinement of injury grading paradigms, standardization of care, and the establishment of effective prospective long-term follow-up mechanisms. A number of initiatives are actively underway to promote these needed advances.

Several investigators have suggested that greater scrutiny of specific elements of BTAI-related imaging may provide an important key to defining optimal type and timing of treatment. Both the Vancouver simplified grading system[57] and the alternate classification scheme proposed by Osgood et al.[34] have promoted the importance of more detailed aortic lesion dimension assessments, parameters not specifically included in SVS criteria, as crucial to determining the need for TEVAR. Initial work by investigators at the University of Maryland[35] has also demonstrated that associated secondary signs of injury available on CTA of the chest may require further consideration. Specifically, this group has highlighted that the presence of extensive mediastinal hematoma and large left hemothorax may prove important hallmarks of impending aortic rupture. In a 15-year retrospective study of 331 patients with BTAI, we examined CTA imaging variable to determine predictors of rupture. We found that injury grade was a predictor of aortic-related mortality. Contrary to the Maryland study, we found that pseudoaneurysm size, lesion/normal aortic diameter ratio, and mediastinal hematoma location and size were not predictors of aortic-related mortality.

There has also been debate regarding what some investigators term "minimal aortic injuries."[34] Optimal management of these BTAI patients, which include grade 1 and 2 injuries, has been debated. Some groups have suggested that these "minimal aortic injuries" do not universally require TEVAR, an approach that conflicts with the present SVS clinical practice guideline suggestions. The findings from research conducted at several high-volume centers, however, suggest a nonoperative approach to initial care of this range of BTAI is safe.[34,35] In the aforementioned ATF study, researchers retrospectively compared grade 1 and 2 injuries treated with TEVAR. They found no significant difference in in-hospital outcomes between patients managed with medical therapy alone or TEVAR.[13] While this existing data suggest that the nonoperative management of SVS grade 2 injuries is safe, the natural history beyond discharge is not well-defined. These patients will require effective longitudinal follow-up and study, ideally in the context of a multicenter study.

Another challenge includes consideration of the fact that BTAI patients commonly have significant associated injuries that are pertinent to overall outcome. In some instances, the optimal care of these associated injuries proves counter to optimal BTAI care. The need to maintain an optimal cerebral perfusion pressure among patients with brain injury, for instance, contrasts with the pharmacologic blood pressure impulse control recommended to minimize wall stress in the injured thoracic aorta. An optimal algorithm should incorporate some consideration of associated injuries into individualized BTAI care.

Ideal timing of BTAI treatment is a remaining issue that requires further study. The results of the American Association for the Surgery of Trauma Aortic Injury Study Group, reported in 2009, suggested that improved outcomes were associated with initial medical management, including blood pressure pulse pressure optimization.[31] This group found that patients treated in a delayed (>24 hours) fashion, after this period of optimization, had improved survival compared with BTAI patients treated operatively within less than 24 hours. There remains a need, however, to adequately define whether specific risk factors associated with BTAI represent a higher risk for early aortic rupture and need for more emergent repair.

Finally, the long-term durability of endovascular devices used for BTAI treatment remains to be determined. Improved conformability to aortic contour and various fixation element changes are attractive features of modern devices. The ongoing study of branched graft devices may soon obviate the need for coverage of the left subclavian artery during TEVAR entirely. However, this remains an unresolved issue of BTAI care. Optimal graft sizing and graft utilization in pediatric patients—or patients with small aortic diameters—are also inadequately studied issues. These challenges are augmented by the fact that optimal device indications and utilization has primarily been subjected only to industry-funded study. These issues require more objective investigation in a large, multicenter fashion.

Vascular Injuries to the Aortic Arch Vessels and Thoracic Outlet Vasculature

While TAI is perhaps the hallmark thoracic vascular injury, a wide variety of traumatic pathologies at various locations within the chest can be encountered.[63] The majority of these injuries are initially diagnosed with contrast-enhanced CT, now ubiquitous to initial trauma evaluations. As with TAI, the patient condition and associated injuries remain considerations in defining optimal management of identified vascular injuries. For unstable patients requiring immediate surgical intervention, particularly after penetrating mechanisms, initial open repair approaches are commonly utilized. The aforementioned issues

regarding initial incision and subsequent extensile options should be considered carefully in these instances.

Ascending Aorta and Transverse Arch

Rupture of the ascending and transverse aortic arch is uncommon, but the exact incidence is unknown due to the lethality of these injuries. A widened mediastinum and cardiac tamponade are frequently associated with ascending aortic ruptures. Repair of these injuries requires a median sternotomy, CPB, and systemic heparinization (Fig. 182.9). Management of the aortic tear may be primary or with an interposition graft. Special attention should be paid to the status of the aortic valve. Injuries to the aortic arch may require hypothermic circulatory arrest and associated antegrade and retrograde cerebral perfusion techniques. Survival depends primarily on the severity of associated injuries.[64-66]

Innominate Artery

Rupture of the innominate artery is the second-most common thoracic arterial injury following blunt trauma. Innominate artery injuries can generally be repaired via a median sternotomy with a right cervical extension when necessary. Blunt injury typically involves the base of the innominate artery, and this is most expeditiously repaired with a bypass from the ascending aorta to the distal innominate artery, followed by oversewing of the innominate stump (Fig. 182.10). Division of the innominate vein is occasionally required for exposure, and shunts or CPBs are often not required. Avoidance of the injured area until completion of the bypass leads to a technically easier repair.[67,68]

Left Common Carotid Artery

The surgical approach to injuries of the proximal left carotid artery mirrors that of the innominate artery—a sternotomy with a left cervical extension, if needed. With injuries of the left carotid origin, bypass graft repair is generally preferred over an end-to-end reanastomosis.[69] The management of a carotid injury in the setting of neurologic disturbances is controversial. Generally, if the patient is evaluated soon after injury, revascularization is recommended because hypotension (rather than ischemic infarct) is the most likely cause of morbidity.[70] Chapter 156 contains additional information on carotid injuries. Recently, traumatic carotid lesions have been managed with endovascular techniques. An endovascular approach is especially useful for extensive lesions with involvement near the skull base, where obtaining proximal and distal vascular control may result in increased morbidity. The goal of endovascular therapy is the elimination of a fistula, aneurysm, or stenosis while preserving native flow to the brain. There have been multiple reports on the successful management of traumatic carotid injuries with endovascular techniques.[66-73] However, the use of stents introduces new considerations, such as the probability of late in-stent thrombosis. The administration of postprocedural medications, such as aspirin and clopidogrel, can minimize the incidence of in-stent thrombosis.[74,75]

(C and D) Placement of an ascending aorta to innominate artery bypass with oversewing of the innominate artery stump. (Courtesy Dr. Anthony L. Estrera.)

Subclavian Vessels

Injuries to the subclavian vessels are usually caused by penetrating wounds. Subclavian vascular injuries require preoperative imaging (generally CTA) for appropriate incision planning. Injuries to the right subclavian artery are best addressed via a median sternotomy with a right cervical extension. Proximal control of left-sided subclavian injuries can be obtained via a left anterolateral thoracotomy. A separate supraclavicular incision can be used for distal control. These two incisions can be connected with a sternotomy to facilitate exposure. This incision should be used sparingly because of reports of postoperative "causalgia" neurologic symptoms.[69] In addition, the second or third portion of the subclavian artery can usually be exposed without the need for clavicular resection or sternotomy.

Endovascular approaches to innominate, intrathoracic carotid, and subclavian arterial injuries have been described in both blunt and penetrating trauma (Fig. 182.11).[76-78]

As with TAI, endovascular capabilities are increasingly being utilized to effectively treat vascular injuries to the vessels of the thoracic arch and thoracic inlet.[62,79-82] Available data suggest that, among appropriately selected patients, endovascular treatment is associated with improved outcome for injuries in these areas—which often represent challenging open exposures for

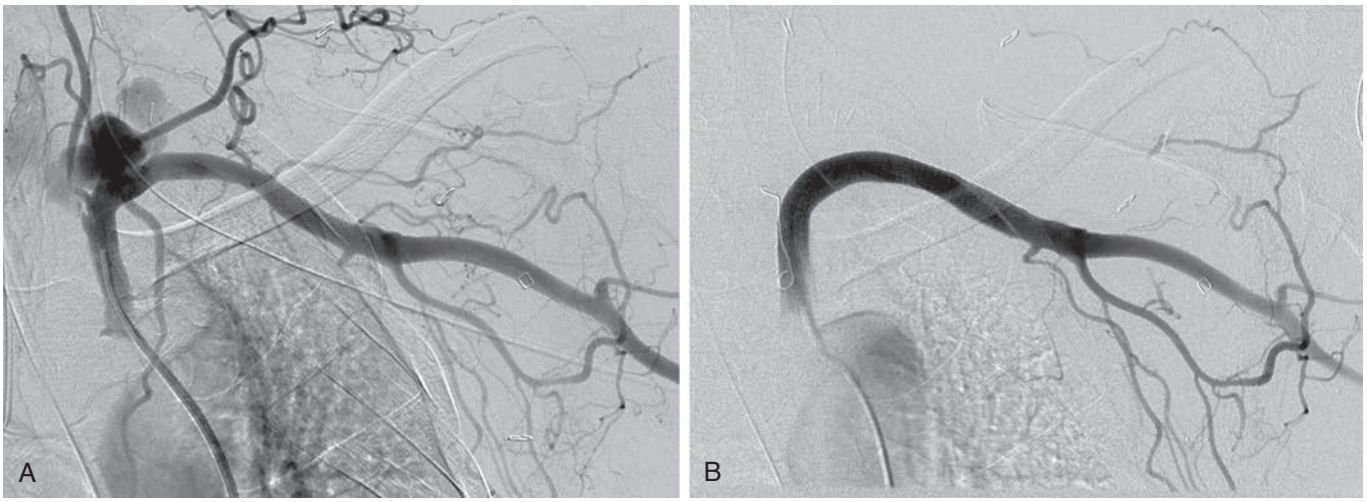

Figure 182.11 (A) Selective left subclavian angiogram of a patient after a stab wound shows a pseudoaneurysm. (B) After coil embolization of the left vertebral artery, endovascular repair of the left subclavian artery injury was performed using a covered stent graft. (Courtesy Dr. Kristofer M. Charlton-Ouw.)

control and repair. In a recent study conducted by Branco and colleagues, investigators found that endovascular treatment of axillo-subclavian injuries was associated with lower in-hospital mortality and surgical site infections than counterparts undergoing open repair of these injuries.[79] A subsequent report used a large cohort of patients from the National Trauma Databank to compare matched populations of vascular injured patients undergoing open or endovascular repair.[80] The study found that outcomes were improved across a wide range of vascular thoracic vascular injuries. Additional literature supports these findings.[63,81] While this evidence suggests that endovascular repair modalities may have improved outcomes compared to open repair of a variety of thoracic vascular injuries during the initial hospitalization, there remains a significant paucity of long-term outcomes. There remains a need to capture this data in order to better define if endovascular repair is to be considered definitive or simply a temporizing/damage control adjunct over the lifespan of a young trauma patient. To this end, the PROspective Vascular Injury Treatment (PROOVIT) registry, developed under the auspices of the American Association for the Surgery of Trauma, is capturing data in a multicenter, multinational fashion to better define the optimal management and follow-up of these injuries.[63]

CONCLUSION

Thoracic vascular injuries remain significant challenges of modern trauma vascular care. Significant strides have been made with regard to diagnostic and initial management capabilities—facilitated by improvements in contrast-enhanced CT imaging and endovascular treatment modalities. There remains, however, a need to better define optimal grading systems and long-term outcomes after these injuries. Ongoing efforts in this regard, including the Aortic Trauma Foundation Prospective Multi-Center, Multi-National TAI registry and the PROOVIT registry, promise to advance additional understanding about the optimal diagnosis, management, and follow-up of these injuries.

ADVANCES IN THE MANAGEMENT OF ABDOMINAL VASCULAR INJURIES 2408

Abstract

Abdominal vascular injuries are the most common cause of death after penetrating abdominal trauma. Accurate diagnosis, rapid surgical exposure and control, and the definitive management of these injuries may challenge the skills and judgment of even the most experienced surgeons. These can be made even more complex by any associated intraabdominal injuries. Rapid transportation to a trauma center, early recognition of the injuries, early surgical intervention, excellent knowledge of the anatomy, and good surgical judgment are critical for optimizing patient survival.

Abdominal vascular injuries are the most common cause of death after penetrating abdominal trauma. Accurate diagnosis, rapid surgical exposure and control, and the definitive management of these injuries may challenge the skills and judgment of even the most experienced surgeons. These can be made even more complex by any associated intraabdominal injuries. Rapid transportation to a trauma center, early recognition of the injuries, early surgical intervention, excellent knowledge of the anatomy, and good surgical judgment are critical for optimizing patient survival.

SURGICAL ANATOMY

For vascular trauma purposes, the abdomen is conventionally divided into the intraperitoneal and retroperitoneal areas. The retroperitoneum is further divided into four distinct zones (Fig. 183.1):

- Zone 1, which includes the midline retroperitoneum extending from the aortic hiatus to the sacral promontory. This zone is subdivided into the supramesocolic and inframesocolic areas. The supramesocolic area contains the suprarenal aorta and its major branches (celiac axis, superior mesenteric artery [SMA], and renal arteries), the supramesocolic inferior vena cava (IVC) with its major branches, and the superior mesenteric vein (SMV). The inframesocolic area contains the infrarenal aorta and IVC.
- Zone 2 (left and right), which includes the kidneys, paracolic gutter, and renal vessels.
- Zone 3, which includes the pelvic retroperitoneum and contains the iliac vessels.
- Zone 4, which includes the perihepatic area containing the retrohepatic IVC and hepatic veins.

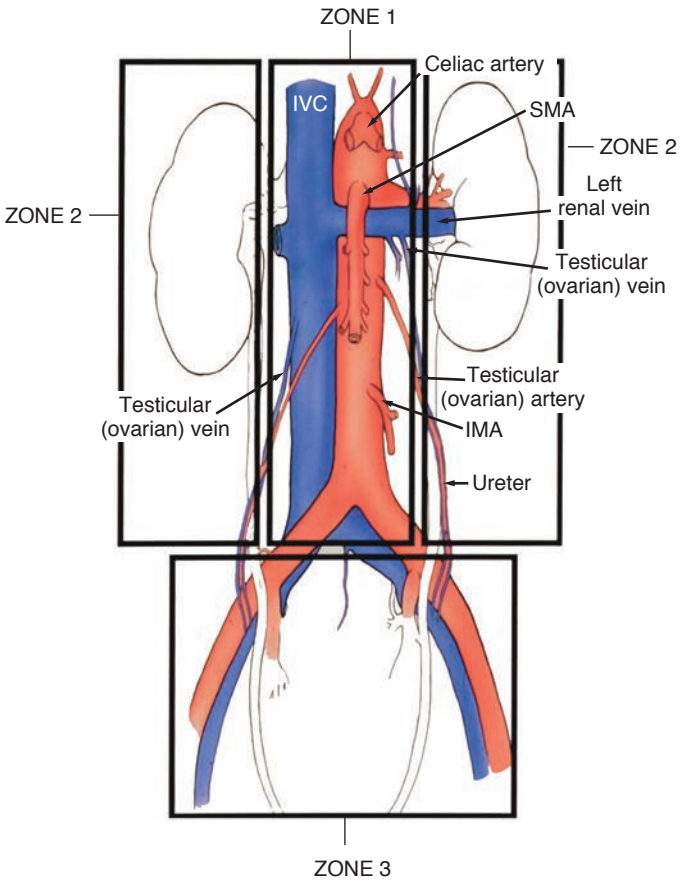

Figure 183.1 Retroperitoneal Vascular Zones. Zone 1 includes the midline vessels from the aortic hiatus to the sacral promontory; zone 2 includes the paracolic gutter and the kidneys; and zone 3 includes the pelvic retroperitoneum. *IMA*, Inferior mesenteric artery; *IVC*, inferior vena cava; *SMA*, superior mesenteric artery.

EPIDEMIOLOGY

Penetrating trauma is responsible for most abdominal vascular injuries and accounts for approximately 90% of cases in urban trauma centers.[1] Low-velocity missiles cause direct injury to the vessel. High-velocity missiles and blast can also cause injury by means of a shock wave and transient cavitation. These injuries may manifest as early or late thrombosis, in addition to hemorrhage.

In patients who undergo exploratory laparotomy for injury, the incidence of vascular trauma is 14.3% for gunshot injuries,[2] 10% for stab wounds,[3] and 3% for blunt injuries.[4]

Blunt abdominal trauma may cause vascular injuries by one of three mechanisms:

1. Rapid deceleration, as occurs in high-speed vehicular collisions or falls from height; this can cause avulsion or intimal tearing and subsequent thrombosis.
2. Direct anteroposterior crushing, from a seat belt or a direct blow to the anterior abdomen.
3. Direct laceration of a major vessel by a bone fragment, for example with severe pelvic fractures.

Abdominal arterial and venous injuries occur with the same incidence. In a review of 302 abdominal vascular injuries from our center, the incidence of arterial injuries was 49% and that of venous injuries was 51%.[1] The most commonly injured abdominal vessel was the IVC, accounting for 25% of injuries, followed by the aorta (21%), iliac arteries (20%), iliac veins (17%), SMV (11%), and SMA (10%). Overall, patients with penetrating trauma who sustained a vascular injury had an average of 1.7 vascular injuries per patient.[1]

CLINICAL PRESENTATION

Many patients with major abdominal vascular injuries die at the scene. Of the patients who are transported to a hospital, approximately 14% lose vital signs en route or on arrival in the emergency department.[1] The clinical presentation depends on the injured vessel, the size and type of injury, the intraperitoneal or retroperitoneal location of injury, the presence of associated injuries, and the time elapsed.

Penetrating injuries to the abdomen associated with hypotension and abdominal distention are highly suggestive of vascular injury. Asymmetric femoral pulses may indicate iliac artery injury. Many patients may be normotensive on admission only to decompensate a few minutes later. Some patients present in a hemodynamically stable condition because of thrombosis of the vessel or containment of the bleeding in the retroperitoneum. In most cases the diagnosis is made intraoperatively.

DIAGNOSTIC EVALUATION

In most patients with abdominal vascular injuries, no investigations are needed because of the altered hemodynamics and obvious need for immediate laparotomy. For penetrating injuries, hemodynamic instability, peritonitis on examination, or an unevaluable patient mandates immediate laparotomy and any vascular injuries will be diagnosed intraoperatively.[5] Whenever possible, plain radiographs should be obtained (Fig. 183.2) for localizing any bullet fragments. If the patient does not require immediate laparotomy and is to undergo a trial of nonoperative management, CT would be the next diagnostic evaluation and has excellent sensitivity and specificity for vascular injury (Figs. 183.3A and B, and 183.4). For blunt trauma, peritonitis or hemodynamic instability with a positive abdominal FAST exam requires immediate laparotomy. For unstable patients with negative FAST, a diagnostic peritoneal aspirate is performed to exclude a false negative FAST and other sources of bleeding are sought. This includes the retroperitoneum, ideally imaged using CT (Fig. 183.5).

TREATMENT

Prehospital Treatment

The most important factor for the survival of salvageable patients with vascular injuries is rapid transportation to a trauma center, followed by immediate surgical control of the bleeding.

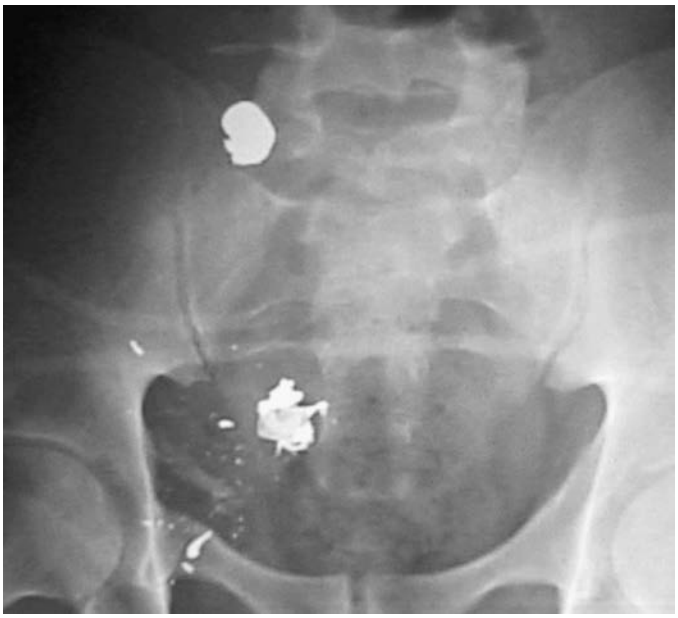

Figure 183.2 The pelvic location of the missile on the abdominal radiograph, combined with hypotension, is highly suggestive of an iliac vascular injury.

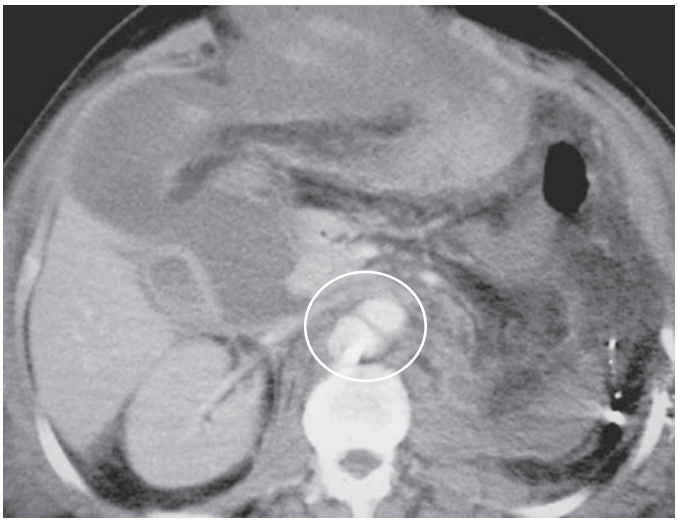

Figure 183.4 Postoperative computed tomography scan of a patient with a gunshot wound shows an abdominal aortic false aneurysm *(circle)*.

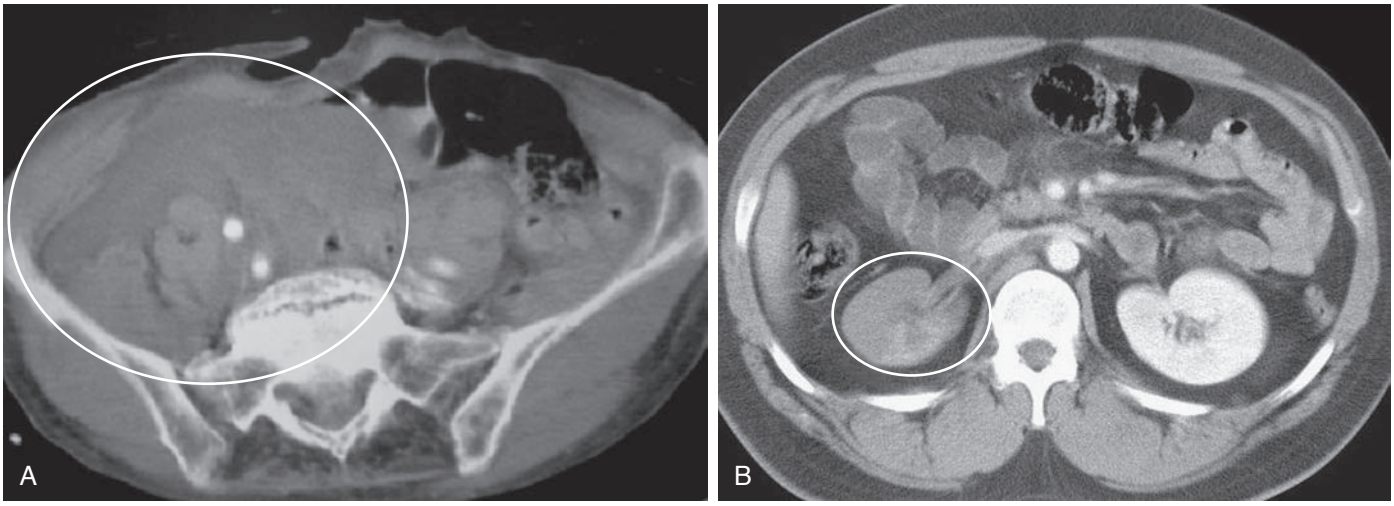

Figure 183.3 (A) Computed tomography (CT) scan of a traffic accident victim shows a large pelvic hematoma *(circle)* due to injury of the right common iliac artery. (B) CT scan with intravenous administration of contrast material in a high-speed traffic accident patient shows poor uptake of the contrast agent in the right kidney because of occlusion of the renal artery *(circle)*.

Figure 183.5 A 5-year-old child presented with a severe pelvic fracture and absent right femoral pulse. Angiography shows a complete occlusion of the right common iliac artery *(arrow)*.

Prehospital advanced life support has no place in penetrating trauma, especially in an urban environment. A policy of "scoop and run" is currently the recommended approach. The role of prehospital intravenous fluid administration is controversial; some studies show improved survival with fluid restriction and others show no effect on survival.[6-8] Experimental work on abdominal aortic injuries has shown that, in the presence of uncontrolled bleeding, aggressive fluid resuscitation increases mortality and the rate and volume of hemorrhage.[9,10] However, avoidance of all fluid resuscitation in near-fatal hemorrhage may result in cardiac arrest before bleeding is controlled.[11] It seems that some degree of controlled hypotension is beneficial and prevents massive exsanguination while avoiding the risk of cardiac arrest due to massive blood loss and severe hypotension.[9,12] Experimental work suggests that a systolic pressure of 80 to 90 mm Hg is the optimal pressure in the presence of active vascular bleeding.[13]

Emergency Department Treatment

The extent of resuscitation required in the emergency department depends on the clinical condition of the patient. For patients arriving in cardiac arrest, endotracheal intubation and a resuscitative thoracotomy should be performed in the emergency department. A left anterolateral thoracotomy through the fourth to fifth intercostal space is performed, the thoracic aorta is cross-clamped, and the heart is resuscitated. If cardiac activity returns, the operation is completed in the operating room. The survival rate after resuscitative thoracotomy for abdominal vascular injuries is approximately 2%.[1]

An attractive alternative to resuscitative thoracotomy for patients with suspected intraabdominal vascular injury, particularly in the pelvis, is endoluminal aortic occlusion with use of a percutaneous balloon inserted through the femoral artery.[14,15] The balloon is inflated in the distal thoracic aorta. The aortic occlusion reduces intraabdominal bleeding and facilitates resuscitation. Experimental work comparing endoluminal balloon aortic occlusion to thoracotomy with aortic clamping in a model of hemorrhagic shock showed that aortic balloon occlusion was associated with increased central perfusion pressures with less physiologic disturbance,[16] and clinical experience with this technique is rapidly increasing.

In all other patients with suspected vascular injuries, large-bone intravenous catheters should be placed in the upper extremities or the central veins of the thoracic inlet. Femoral vein catheters should be avoided in case the victim has an injury to the IVC or the iliac veins. As discussed earlier, the concept of controlled hypotension should be borne in mind, and aggressive fluid resuscitation should be avoided. Except for patients in cardiac arrest or at risk for imminent cardiac arrest, endotracheal intubation should be avoided in the emergency department because rapid sequence induction is often associated with cardiovascular decompensation.

Surgical Treatment

General Principles

All possible steps should be taken to mitigate heat loss and hypothermia. All infused fluids should be prewarmed to 40°C to 42°C, and the patient's extremities should be covered with a warming blanket. Rapid infusion devices should be ready, and the blood bank should be notified. After a vascular injury is identified, the aggressive replacement of shed blood with products in a 1:1:1 ratio directed by a massive transfusion protocol has been demonstrated to improve outcomes. The patient's entire torso, from the neck to the knees, should be prepared and draped. Although the initial incision is a full midline laparotomy, additional thoracotomy or saphenous vein harvesting may become necessary. The surgical team should be ready, and the skin preparation should be performed before induction of anesthesia because it is often associated with rapid hemodynamic decompensation in these patients.

Some surgeons have advocated a preliminary left thoracotomy and aortic cross-clamping to prevent cardiovascular collapse after anesthesia and laparotomy.[19,20] The effectiveness of this procedure has been challenged by other authors.[21] We believe that this approach should be considered only for patients at risk of imminent cardiac arrest. A thoracotomy is an additional traumatic insult that may aggravate hypothermia and coagulopathy and has little effect on the control of bleeding from major venous injuries. We advocate an immediate laparotomy, temporary control of bleeding by direct compression, and aortic cross-clamping, if necessary, at the diaphragm. In our experience, this is almost always possible, even in obese patients. To facilitate aortic exposure, division of the left crus of the diaphragm may

be necessary. In cases where a retroperitoneal hematoma extends high toward the aortic hiatus, infradiaphragmatic exposure of the aorta is difficult, and a left thoracotomy may be necessary for aortic control.

Endoluminal aortic occlusion, as described before, is promising but still underused. The use of this technique intraoperatively can reduce the need for thoracotomy for proximal vascular control. In addition, it may make the exploration of anatomically difficult, upper zone 1 hematomas safer and easier. Training of surgeons in the use of this technique may add a useful tool to the armamentarium available for the management of these complex cases.

Retroperitoneal Hematoma

The management of retroperitoneal hematomas depends on the mechanism of injury. As a general rule, almost all hematomas due to penetrating trauma should be explored, irrespective of size. Underneath a small hematoma, there is often a vascular or hollow viscus perforation. The only exception to this recommendation is a contained zone 4 retrohepatic hematoma. Surgical exploration of the retrohepatic vena cava or the hepatic veins is extremely challenging and in most cases will be detrimental because these contained venous injuries do very well with nonoperative management.

Retroperitoneal hematomas due to blunt trauma rarely require exploration because of the very low incidence of underlying vascular or hollow viscus injuries requiring surgical repair.[22] If the hematoma is in zone 1, it should be explored. However, in patients with zone 2 hematomas, surgical exploration may result in the unnecessary loss of the kidney. Similarly, exploration of a stable zone 3 hematoma due to pelvic fractures may cause severe bleeding that is uncontrollable. Exploration of zone 2 and 3 retroperitoneal hematomas should therefore be limited to patients with expanding, pulsatile, or leaking hematomas. In addition, zone 3 pelvic hematomas associated with an absent ipsilateral femoral pulse should also be explored because of the potential for an iliac artery injury. Paraduodenal hematomas also require exploration to exclude an underlying duodenal injury. Finally, hematomas at the root of the mesentery in the presence of ischemic bowel may harbor an injury to the SMA and should be explored. Exploration of these hematomas is technically difficult and potentially dangerous and should not be performed in the absence of ischemic bowel. Unexplored hematomas should be evaluated postoperatively using color-flow Doppler studies (which may be difficult because of bowel gas), CT angiography, or catheter-based angiography. With the advancement of endovascular technology and the availability of hybrid operating rooms with angio-interventional capabilities, there is now the option to perform on-table diagnostic angiography instead of opening a contained retroperitoneal hematoma. Any significant injuries may be managed endovascularly, if amenable, with stenting or embolization. This approach has the additional advantages of keeping the retroperitoneum intact, especially important in the presence of associated hollow viscus injuries.

Once the hematoma is open, in the presence of severe active bleeding, the immediate priority is to control the bleeding by direct compression. After this critical task is achieved, the next step is to identify the bleeding vessel and obtain proximal and distal control. If control is difficult or the patient is severely hypotensive, the abdominal aorta can be compressed digitally or with an aortic compressor at the aortic hiatus. After dissection of the peritoneum over the aorta and, if necessary, division of the left crus of the diaphragm (at the 2-o'clock position to avoid bleeding), the aorta can be cross-clamped. Endoluminal aortic occlusion with a percutaneously placed catheter balloon, as described before, is an attractive but still underused alternative.

The exploration of the area of bleeding or hematoma should proceed systematically. Each anatomic zone requires a different technical maneuver. Zone 1 supramesocolic bleeding or hematoma is the most difficult to approach because of the dense concentration of major vessels (aorta, celiac artery, SMA, renal vessels, IVC), the difficult exposure of many of these vessels, and the difficult proximal control of the infradiaphragmatic aorta. For some injuries, the only safe way to achieve proximal aortic control is through a left thoracotomy or with endoluminal aortic occlusion. The supramesocolic aorta, along with the origins of its major branches, is best exposed by mobilization and medial rotation of the viscera in the left upper abdomen. The first step of this approach is to divide the peritoneal reflection lateral to the left colon, the splenic flexure of the colon, and the spleen. The fundus of the stomach, spleen, tail of the pancreas, colon, and left kidney are then rotated to the right. This maneuver provides exposure of the aorta, origin of the celiac axis, SMA, and left renal vessels (Fig. 183.6). Some surgeons prefer not to include the left kidney in the medial rotation.[23] However, for injuries involving the posterior wall of the aorta, inclusion of the left kidney in the visceral rotation

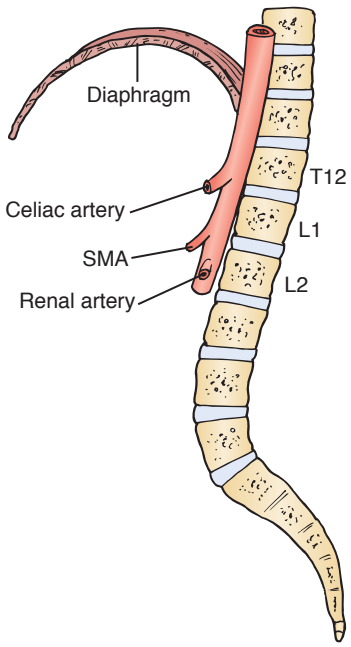

Figure 183.6 Left medial visceral rotation provides good exposure of the supramesocolic aorta and the origin of the celiac axis, superior mesenteric artery *(SMA)*, and left renal vessels.

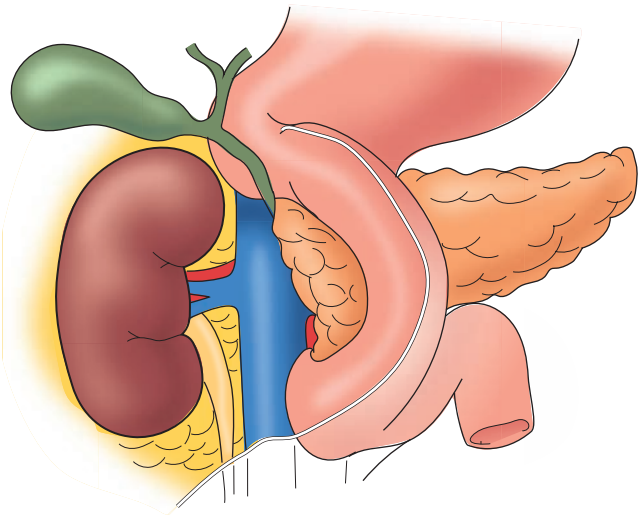

Figure 183.7 Medial visceral rotation of the right colon and hepatic flexure and Kocherization of the duodenum and pancreas provide excellent exposure of the inferior vena cava and the origins of the renal veins. (From Buckman RF, Pathak AS, Badellino MM, Bradley KM. Injuries of the inferior vena cava. *Surg Clin North Am*. 2001;81:1431-1447.)

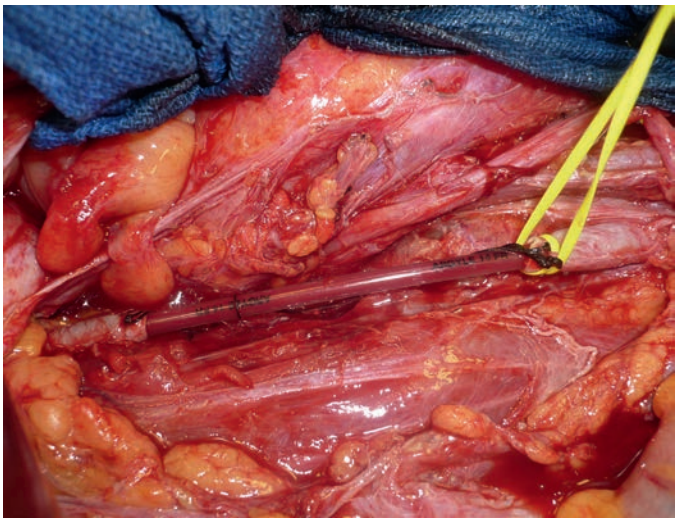

Figure 183.8 Temporary arterial shunt for damage control in a hemodynamically unstable patient with a gunshot wound and complete transection of the iliac artery.

improves the exposure. In suspected supramesocolic IVC injuries, zone 1 should be explored through a medial rotation of the right colon and hepatic flexure and Kocher mobilization of the duodenum and head of the pancreas (Fig. 183.7). The inframesocolic zone 1 area can be approached by retracting the transverse colon cephalad and displacing the small bowel to the right. The peritoneum over the aorta and IVC is then incised, and the vessels are exposed. An alternative approach is medial rotation of the right or left colon.

Zone 2 bleeding or hematoma is explored by mobilization and medial rotation of the right colon, duodenum, and head of the pancreas on the right side or the left colon on the left side. The source of bleeding in zone 2 is the renal vessels or the kidneys.

Zone 3 vessels are explored by dissection of the paracolic peritoneum and medial rotation of the right or left colon. In some cases, direct dissection of the peritoneum over the vessels can provide the necessary exposure.

The reconstruction of major vessels with synthetic grafts in the presence of intestinal spillage poses significant risks for graft infection. Copious irrigation before graft placement, use of autologous graft material whenever possible, and omental wrapping or soft tissue coverage for polytetrafluoroethylene (PTFE) grafts will reduce the risk of infection.

Damage Control Procedures

Many patients with major abdominal vascular injuries require massive blood transfusions, are hypotensive, and become severely hypothermic, acidotic, and coagulopathic intraoperatively. Persistent attempts to definitively reconstruct the injury are ill advised and will result in increased mortality. These patients should undergo early damage control and definitive reconstruction at a later stage when their physiology improves. Earlier reports recommended that damage control procedures be considered in patients in extremis who had exhausted their physiologic reserves and were in danger of irreversible shock and death. However, to be effective, damage control should not be a procedure of last resort but should be considered at a much earlier stage, before the patient becomes severely hypotensive and coagulopathic.[24] This concept is even more important in patients with major comorbidities, such as older age or chronic medical problems, and in suboptimal environments, such as small community hospitals or combat zones.

With the damage control approach, all complex venous injuries are ligated, arterial injuries are shunted,[25] and any diffuse retroperitoneal or parenchymal bleeding is controlled by tight gauze packing. If commercially produced vascular shunts are not available, temporary intraluminal shunts can be constructed from sterile intravenous or nasogastric tubing.[26] The shunt is secured with proximal and distal ligatures (Fig. 183.8). The abdomen is then closed temporarily with a prosthetic material or vacuum dressing techniques (Fig. 183.9), and the patient is transferred to the intensive care unit (ICU) for further resuscitation. The abdomen should never be closed primarily because of the very high incidence of abdominal compartment syndrome. The patient is returned to the operating room after resuscitation and stabilization for definitive vascular repair and abdominal wall closure.

Endovascular Techniques

Endovascular techniques have revolutionized the management of blunt thoracic aorta and other arterial injuries.[27] Hybrid operating rooms (Fig. 183.10) with angiographic radiology capabilities provide an opportunity to improve the management of abdominal vascular injuries by either temporary control of life-threatening bleeding or definitive care with angioembolization or stenting. In the appropriate cases the combination of endovascular adjuncts and open surgery may be lifesaving.

Figure 183.9 Temporary closure of the abdomen with the negative pressure dressing technique. After damage control procedures, the abdomen should never be closed primarily because of the risk of abdominal compartment syndrome.

Figure 183.10 Hybrid operating rooms allow combined open surgical and endovascular procedures.

The role of endovascular techniques in penetrating abdominal vascular trauma, which is almost always associated with severe active bleeding, is usually limited. However, the use of endoluminal balloons for temporary proximal aortic control can be a useful adjunct during open surgery. In addition, endovascular techniques may be the best therapeutic intervention in most cases with delayed vascular complications such as aneurysms, arteriovenous fistulae, and arterial occlusions.

Abdominal Compartment Syndrome

The normal intraabdominal pressure in the resting supine position is near zero. Elevation of the intraabdominal pressure greater than 12 mm Hg constitutes a diagnosis of intraabdominal hypertension.[28] A pressure that exceeds 20 mm Hg in addition to organ dysfunction results in abdominal compartment syndrome. Abdominal compartment syndrome is characterized by a tense abdomen, tachycardia with or without hypotension, respiratory dysfunction with high peak inspiratory and plateau pressures in mechanically ventilated patients, and oliguria. However, significant organ dysfunction may begin long before classic abdominal compartment syndrome is manifested.

All patients with severe abdominal trauma, especially vascular trauma, are at risk for development of abdominal compartment syndrome. Major risk factors include massive blood transfusions, prolonged hypotension, hypothermia, aortic cross-clamping, damage control procedures, and closure of the abdominal wall. After severe trauma, the abdomen should never be closed under tension. Similarly, after damage control procedures, the abdominal wall fascia should not be closed because progressive postoperative bowel edema will frequently result in abdominal compartment syndrome.

The diagnosis of abdominal compartment syndrome is based on clinical examination and intraabdominal pressure measurements. All high-risk patients and those in whom abdominal compartment syndrome is suspected clinically should be monitored closely with serial intraabdominal pressure measurements. The intraabdominal pressure can be measured reliably through the bladder catheter. The catheter is used to empty the bladder. Approximately 20 mL of sterile saline is injected back into the bladder to allow pressure transduction without the false elevation in pressure expected from bladder wall tension in a full bladder. The pressure is then measured through the catheter by either a simple water column or a commercial pressure transduction device. Definitive management requires surgical decompression. In general, pressures higher than 20 to 30 mm Hg are considered strong indicators for surgical decompression of the abdomen. If organ dysfunction is present, the pressure threshold may be lower. The abdomen can be opened in the operating room or even in the ICU if necessary. Temporary abdominal wall closure can be achieved with the use of a commercially available vacuum closure device, or a sterile x-ray cassette cover, laparotomy sponges, closed suction drains, and sticky drapes can be used to accomplish temporary coverage (see Fig. 183.9). When the bowel edema improves, usually within 2 to 3 days, the patient is returned to the operating room for definitive abdominal wall closure.

SPECIFIC VASCULAR INJURIES

Abdominal Aorta Injuries

Anatomy

The aorta descends into the retroperitoneum between the two crura of the diaphragm at the T12-L1 level and bifurcates into the common iliac arteries at the L4-L5 level, which approximately corresponds to the level of the umbilicus. The first branches of the abdominal aorta are the phrenic arteries that originate from its anterolateral surface. Immediately below is the celiac trunk that originates from the anterior surface of the aorta, and 1 to 2 cm below that is the SMA, followed by the renal arteries 1 to 1.5 cm below the origin of the SMA and finally, the inferior mesenteric artery (IMA), 2 to 5 cm above the bifurcation.

Mechanism of Injury

Blunt injury to the abdominal aorta is extremely rare, diagnosed in 0.04% of all blunt trauma admissions.[29] Fractures of the thoracolumbar spine and seat belt injuries are associated with an increased risk of abdominal aortic injuries.[29,30] Intimal dissection and thrombosis are the most common lesions in patients reaching the hospital alive. False aneurysms occur less frequently. Patients with free ruptures die at the scene and rarely receive medical care.[30,31] In a review of 28 cases with blunt abdominal aortic injuries, intimal tears or large intimal flaps were the most common lesion (60%), followed by free rupture (30%) and pseudoaneurysm (10%).[32]

Penetrating injuries are by far the most common cause of abdominal aortic injuries. In a review of 1218 patients with abdominal gunshot injuries from our center, there were 33 abdominal aortic injuries (2.7%). In 529 knife wounds to the abdomen, the aorta was injured in 1.5%.[33] The infrarenal aorta is injured in 50% of patients, the supraceliac aorta in 25%, and the aorta between the celiac trunk and the renal arteries in 25% of patients.[34]

Clinical Presentation

The clinical presentation depends on the mechanism of injury (blunt or penetrating), type of aortic injury, presence of free intraperitoneal bleeding or retroperitoneal hematoma, associated injuries, and time elapsed since the injury. In blunt trauma, two-thirds of patients have acute symptoms of bleeding or visceral or lower extremity ischemia. The diagnosis is made during the initial hospitalization by means of CT or angiography or at laparotomy. In one-third of cases the diagnosis is made many months or even years after the injury.[29-31]

The clinical presentation of penetrating aortic injuries is usually dramatic. Many victims die at the scene. Of those who are treated, approximately 28% have an unrecordable blood pressure, and approximately 21% require a resuscitative thoracotomy.[33] In approximately 18% of cases the bleeding is temporarily contained in the retroperitoneum and the patients are normotensive on admission.[34] On rare occasions the injury is missed at operation only to manifest at a later date as a false aneurysm or arteriovenous fistula (see Fig. 183.4).

Management

Almost all patients with penetrating aortic injuries require open repair. In blunt trauma the management depends on the location and type of the injury. Many patients with small intimal tears can safely be managed nonoperatively. More severe blunt injuries with free rupture or large intimal flaps require open or endovascular repair.[32] In a National Trauma Data Bank analysis of 436 patients with blunt abdominal aortic injuries, 394 patients (90%) were managed nonoperatively and 29 (7%) underwent endovascular repair, with only 13 patients (3%) undergoing open aortic repair or extraanatomic bypass.[35]

Endovascular Treatment

Endovascular management has a definitive role in selected cases of infrarenal aortic injury. Patients with limited infrarenal aortic dissection, large intimal flaps, false aneurysms, or aortocaval fistulae have been treated successfully with angiographically placed stents.[36,37]

Surgical Treatment

The surgical exposure of the vascular structures in zone 1 is achieved by medial visceral rotation, as described in the section on retroperitoneal hematoma (see Fig. 183.6). For high supramesocolic injuries, a left thoracotomy may be necessary for cross-clamping of the aorta. Approximately 93% of patients with penetrating trauma have other associated intraabdominal injuries, the most common being injuries to the small bowel (45%), colon (30%), and liver (28%).[33] Before any definitive management that requires a prosthetic graft, all enteric spillage should be controlled and the peritoneum should be washed out. Lateral aortorrhaphy is possible in most cases. More complex repairs with prosthetic grafts may be necessary.[38] Many authors do not consider the presence of enteric spillage a contraindication to the use of prosthetic material.[38]

Mortality

The prognosis of abdominal aortic injuries after blunt trauma is significantly better than that of injuries due to penetrating trauma. The reported overall mortality in blunt trauma is approximately 30%.[35]

The mortality after penetrating trauma in two large series with 146 patients was 67%.[33,38] In another series of 57 patients with gunshot wounds, the mortality rate was 85%.[39] Suprarenal aortic injuries have a significantly worse outcome than infrarenal injuries.[34] The mortality in patients undergoing emergency center resuscitative thoracotomy is almost 100%.[33,34] The prognosis of penetrating abdominal aortic injuries is significantly better than that of injuries to the thoracic aorta, most likely owing to the retroperitoneal containment of bleeding in abdominal injuries. In a comparison of 67 abdominal aortic injuries with 26 thoracic aortic injuries, the mortality rates were 76% and 92%, respectively.[33]

Celiac Artery Injuries

Anatomy

The celiac artery originates from the anterior wall of the abdominal aorta, immediately below the aortic hiatus, at the level of T12-L1 (see Fig. 183.6). The main trunk is 1 to 1.5 cm long, and at the upper border of the pancreas it has three branches (the tripod of Haller): the common hepatic artery, left gastric artery, and splenic artery. Because of the extensive fibrous, ganglionic, and lymphatic tissues that surround the trunk, surgical dissection may be tedious.

Mechanism of Injury

Injuries to the celiac artery are rare and almost always due to penetrating trauma. In a review of 302 abdominal vascular injuries, the celiac artery was involved in 10 cases (3.3%).[1]

Surgical Treatment

The surgical exposure can be achieved either by direct dissection over the upper abdominal aorta through the lesser sac or by medial rotation of the upper abdominal viscera, as described previously. The rotation does not need to include the left kidney. The celiac artery can be ligated without ischemic sequelae to the stomach, liver, or spleen because of the rich collateral circulation of these organs. The left gastric and splenic arteries may also be ligated with impunity. Ligation of the common hepatic artery is usually well tolerated because of adequate supply from the portal vein and the gastroduodenal artery.

Mortality

The reported mortality rate of celiac artery injuries ranges from 38% to 75%.[40] However, among the 50 collectively reported cases of celiac artery injuries, most patients had other vascular injuries that contributed to the high mortality.

Superior Mesenteric Artery Injuries

Anatomy

The SMA originates from the anterior surface of the aorta, immediately below the celiac artery, behind the pancreas at the L1 level (see Fig. 183.6). It then proceeds over the uncinate process of the pancreas and the third part of the duodenum and enters the root of the mesentery. The SMA has the following branches: inferior pancreaticoduodenal artery, middle colic artery, arterial arcade with 12 to 18 intestinal branches, right colic artery, and ileocolic artery. SMA injuries are divided into four zones[41]:

- Zone 1, between the aortic origin and the inferior pancreaticoduodenal artery.
- Zone 2, between the inferior pancreaticoduodenal artery and the middle colic artery.
- Zone 3, distal to the middle colic artery.
- Zone 4, the segmental intestinal branches.

As a general rule, ligation of the SMA in zones 1 and 2 results in severe ischemia of the small bowel and right colon. Ligation of zones 3 and 4 may result in localized ischemia of the small bowel requiring segmental resection.

Mechanism of Injury

The SMA is second to the renovascular system as the most commonly injured abdominal vessel after blunt trauma. Blunt trauma is responsible for between 10% and 20% of all SMA injuries[42,43] and can cause thrombosis of the artery by a direct blow, crushing of the abdomen, or seat belt injuries. Deceleration injuries may cause avulsion of the vessel from its origin in the aorta or intimal tear and subsequent thrombosis. Penetrating injuries are the most common mechanism of injury. Because of the anatomic location of the artery, multiple significant associated injuries are common.[44]

Clinical Presentation

The clinical presentation depends on the mechanism of injury, nature of the vascular injury, presence of associated intraabdominal injuries, and time elapsed since injury. Isolated thrombosis of the SMA due to blunt trauma may be missed during the initial evaluation, only to manifest at a later stage with bowel necrosis. Most patients with penetrating trauma present in severe shock. Patients with contained hematomas may be normotensive or mildly hypotensive on admission.

Surgical Treatment

The operative findings may include various degrees of hemoperitoneum, hematoma around the SMA, ischemic bowel, or any combination of these (Fig. 183.11).

After temporary control of the bleeding by direct compression and, if necessary, cross-clamping of the aorta, the SMA should be explored.

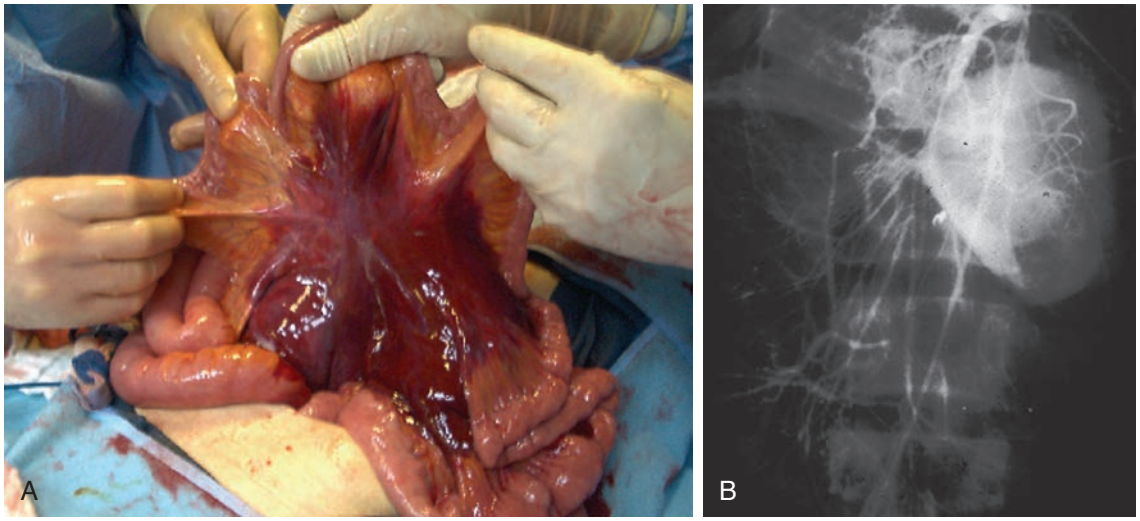

Figure 183.11 (A) Traffic accident victim with a large hematoma at the base of the mesentery found at laparotomy. This is suggestive of a superior mesenteric artery (SMA) injury and needs to be evaluated by angiography, preferably postoperatively. (B) Postoperative angiography shows a large SMA false aneurysm.

Exposure

Exposure of the retropancreatic SMA can be achieved by medial rotation of the left colon, gastric fundus, spleen, and tail of the pancreas, as described earlier. The kidney does not need to be rotated unless injury to the posterior wall of the aorta is suspected. In cases of severe bleeding when immediate exposure is critical, stapled division of the neck of the pancreas may provide fast and direct exposure of the SMA and the portal vein. Exposure of the infrapancreatic SMA can be achieved by cephalad retraction of the inferior border of the pancreas and direct dissection, or it can be achieved through the root of the small bowel mesentery by incising and dissecting the tissues to the left of the ligament of Treitz. An extensive Kocher maneuver may be required to expose this segment of the SMA. More distal sections of the SMA can be approached directly.

Exploration of a hematoma at the root of the mesentery is always a difficult and potentially dangerous task, even in the hands of experienced surgeons. In penetrating trauma or blunt trauma with ischemic bowel, all hematomas around the SMA should be explored. However, it is our practice and recommendation not to explore stable hematomas after blunt trauma in the absence of bowel ischemia. In these patients the SMA is evaluated postoperatively by means of angiography or CT angiography (see Fig. 183.11B).

Operative Management

Sharp partial transections of the SMA, such as those inflicted by knife wounds, can be managed by lateral arteriorrhaphy with 6-0 vascular sutures. This approach is possible in approximately 40% of cases.[45] Because mobilization of the SMA is restricted by the surrounding dense neuroganglionic tissue and its multiple branches, an end-to-end anastomosis is rarely possible.

Depending on the site of SMA injury, the condition of the patient, and the color of the bowel, these injuries can be managed by ligation or an interposition graft. Ligation of the SMA distal to the middle colic artery is associated with a moderate risk of bowel ischemia. Ligation of the proximal SMA results in ischemic necrosis involving the small bowel and the right colon. The first 10 to 20 cm of the jejunum may survive through collaterals from the superior pancreaticoduodenal artery. Ligation of the SMA proximal to the origin of the inferior pancreaticoduodenal artery may preserve critical collateral circulation to the proximal jejunum and is preferable to a more distal ligation. Ligation of the proximal SMA should be performed only in the presence of necrotic bowel. Ligation should be avoided in all other circumstances because of the catastrophic consequences of short bowel syndrome. In patients in critical condition with severe hypothermia, acidosis, and coagulopathy, a damage control procedure with a temporary endoluminal shunt should be considered.[46]

Definitive reconstruction is performed at a later stage after resuscitation and normalization of the patient's physiologic parameters. The reconstruction can be performed with a saphenous vein or PTFE graft between the distal stump of the SMA and the anterior surface of the aorta. In the presence of an associated pancreatic injury, the vascular anastomosis should be performed away from the pancreas, and every effort should be made to protect it from pancreatic enzymes by use of omentum and surrounding soft tissues (Fig. 183.12).

Postoperative Considerations

Postoperatively, the patient should be monitored closely for any signs of bowel ischemia. The threshold for second-look laparotomy within the first 24 hours of operation should be low. Failure to improve postoperatively and the persistence of metabolic acidosis despite adequate fluid resuscitation should prompt re-exploration of the abdomen to rule out bowel ischemia. Some authors practice mandatory second-look laparotomy. Damage control techniques allow inspection of the bowel through the transparent material used for temporary closure of the abdomen.

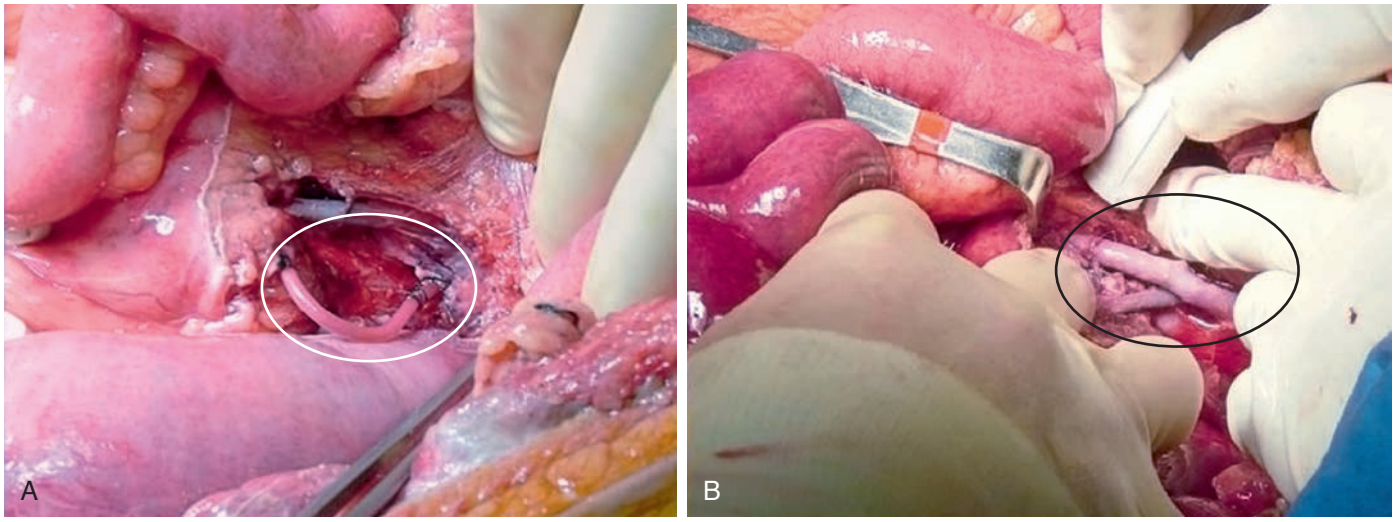

Figure 183.12 (A) Damage control with a temporary endoluminal shunt *(circle)* of the superior mesenteric artery. (B) Definitive reconstruction with a saphenous vein graft *(circle)* 18 hours later.

Figure 183.14 Angiography shows an intimal tear of the right renal artery *(circle)* due to a fall from a height. Management with an endovascular stent was successful.

Mortality

The mortality directly related to SMA injuries is difficult to assess because most patients have multiple severe injuries, including other major vascular injuries. The reported mortality varies from 33% to 68%.[42,43,45,47]

Renovascular Injuries

Anatomy

The renal arteries originate from the aorta at the L2 level (see Fig. 183.6). The right renal artery emerges at a slightly higher level and is longer than the left and courses under the IVC. Approximately 30% of the population has more than one renal artery, often an accessory one to the lower pole of the kidney. The renal veins lie in front of the renal arteries (Fig. 183.13). The left renal vein is significantly longer than the right and courses in front of the aorta. It has collateral branches from the left gonadal vein inferiorly, the left adrenal vein superiorly, and a descending lumbar vein posteriorly.

Mechanism of Injury

Renal artery injuries account for approximately 0.05% of all blunt trauma admissions.[48] The left renal artery is 1.3 to 1.6 times more likely to be injured than the right renal artery.[48,49] It has been suggested that the right renal artery is protected from deceleration injuries because of its course underneath the IVC.[50] Rapid deceleration accidents may cause intimal tears and subsequent arterial thrombosis at a later stage. In approximately 50% of cases with blunt renal artery injury, there is thrombosis or an intimal flap (Fig. 183.14; see also Fig. 183.3B). Avulsion of the artery occurs in 12% of cases.[51] In 9% to 14% of renovascular injuries, the renal artery is involved bilaterally.[49,51]

Clinical Presentation

The diagnosis of renovascular injury after penetrating trauma is almost always made intraoperatively. However, in blunt trauma, the diagnosis is usually made during routine CT evaluation of the abdomen (Fig. 183.15; see also Fig. 183.3). The clinical presentation is subtle and nondiagnostic, and the diagnosis is often delayed. In earlier reports, when CT evaluation of the abdomen was not as common, up to 50% of patients did not receive timely treatment because of delayed diagnosis.[51] Abdominal contrast-enhanced CT is highly sensitive in diagnosing renovascular trauma and should be the first line investigation (see Fig. 183.3).[52] In addition, CT provides useful information about associated injuries.

Endovascular Treatment

Endovascular treatment may play an important role in selected cases of blunt renovascular trauma, and it should be considered the first-line therapeutic option in patients in stable condition with intimal tears, acute occlusions, false aneurysms, and arteriovenous fistulae (see Fig. 183.15). The experience with this technique is still limited, and the follow-up is short. However, it is very promising and most likely will increase the number of patients undergoing revascularization.[53-55] In a National Trauma Data Bank study covering the period 1993–2001, none of the 517 blunt renal artery injuries were managed with endovascular techniques.[48] In a more recent study from the same data bank, covering the period 2004–09, only 3.2% were managed with endovascular stenting.[56] This reluctance to pursue endovascular treatment might be due in part to the frequently delayed diagnosis, which is considered by many surgeons a contraindication for revascularization.

Surgical Treatment

The management of renovascular injuries depends on the mechanism of injury, time of diagnosis, ischemia time, general condition of the patient, and presence of a contralateral normal kidney. In penetrating injuries the diagnosis is almost always made early during exploratory laparotomy, and depending on the extent of the injury and the condition of the victim, reconstruction of the vessels or nephrectomy is performed.

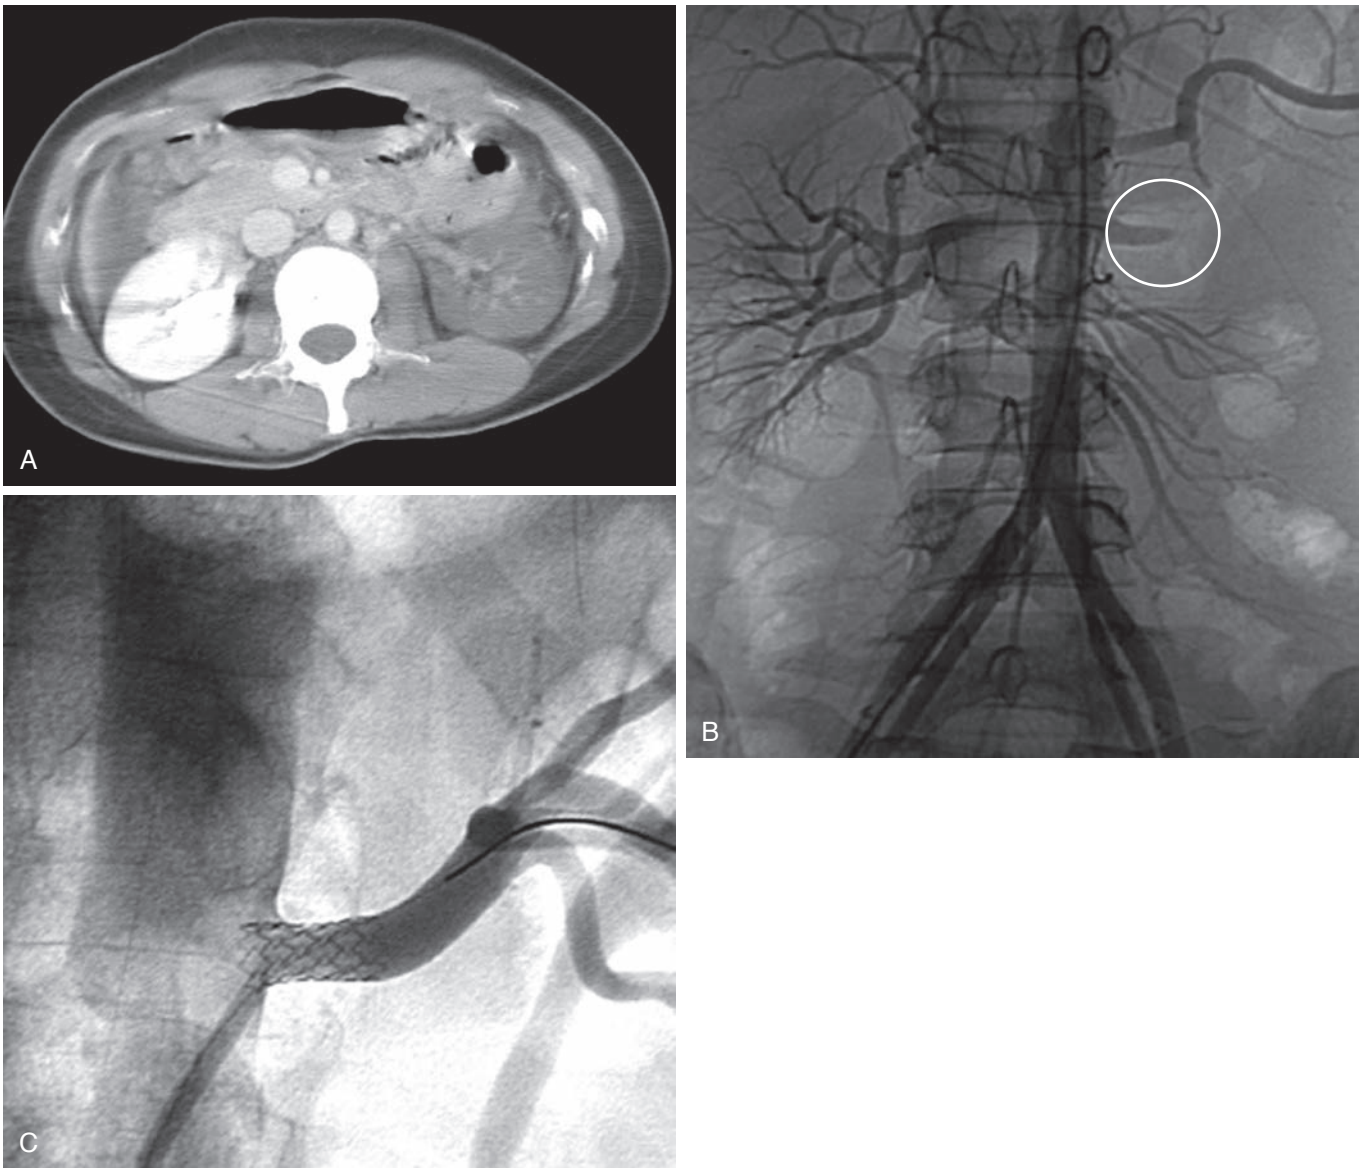

Figure 183.15 (A) Computed tomography scan shows a nonfunctioning left kidney after a traffic injury. (B) Angiography shows complete thrombosis of the renal artery *(circle)*. (C) Revascularization with an angiographically placed endovascular stent.

Revascularization

As a general rule, all zone 2 hematomas resulting from penetrating trauma should be explored. The only exception may be a stable perinephric hematoma away from the hilum.[57] However, in blunt trauma the management of renal artery injuries is complicated by the often-delayed diagnosis and prolonged ischemia of the kidney. Renal function is severely affected after 3 hours of total ischemia and 6 hours of partial ischemia, although with collateral circulation from the renal capsule or surrounding soft tissues, kidney function may be preserved despite prolonged ischemia.[52]

In stable patients diagnosed with renovascular trauma within 4 to 6 hours of injury, the general recommendation is revascularization.[52,58] However, revascularization is rarely performed, even in patients with no other injuries. In a study based on the National Trauma Data Bank, which is maintained by the Committee on Trauma of the American College of Surgeons, only 9% of the 517 patients with renal artery injury due to blunt trauma underwent revascularization. Of the remaining cases, 73% had no kidney exploration, and 18% underwent immediate nephrectomy. In the group of 87 patients with isolated renal artery injuries, 8% underwent revascularization, 8% had early nephrectomy, and 84% were observed. Multiple regression analysis adjusting for age, Injury Severity Score, and severe associated injuries showed that patients treated with revascularization had a significantly longer ICU and hospital stay than observed patients did.[48] In patients with bilateral injuries or injury to a solitary kidney, some authors recommend revascularization even up to 20 hours after the injury.[58] However, most surgeons will avoid revascularization in patients diagnosed more than 6 hours after trauma, unless the injury involves both kidneys

or a solitary kidney. The results after revascularization are generally disappointing, and successful surgical revascularization has been reported mainly by surgeons with extensive experience in renovascular surgery. The cumulative success rate of revascularization is 28%.[49] Even after successful revascularization, subsequent hypertension develops in 12% to 57% of patients, and most require elective nephrectomy.[49,58,59] The overall poor long-term results have led some authors to suggest that revascularization should be considered only in patients with bilateral renal artery occlusion or those with injury to a solitary kidney.[49,58]

Nonoperative management is certainly an acceptable option, especially in patients with delayed diagnosis, those with other major extraabdominal injuries or significant hemodynamic instability, and those with a contralateral normally functioning kidney. In a National Trauma Data Bank review of 778 cases with blunt renal artery injuries, most patients (62%) were managed without any intervention. Of patients managed nonoperatively, 32% to 40% develop renovascular hypertension.[49,51,56,58] In most patients the hypertension develops within 1 year of the injury, with a mean of approximately 3 months.[49]

The advancement of endovascular techniques has opened new horizons in the management of these injuries. We recommend liberal revascularization with endovascular techniques because of the safety of this approach and the potential for renal salvage even after prolonged ischemia. Even if late hypertension develops, medical management and nephrectomy are effective ways to address this problem. If stenting is not possible, we advocate observation and long-term monitoring for hypertension. Surgical revascularization should be considered only in renovascular injuries diagnosed intraoperatively, provided the patient's condition is stable enough to tolerate the procedure, or in the rare case of bilateral injuries or injury to a solitary kidney.

Surgical Reconstruction

Surgical reconstruction of a renal artery injury can be achieved by simple arteriorrhaphy, vein patch, resection and anastomosis, and interposition grafting. For complex, time-consuming arterial reconstructions, the kidney should be perfused intermittently with iced heparinized lactated Ringer solution or University of Wisconsin solution. Postrevascularization administration of mannitol may improve the parenchymal blood flow and alleviate the reperfusion injury.

Venous Injuries

Renal vein injuries can be managed by lateral venorrhaphy if feasible. Extensive injuries should be managed by ligation. Complex reconstruction, especially in a hemodynamically unstable patient, should be avoided. Ligation of the left renal vein near the IVC is well tolerated because of venous drainage through the left gonadal vein, left adrenal vein, and lumbar veins.

Mortality

The true mortality rate of renovascular injuries is difficult to estimate because there are other major injuries in most cases. The reported mortality rate varies from 0% to 57%.[52] The mortality in renovascular injuries due to blunt trauma is low because of the occlusive nature of most arterial injuries.[48]

Inferior Mesenteric Artery Injuries

Anatomy

The IMA originates from the anterior surface of the aorta 3 to 4 cm above the aortic bifurcation. It provides blood supply to the left colon, sigmoid, and upper part of the rectum. It communicates with the SMA through the marginal artery of Drummond.

Mechanism of Injury

Injuries of the IMA are rare. They are almost always due to penetrating trauma and account for 1% of all abdominal vascular injuries.[1]

Surgical Treatment

The diagnosis of IMA injury is made intraoperatively. Ligation is well tolerated, and no cases of colorectal ischemia have been reported in trauma cases.

Iliac Vascular Injuries

Anatomy

The abdominal aorta bifurcates into the two common iliac arteries at the L4-L5 level. The common iliac arteries divide into the external and internal iliac arteries over the sacroiliac joint. The ureter crosses over the bifurcation of the common iliac artery.

The common iliac veins join at the L5 level, below the level of the aortic bifurcation and underneath the right common iliac artery, to form the IVC (Fig. 183.16).

Mechanism of Injury

Penetrating trauma is by far the most common cause of iliac vascular injuries. Approximately 10% of patients who undergo laparotomy for gunshot wounds and 2% of patients with laparotomies due to stab wounds have iliac vascular injuries.[60] Injury

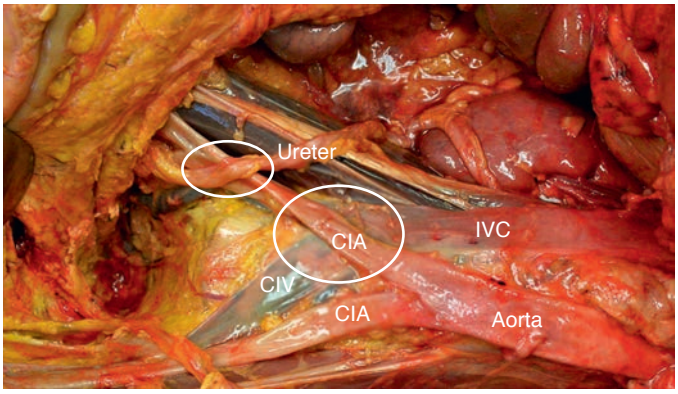

Figure 183.16 Anatomy of the Iliac Vessels. Note the confluence of the two common iliac veins *(CIVs)* behind the proximal right common iliac artery *(CIA, large circle)*. Also note the position of the ureter over the bifurcation of the common iliac artery *(small circle)*. *IVC*, Inferior vena cava.

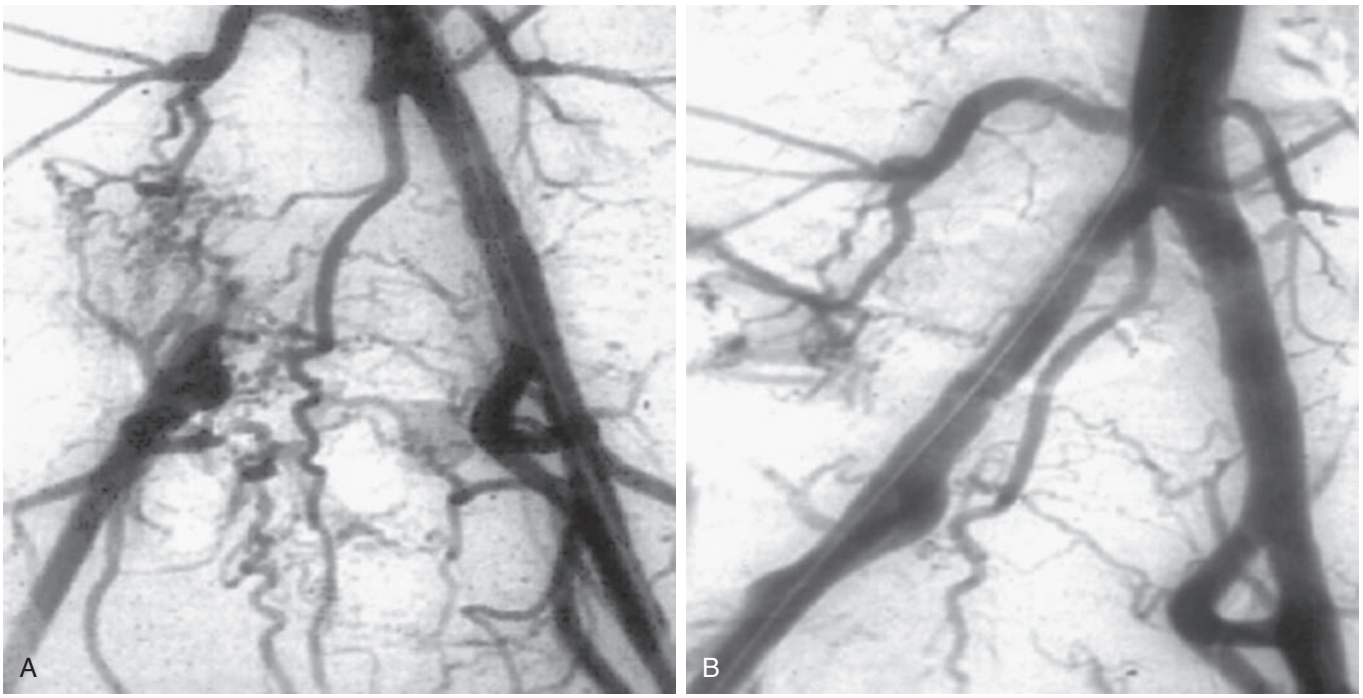

Figure 183.17 (A) Right common iliac artery thrombosis in a 16-year-old patient diagnosed many months after a motor vehicle accident. (B) Management with an endovascular stent was successful.

to the common or external iliac artery due to blunt trauma is not common, although there are many case reports. Direct laceration of the iliac vessels from a pelvic fracture or stretching of the iliac artery over the pelvic wall, resulting in intimal tear and subsequent thrombosis, is the usual mechanism of injury after blunt trauma (see Fig. 183.5).[61] Approximately 26% of patients with iliac vascular injuries have combined arterial and venous injuries.[60] Penetrating injuries usually involve the common iliac vessels, whereas blunt trauma usually affects branches of the internal iliac artery.

Clinical Presentation

The presence of a penetrating injury in the lower abdomen associated with severe hypotension and abdominal distention is highly suggestive of iliac vascular injuries. An absent or diminished femoral pulse in a patient with penetrating abdominal trauma or pelvic fracture is diagnostic of an injury to the common or external iliac artery. In rare cases of blunt trauma, thrombosis of the iliac artery may not be diagnosed during the initial workup because of the subtle clinical symptoms. In blunt trauma the diagnosis modality of choice is CT angiography.

Endovascular Treatment

Endovascular techniques may play an important role in selected cases of iliac artery injury, especially after blunt trauma. Patients with false aneurysms, arteriovenous fistulae, or large intimal tears with or without thrombosis may benefit from angiographically placed endovascular stents (Fig. 183.17).[62,63] Because of its safety and low complication rate, this should be the first line therapeutic option in elective cases in patients with subacute or chronic traumatic lesions of the common or external iliac arteries.

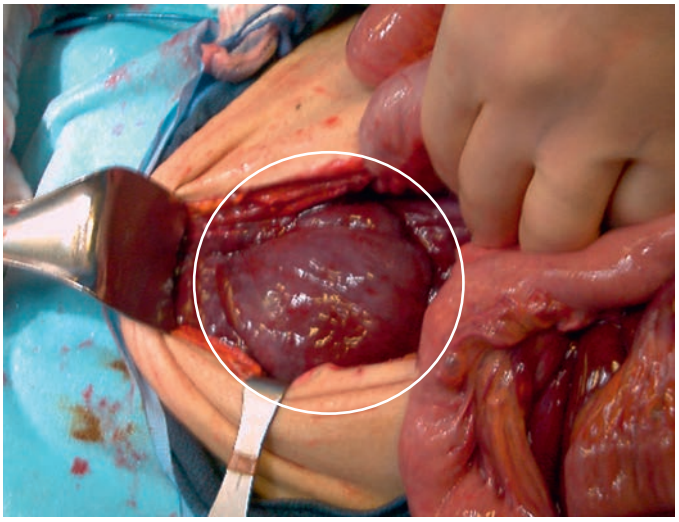

Figure 183.18 Large hematoma in the pelvis *(circle)* after a gunshot wound. This is highly suggestive of an iliac vascular injury, and proximal control should be obtained as soon as possible.

Surgical Treatment

Exposure

The operative findings may include free intraperitoneal bleeding, a zone 3 pelvic hematoma, or a combination of the two (Fig. 183.18). Zone 3 hematomas due to blunt trauma should be explored only if there is associated intraperitoneal leak, if they are expanding rapidly, or if there is an absent or diminished femoral pulse. In penetrating trauma, all hematomas should be explored. Any active bleeding is initially exposed by direct dissection of the overlying peritoneum, although medial rotation

of the right or left colon may provide better exposure. The ureter, which crosses over the bifurcation of the common iliac artery, should be identified and protected during the dissection. In addition, care should be taken to avoid iatrogenic injury to the iliac veins that lie directly under the arteries. Isolation and control of the internal iliac artery are essential in arterial injuries because bleeding may persist despite proximal and distal control. If exposure of the distal iliac vessels is difficult, especially in male patients with a narrow pelvis, extension of the midline incision by adding a transverse lower abdominal incision or longitudinal incision through the inguinal ligament may be necessary.[60]

Arterial Injuries

Small arterial injuries can be repaired with 4-0 or 5-0 vascular sutures, with care taken to avoid significant stenosis of the vessel. If necessary, a vein or PTFE patch can be used to avoid stenosis. In most gunshot injuries and in all patients with blunt trauma, reconstruction by an end-to-end anastomosis or with a prosthetic graft (6 to 8 mm) is usually necessary. Local heparin solution should be administered to prevent thrombosis during the repair. The need for systemic anticoagulation intraoperatively remains debated; however, it should not be used if there are concomitant injuries such as a traumatic brain injury. A balloon-tipped catheter should always be passed proximally and distally to remove any clots. Complex arterial reconstructions with an extraanatomic bypass or with a mobilized internal iliac artery have little or no role in the acute management of trauma. Extraanatomic bypass should be considered only in late cases with severe purulent peritonitis or infected grafts. There is evidence that the presence of enteric contamination is not a contraindication to synthetic graft use.[64] However, many vascular surgeons still recommend that an extraanatomic bypass be considered in the presence of significant enteric contamination. If prosthetic material is used, it is important that any enteric spillage be controlled and that the peritoneal cavity be meticulously cleaned before prosthetic graft repair.

It is the authors' opinion that ligation of the common or external iliac arteries should never be performed, even for damage control in patients in critical condition. Ligation is poorly tolerated by most patients and is associated with a high incidence of limb loss, and subsequent attempts to revascularize the leg may cause severe reperfusion injury and organ failure or death. In patients who need damage control, flow can be restored with a temporary intraluminal shunt (see Fig. 183.8); definitive reconstruction of the vessel is performed at a later stage when the patient's condition has stabilized.

Venous Injuries

Iliac venous injuries can be technically more challenging than arterial injuries because of the difficult exposure caused by their location behind the arteries (see Fig. 183.16). This problem is even more difficult on the right side because of the location of the right common iliac artery and the confluence of the two common iliac veins behind the right common iliac artery. Despite these difficulties, the recommendation to transect the iliac artery to access the underlying vein[65] is extreme and should not be performed. In most cases, careful mobilization and retraction of the artery provides satisfactory exposure of the vein. Ligation and division of the internal iliac artery may be helpful in providing better exposure. Repair of the iliac veins by means of lateral venorrhaphy should be considered only if it can be performed without producing major stenosis. Ligation is generally preferable to a repair that produces severe stenosis because of the risk of thrombosis and pulmonary embolism.[60] Complex reconstruction with spiral grafts or prosthetic materials, especially in a critically ill patient, is not recommended. Ligation is usually well tolerated, although patients may develop transient leg edema. On rare occasion, ligation results in massive edema of the leg and compartment syndrome that requires fasciotomy. The management of iliac venous injuries in the presence of associated iliac artery injuries is even more controversial. We do not recommend complex venous reconstruction because patients with combined arterial and venous injuries are invariably in extremely critical condition, and any procedures that prolong the operation or increase blood loss should be avoided. However, many authors recommend venous reconstruction with patch venoplasty or PTFE grafts, although there is no evidence of improved outcome with this approach.

Compartment Syndrome

Many patients with iliac vascular injuries develop extremity compartment syndrome. In this case, fasciotomy should be performed without delay, often before arterial reconstruction. However, the role of prophylactic fasciotomy is controversial and has been challenged by many authors. Prophylactic fasciotomy is a major procedure that is often associated with increased bleeding due to coagulopathy and increased venous pressures.[66,67] If fasciotomy is not performed, the patient should be monitored closely with frequent clinical examinations and compartment pressure measurements. Fasciotomy should be performed at the first signs of compartment syndrome.[60] Perioperative administration of mannitol may play a beneficial role in reducing the effects of reperfusion injury and inhibiting the development of compartment syndrome and the need for fasciotomy.[67,68]

Mortality

The reported overall mortality varies from 30% to 50% in arterial injuries and 25% to 40% in venous injuries. In isolated iliac vascular injuries, the mortality is approximately 20% for arterial injuries and approximately 10% for venous injuries.[60]

Inferior Vena Cava Injuries

Anatomy

The IVC is formed by the confluence of the two common iliac veins in front of the L5 vertebra and underneath the right common iliac artery. It ascends over the spine to the right of the aorta; at the level of the renal veins it deviates farther to the right, courses behind the liver, crosses the diaphragm, and, after a short course of 2 to 3 cm in the chest, drains into the right atrium of the heart. In its course, the IVC receives four or five pairs of lumbar veins, the right gonadal vein, the renal veins, the right adrenal vein, the hepatic veins, and the phrenic

veins. All lumbar veins are below the renal veins, and except for the right adrenal vein, there are no other venous branches between the renal veins and hepatic veins. Besides the three major hepatic veins, there are six to eight accessory veins inferiorly. Some of the accessory veins are large and may bleed profusely in the case of injury or iatrogenic avulsion.

Mechanism of Injury

The IVC is the most commonly injured abdominal vessel and accounts for approximately 25% of abdominal vascular injuries.[1] Blunt trauma is responsible for approximately 10% of IVC injuries, and it usually involves the retrohepatic segment of the vein.[69] In approximately 18% of patients with penetrating IVC injuries, there is an associated aortic injury.[70]

Clinical Presentation

More than half the patients with IVC injuries who reach the hospital alive are hypotensive, and approximately 18% require emergency thoracotomy.[70,71] Many patients with contained hematomas may be hemodynamically stable on admission. The diagnosis is almost always made intraoperatively.

Surgical Exposure

Many injuries to the IVC, especially those involving the infrarenal IVC, present with stable hematomas because of the low existing pressures within the IVC. As a rule, all hematomas due to penetrating trauma should be explored. An exception to this approach is the stable retrohepatic hematoma. Exploration of these hematomas is extremely difficult and may lead to uncontrollable hemorrhage and death. The infrarenal and juxtarenal IVC are best exposed by mobilization and medial rotation of the right colon, the hepatic flexure of the colon, and the duodenum (see Fig. 183.7). Exposure of the retrohepatic IVC is technically challenging and usually requires extensive mobilization of the liver by dividing its ligaments and extending the incision to include a right subcostal incision, right thoracotomy, or sternotomy. In our experience, addition of a subcostal incision provides excellent exposure and is the preferred initial step. If this is insufficient to allow access to the injury, a median sternotomy is performed. This provides excellent exposure to the injured structures, and if total hepatic vascular occlusion or an atriocaval shunt is required, it allows access to the right atrium as well as the suprahepatic vena cava. Alternatively, if the patient already has a right thoracotomy, connecting this incision to the laparotomy and incising the diaphragm circumferentially, leaving sufficient cuff for reconstruction, allows excellent exposure to all of these structures. These additional incisions should be considered only if perihepatic packing is not effective in controlling the hemorrhage. In cases in which packing is not effective and the additional incisions are not sufficient for adequate visualization and repair of the IVC or hepatic veins, more radical maneuvers including hepatic vascular isolation, an atriocaval shunt, or division of the liver should be considered.

Hepatic Vascular Isolation

Hepatic vascular isolation involves cross-clamping of the infradiaphragmatic aorta, suprahepatic IVC, infrahepatic IVC above the renal veins, and portal triad. Failure to clamp the aorta as a first step may result in severe hypotension and possible cardiac arrest due to the reduced venous return after occlusion of the IVC. The suprarenal IVC can be cross-clamped in the space between the superior surface of the liver and the diaphragm. However, with a juxtahepatic venous injury, this maneuver may worsen the injury if it is done incorrectly. As discussed previously, accessing the suprahepatic IVC through a sternotomy or right thoracotomy[71] may be preferable because this will also improve exposure of the injury, facilitating what is under even the best of conditions a challenging repair. Even with hepatic vascular isolation, some backbleeding can be anticipated.

Atriocaval Shunt

The atriocaval shunt requires placing a tube through a purse-string suture in the appendage of the right atrium and directing it into the IVC, distal to the caval injury. Tourniquets should be applied around the intrapericardial IVC and the suprarenal IVC.[72] A large-bore thoracostomy tube or a large endotracheal tube with clamp occlusion of the proximal end and one or two holes created to correspond to the endoatrial part of the tube can be used as a shunt. If an endotracheal tube is used, the inflated balloon can replace a tourniquet around the suprarenal IVC (Fig. 183.19). This is preferable to dissection around the IVC for tourniquet placement. Although numerous reports have highlighted the extremely poor results with atriocaval shunts, in our experience, patients have survived when the shunt was used early. This approach entails a major escalation of the operation, but in appropriate cases, it should be used early in the operation.

Division of the Liver

Another option is to divide the liver along the gallbladder-IVC plane to provide direct exposure to the IVC. This approach increases bleeding, especially in an already coagulopathic patient, and should be avoided except when the liver is already severely injured and the IVC can be exposed with minimal dissection.

Surgical Options

In most patients the IVC can be repaired by lateral venorrhaphy with 3-0 or 4-0 vascular suture material (Fig. 183.20). Most posterior caval wounds can be exposed and repaired by rotating the IVC. In some patients with anterior and posterior caval injuries, the posterior wound can be exposed and repaired from within the vein by extending the anterior wound. Ligation of the vein should be considered in hemodynamically unstable patients with severe infrarenal injuries or when repair produces major stenosis. Ligation of the suprarenal IVC is not an acceptable option because it results in renal failure. In unstable patients an intravascular shunt should be used to temporize.

Postoperatively, patients with IVC ligation should have their lower extremities wrapped with firm elastic bandages and elevated. Most patients develop temporary edema that subsides within a few weeks. However, some patients develop extremity compartment syndrome and require fasciotomy.

In patients with severe IVC stenosis after lateral venorrhaphy, there is a risk of thrombosis and pulmonary embolism. If this

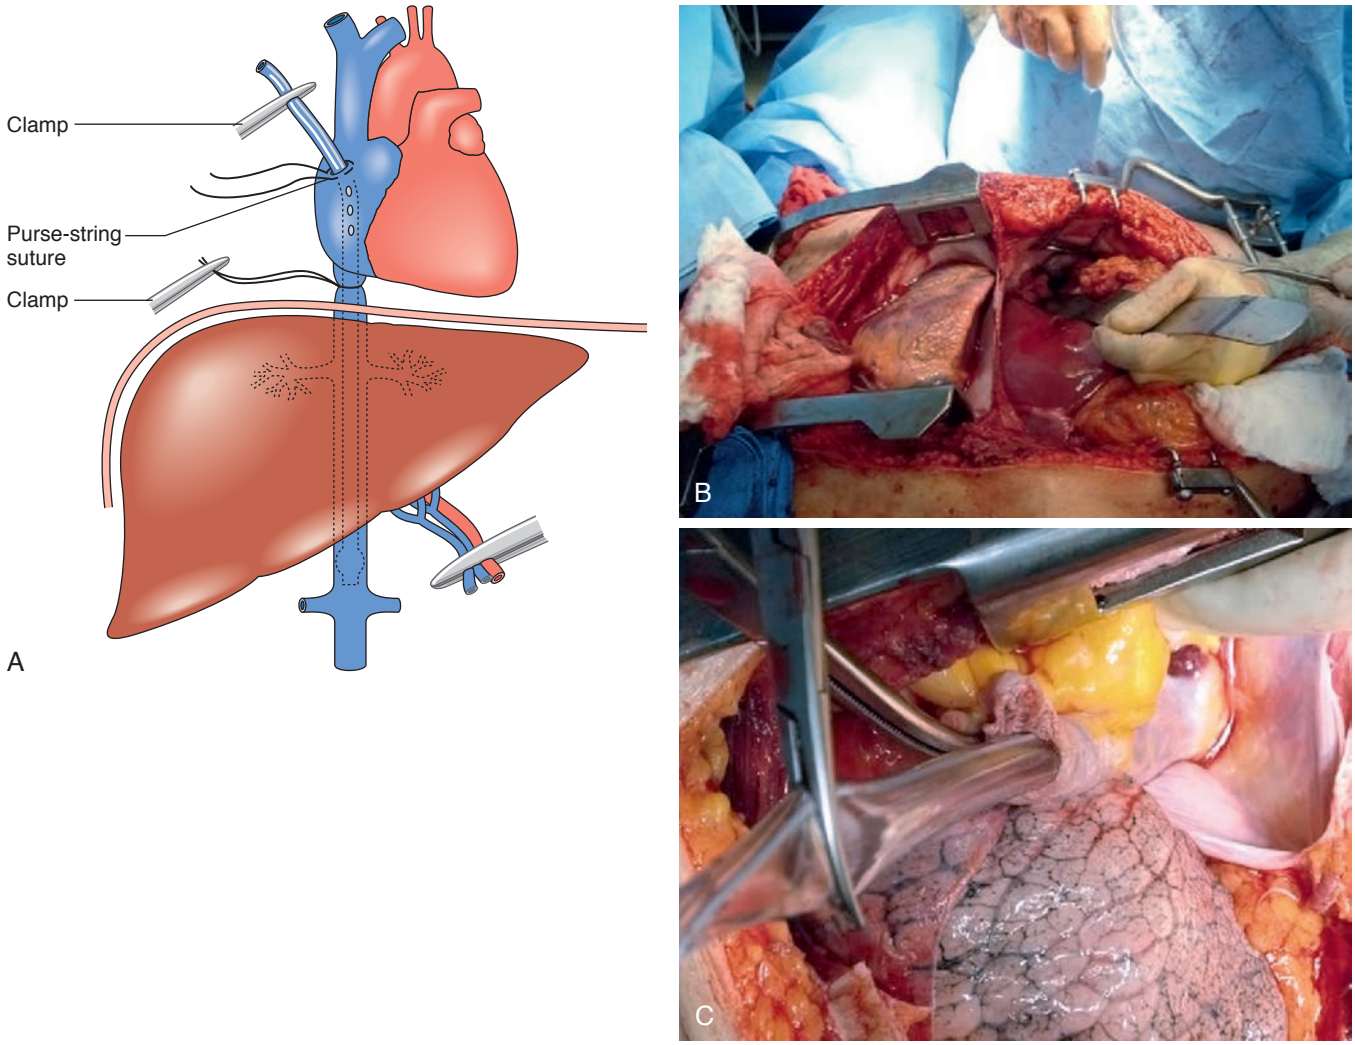

Figure 183.19 (A) Atriocaval shunt for severe retrohepatic inferior vena cava (IVC) injuries. An endotracheal tube is placed through a purse-string suture in the right atrial appendage, and the cuff is inflated above the renal veins. A tourniquet is applied in the intrapericardial IVC. Note the extra holes in the endoatrial part of the tube. This technique should be considered when liver packing does not control hemorrhage. (B) Median sternotomy with laparotomy in preparation for atriocaval shunt placement. (C) Insertion of the shunt through the right atrium.

cannot be avoided, a caval filter or clips should be deployed above the site of stenosis.

Mortality

Approximately half the patients with IVC injuries die before reaching medical care, and among those who arrive at the hospital with signs of life, the mortality ranges between 20% and 57%.[69] In a study of 136 cases with IVC injuries, Kuene et al.[69] reported an overall mortality of 52%. In patients reaching the operating room alive, the mortality was 35%. The mortality was significantly higher in suprarenal injuries.

Portal Venous System Injuries

Anatomy

The portal vein is 6 to 10 cm long and is formed by the confluence of the SMV and the splenic vein behind the neck of the pancreas, to the right of L2, and to the left of the IVC. It passes behind the first part of the duodenum and enters the hepatoduodenal ligament. In the hepatoduodenal ligament, it courses between and behind the common bile duct to the right and the hepatic artery to the left. In the hilum of the liver, it splits into right and left branches. The portal vein has no valves and provides approximately 80% of the hepatic blood flow. The SMV trunk crosses over the third part of the duodenum and the uncinate process of the pancreas. It then passes behind the neck of the pancreas, where it joins the slightly smaller splenic vein to form the portal vein. The splenic vein courses along the superior border of the pancreas and drains the inferior mesenteric vein, just before the confluence with the SMV.

Mechanism of Injury

Injury to the portal vein trunk is relatively rare and is found in approximately 1% of patients undergoing laparotomy for trauma.[73] More than 90% of portal vein injuries are due to penetrating trauma. Because of its proximity to other major

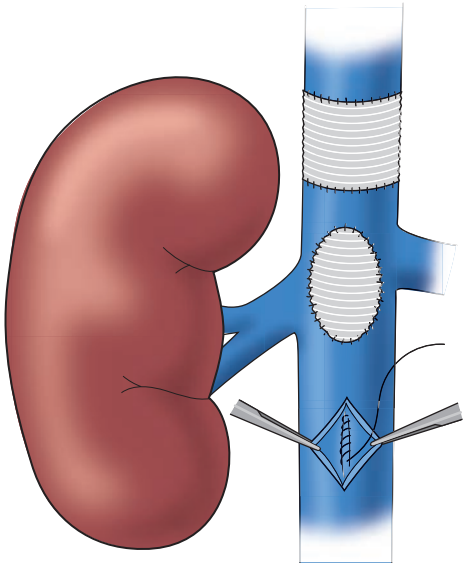

Figure 183.20 Injuries to the inferior vena cava can be managed with lateral venorrhaphy, patch repair or interposition graft. Perirenal and suprarenal injuries should not be ligated.

vessels, the incidence of associated vascular injuries is high, ranging from 70% to 90% of cases.[74]

Clinical Presentation

Most patients with penetrating injuries to the portal venous system present with signs of hemorrhagic shock and require emergency laparotomy. In blunt trauma the injury usually involves the SMV and is due to a direct blow to the abdomen or deceleration forces. These mechanisms often result in thrombosis of the vessels and occasionally avulsion and bleeding. In cases with thrombosis, the diagnosis is delayed and is often made on CT.

Surgical Treatment

The operative findings usually include a combination of local hematoma and various degrees of hemorrhage. Exposure of the retropancreatic portal vein and its major branches can be achieved by mobilization and medial rotation of the right colon and hepatic flexure of the colon and extensive Kocher mobilization of the duodenum. However, this approach often does not provide satisfactory exposure, especially in patients with associated injuries to the SMA. In these cases, stapled division of the neck of the pancreas provides excellent exposure and should be considered early (Fig. 183.21). The suprapancreatic portal vein can be exposed by a combination of mobilization and medial rotation of the right colon and hepatic flexure and a Kocher maneuver.

The portal vein and SMV should be repaired if this can be achieved with lateral venorrhaphy. Complex reconstructive procedures, such as interposition grafts, are rarely feasible or advisable because of the patient's poor condition. Approximately 80% of patients have other vascular injuries that contribute to blood loss and coagulopathy. Complex reconstruction should be undertaken only in patients with associated hepatic artery injury that cannot be repaired. Ligation of both the portal vein and the hepatic artery is not compatible with life. In these cases, reconstruction of the portal vein with a saphenous vein graft should be considered.[74]

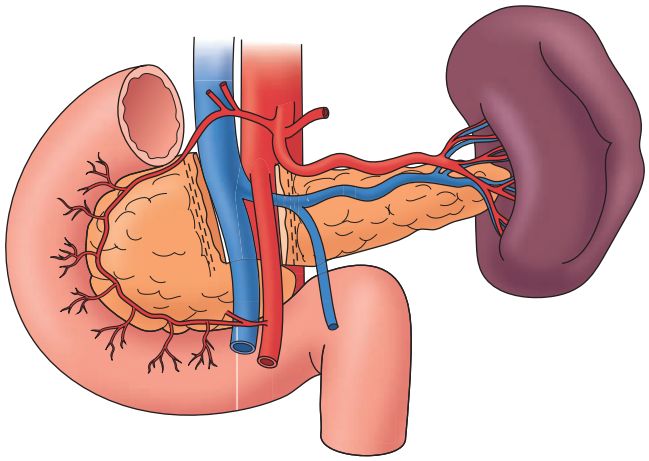

Figure 183.21 Stapled division of the neck of the pancreas provides good exposure of the retropancreatic portal vein and the superior mesenteric vessels.

Ligation of the portal vein with a patent hepatic artery is compatible with life, and the survival ranges from 55% to 85%.[75,76] After ligation of the portal vein or SMV, the bowel becomes massively edematous, and patients can develop patchy bowel wall necrosis. The abdomen should never be closed primarily because, without exception, all patients develop abdominal compartment syndrome. Temporary abdominal wall closure should be performed. Second-look laparotomy should be performed in 24 to 72 hours to check the viability of the bowel.

Postoperatively, massive fluid replacement is required because of sequestration in the splanchnic bed. During the next few days, there is significant improvement of bowel edema due to enlargement of the collateral circulation, and abdominal wall closure may be possible. Experience with the long-term effects of portal ligation is limited, but there is evidence that most survivors do not develop portal hypertension.[73,75,76]

Mortality

The mortality in portal vein injuries is high and ranges between 50% and 72%.[1,75,76] Most patients have other major injuries, making it difficult to assess the mortality directly related to isolated portal vein injuries.

ADVANCES IN THE MANAGEMENT OF ABDOMINAL VASCULAR INJURIES

There have been some significant advances in the management of abdominal vascular injuries in the past decade. The policy of "scoop and run" and early surgical control of bleeding have now become the standard of care and have improved survival in patients with vascular injuries. The concept of damage control has gained popularity and acceptance, and as a result, many patients with vascular injuries have been saved. The recognition of abdominal compartment syndrome and the use of temporary

abdominal wall closure are also important steps in improving outcomes. Endovascular technology has revolutionized the management of selected patients with specific vascular occlusions, arteriovenous fistulae, and false aneurysms. Hybrid operating rooms with angiographic radiology capabilities provide an opportunity to improve the management of abdominal vascular injuries by either temporary control of life-threatening bleeding with endovascular balloon tamponade or definitive care with angioembolization or stenting. The development of intraoperatively placed sutureless, expandable stent-grafts during open surgery is promising and may allow quick and safe vascular reconstruction. Finally, research into powerful new hemostatic agents is promising, and these agents may have a major impact on the management of abdominal vascular injuries.

This three-study series (two human, one animal) demonstrates the impact of controlled resuscitation in traumatic hemorrhagic shock. The first study by Bickell and associates in hypotensive patients who sustained penetrating torso injuries demonstrated improved outcomes, including survival, with delayed fluid resuscitation. The second study randomized penetrating and blunt trauma patients in hemorrhagic shock to resuscitation targeted at conventional (>100 mm Hg) versus low (70 mm Hg) systolic blood pressure, with no difference in mortality. In the penetrating aortic injury model of uncontrolled hemorrhage used in the animal study, the response to varied fluid infusion rates raises the possibility that a more moderate resuscitation strategy may be the key to maximizing survival.

This chapter covers the diagnosis and management of vascular injuries to the extremities. Information relating to the epidemiology and pattern of extremity vascular injury is contained in Chapter 180 of this book. The focus is on arterial injuries distal to the deltopectoral groove (axillary artery and distal) and the inguinal ligament (common femoral artery and distal) resulting from blunt and penetrating noniatrogenic trauma. The assessment and management of such injuries continues to evolve, and this chapter's emphasis remains on capturing recent data while retaining elements describing traditional (and in most cases still useful) management techniques.

EPIDEMIOLOGY AND PATTERN OF INJURY

Trauma represents a leading cause of morbidity and mortality around the world.[1] The overall incidence of trauma and vascular injuries is increasing, and although vascular injuries are present in only 1% to 2% of injured patients, these patients account for a far greater share of morbidity, mortality, and resource utilization than those without such injuries.[2,3] In modern series, vascular injuries to the extremities occur in 0.5% to 1% of

Abstract

This chapter covers the diagnosis and management of vascular injuries to the extremities. Information relating to the epidemiology and pattern of extremity vascular injury is contained in Chapter 180 of this book. The focus is on arterial injuries distal to the deltopectoral groove (axillary artery and distal) and the inguinal ligament (common femoral artery and distal) resulting from blunt and penetrating noniatrogenic trauma. The assessment and management of such injuries continues to evolve, and this chapter's emphasis remains on capturing recent data while retaining elements describing traditional (and in most cases still useful) management techniques.

injured patients but account for 20% to 50% of all vascular injuries (Table 184.1).[2-5] As is typical for the general population of injured patients, those with extremity vascular injuries tend to be young, with average ages in the 30s, and predominantly (70% to 90%) male (Table 184.1).[2-4,6]

Mortality

Extremity vascular injuries result from blunt and penetrating mechanisms with nearly equal frequency. Patients with blunt injuries experience mortality rates between 2% and 5%, whereas penetrating injuries generally result in fewer deaths.[7] The discrepancy is predominantly due to a greater incidence of concomitant nonvascular injuries in blunt trauma patients. Perkins et al.[3] reported double the rate of packed red blood cell use and massive transfusion as well as a hospital length of stay three times longer in patients with blunt injuries than with penetrating, indicating a more severe overall injury complex. In some instances mortality can be attributed to the extremity vascular injury itself, and in such cases penetrating injuries to proximal extremity arteries predominate. Dorlac et al.[8] identified 14 cases of prehospital exsanguination from isolated extremity vascular injuries. All of these injuries resulted from penetrating mechanisms, and 79% of patients exsanguinated from an artery proximal to the knee or elbow. Similar results were noted in an autopsy study by Bilgen et al.,[9] who found that a penetrating mechanism was responsible for 95% of lethal extremity vascular injuries and that 84% of these injuries were to proximal arteries. We performed a study of isolated lower extremity arterial injuries, revealing a 2.8% mortality rate with 78% of deaths due to penetrating trauma. Proximal arterial injuries resulted in greater mortality than distal ones.[10]

Amputation

Amputation rates in patients with extremity vascular injury range from 7% to 30%, with most amputations performed in patients with blunt mechanisms.[3,10] The high amputation rates seen in patients with blunt vascular injuries to the extremities can be attributed to the high-energy mechanism of such injuries and the resultant amount of damage to bone, nerve, and soft tissue, and not typically to the vascular injury itself.[10-15] Amputation is much more common when the lower extremity is involved and is most common at the popliteal level in the lower extremity and with arterial injury at the forearm level in the upper extremity.[5,7,10,14,]

Location of Injury

In large series examining both blunt and penetrating mechanisms, arterial injuries occur with nearly equal frequency in the upper and lower extremities.[4-6,16,] In the upper extremity, regardless of mechanism, the most frequently injured arterial level is that of the forearm vessels. In the lower extremity, however, mechanism influences the arterial injury pattern, with the popliteal artery most frequently injured in blunt trauma and the superficial femoral artery (SFA) most frequently injured in penetrating trauma (Fig. 184.1). A blunt mechanism of injury is seen more frequently in lower extremity than in upper extremity arterial injuries, and lower extremity injuries have accordingly higher incidences of associated tissue injuries, complications, and mortality.[16]

Associated Tissue Injuries

In extremities sustaining arterial injuries, other tissues are injured with varying frequency, based on the mechanism and arterial level of injury. In general, fractures are seen with high frequency in blunt limb trauma, with rates as high as 80% to 100% in some series.[17,18] In penetrating trauma, fractures are seen in only 15% to 40% of limbs with an arterial injury.[18-20] Regardless of mechanism, fractures, especially comminuted ones, consistently represent a risk factor for amputation when they are found in association with extremity vascular injury.[10,15,17-19,]

The incidence of named venous injury concomitant with extremity arterial trauma ranges between 15% and 35%. The presence of a vein disruption does not consistently predict amputation, and there is no broad consensus as to whether such injuries should be repaired and whether failing to do so predisposes the patient to long-term morbidity. Long-term limb

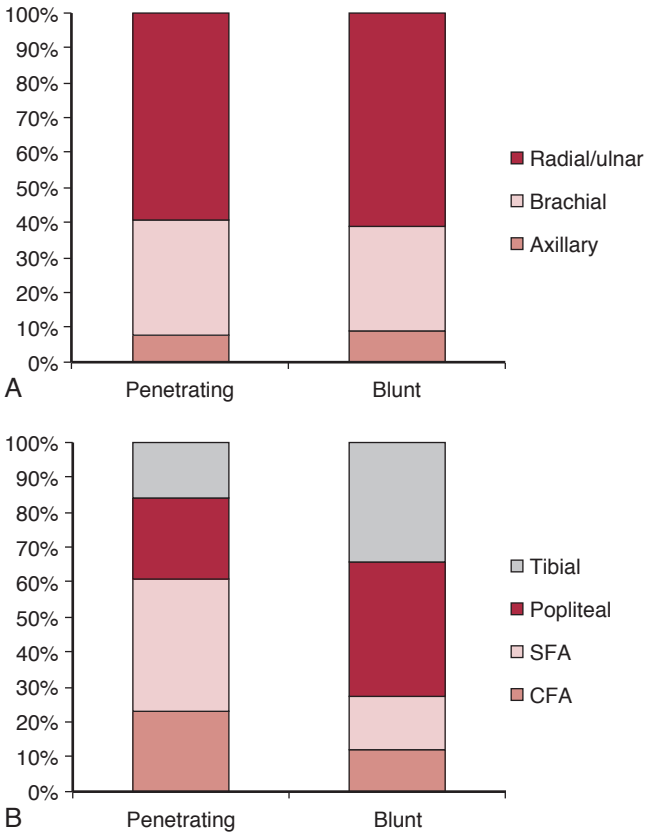

Figure 184.1 Relative frequency of injury to upper extremity (A) and lower extremity (B) arteries resulting from blunt and penetrating trauma. *CFA,* Common femoral artery; *SFA,* superficial femoral artery. (Data from references 4, 5, 8, and 17.)

edema in particular appears to be unrelated to whether a venous injury was repaired or not.[17]

The presence of a peripheral nerve injury associated with extremity vascular trauma can be difficult to detect acutely, and thus such injuries may be underreported in most of the literature on extremity vascular trauma. For the lower extremity, most studies report rates around 10%; upper extremity vascular trauma is associated with a much higher incidence of nerve injury, around 40% to 50%. Like concomitant vein injuries, a nerve injury does not predict amputation, even in severely injured limbs.[21]

Significant soft tissue disruption often accompanies extremity vascular trauma. As with nerve injuries, the incidence appears to be higher in the upper extremity, reported as 40% to 70%, than in the lower extremity, for which rates are typically reported to be 30%. The presence of a significant soft tissue deficit does appear to correlate with amputation in lower extremity arterial trauma.[15,17,18,]

DIAGNOSIS AND WORKUP

The efficient diagnosis and rapid localization of extremity vascular injuries are of great importance in the evaluation of a trauma patient. In cases in which a patient presents with "hard signs" of vascular (primarily penetrating arterial) injury, the existence and location of the injury are generally obvious, and the next step in management is operative exploration and repair.[22] The diagnosis of injuries in patients presenting with only "soft signs" of vascular injury is more challenging, and such patients typically require specific diagnostic testing in addition to the secondary trauma survey (Box 184.1). Conventional catheter-based angiography, once considered the "gold standard" for the preoperative diagnosis and localization of extremity vascular injuries, has been largely supplanted by other diagnostic techniques.

BOX 184.1 Clinical Signs of Extremity Arterial Injury

Hard Signs

- Absent distal pulse
- Palpable thrill or audible bruit
- Actively expanding hematoma
- Active pulsatile bleeding

Soft Signs

- Diminished distal pulse
- History of significant hemorrhage
- Neurologic deficit
- Proximity of wound to named vessel

Physical Examination and Doppler Indices

A number of studies speak to the diagnostic sensitivity of the combination of physical examination and measurement of Doppler-derived blood pressures in detecting extremity arterial injuries resulting from penetrating trauma. Frykberg et al.[23] studied 310 patients with penetrating injuries to the extremities, most presenting with proximity of the wound to a major vascular structure as the sole outward sign of vascular injury. Physical examination alone identified 21 of 23 major arterial injuries, most patients with an injury presented with more than one hard sign, and all patients with hard signs were found to have a significant injury. This resulted in a positive predictive value of physical examination alone of 100% and a negative predictive value of 99%. A prospective study in which routine angiography was used to screen for arterial injury in patients with soft signs was performed by Weaver et al.[24] They found that proximity alone was a poor predictor of significant arterial injury, with no surgically significant arterial injuries identified in the population in whom proximity was the sole angiographic indication. They also found that an isolated Doppler-derived pressure index of 0.99 or less (arterial pressure distal to presumed injury/normal brachial arterial pressure) had a sensitivity of 82% and a specificity of 40% for the detection of a significant arterial injury. These results were confirmed in a similar study by Schwartz et al.,[25] who found a sensitivity of 86% for a pressure index of less than 1.0. In both of these studies, a pulse deficit in the injured extremity correlated very well with the presence of a significant arterial injury. For upper extremity injuries and in situations in which both lower extremities are injured, the pressure used to calculate an "injured extremity index" may be obtained from any uninjured extremity with reliability similar to that of the ankle-brachial index.[24,25]

Fewer specific data are available on the reliability of physical examination and Doppler indices in detecting arterial injury in blunt extremity trauma, but the excellent results in penetrating injuries have been extrapolated to this population. Rozycki et al.[14] cited a 66% rate of pulse diminishment and a 31% rate of pulselessness in a population of bluntly injured extremities with arterial injuries. In a series of 500 blunt popliteal artery injuries, Wagner et al.[17] similarly reported a pulselessness rate of 94% and a diminished pulse rate of 4%.

All patients presenting with trauma to the extremities and hard signs of arterial injury should have those injuries surgically explored in an expeditious manner. Patients presenting with soft signs should undergo a complete pulse examination and a measurement of Doppler pressures in the injured limb distal to the suspected injury for the calculation of a pressure index. If the index is less than 1.0, a further diagnostic and localization study should be performed. The proximity of an extremity wound to a named vessel alone should not prompt a localization study in the absence of a diminished or absent pulse or a Doppler index of less than 1.0.

Computed Tomographic Angiography

Computed tomographic angiography (CTA) is the diagnostic modality most frequently used to identify and localize extremity arterial injuries, having largely supplanted catheter-based angiography (Figs. 184.2 and 184.3). Most seriously injured patients undergo contrasted CT scans as part of their initial evaluation, and scans are frequently completed within minutes of a patient's presentation to a trauma center. CTA offers the benefit of imaging the bone and soft tissues of the injured extremity simultaneously with arterial interrogation. In addition, CTA can assist in the diagnosis of major venous injuries if a delayed phase scan is performed.

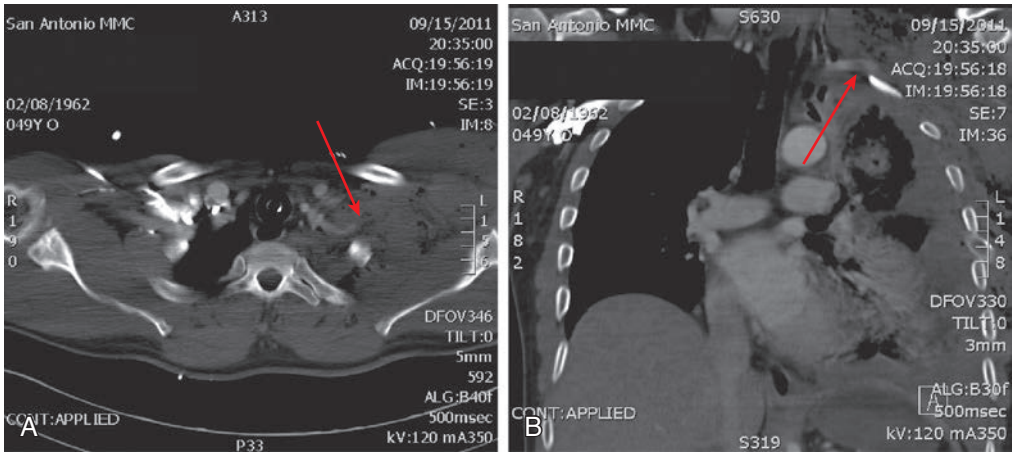

Figure 184.2 Computed tomographic angiography images from a patient sustaining a gunshot wound to the left shoulder with a pulseless left upper extremity. Note abrupt truncation of the left subclavian artery as it enters a large hematoma (A, *arrow*). Coronal reconstruction images reveal occlusion with intraluminal filling defect at the thoracic outlet (B, *arrow*).

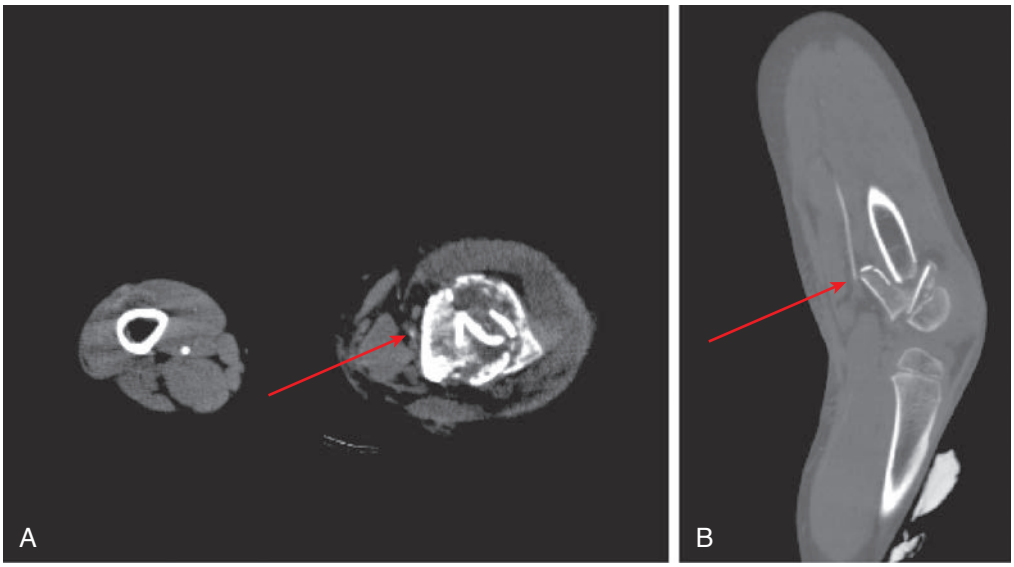

Figure 184.3 Computed tomographic angiography images from a patient sustaining blunt trauma to the left lower extremity with comminuted femur fracture. Note diminutive (likely spasm) left superficial femoral artery at the level of the fracture (A, *arrow*) just proximal to its abrupt truncation, seen best on reconstructed images (B, *arrow*).

Patterson et al.[26] reviewed nine studies published from 2001 to 2009 covering 540 patients undergoing CTA to diagnose extremity arterial injuries. There was a total of seven missed injuries, for a rate of 1.3%. The sensitivities reported in the nine studies averaged greater than 95%, with specificities greater than 90%. A prospective study by Inaba et al.[27] of patients with both blunt and penetrating extremity trauma and clinical "soft signs" revealed 100% sensitivity and specificity for arterial injury detection. Seamon et al.[28] performed a study in which 21 patients received CTA followed by conventional angiography. The criterion for entry was a Doppler index of less than 0.9 in the injured extremity. CTA identified nine injuries, all confirmed at operation or by conventional angiography. No significant arterial injuries were found with conventional angiography after being missed on CTA, although three cases of arterial spasm were discovered in this manner and treated nonoperatively. In this prospective study, CTA was obtained within minutes, whereas angiography took more than 2 hours on average. CTA was also associated with a cost savings of more than $15,000 per patient.

CTA has some limitations in the evaluation of limb trauma with some studies reporting inconsistent contrast opacification of the arterial system if the timing of the intravenous bolus is not optimal. In addition, imaging artifact from metal fragments can limit diagnostic utility. In patients with a large number of fragments, such as those with shotgun injuries, conventional angiography may offer better diagnostic capability than CTA.[27] Despite these limitations, CTA should be considered the initial diagnostic and localization modality of choice in stable patients with blunt or penetrating extremity trauma presenting with soft signs of extremity arterial injury. Conventional angiography should be reserved for unique cases and intraoperative use.

Duplex Ultrasonography

The use of duplex ultrasonography (DUS) in the diagnosis of extremity vascular trauma has been limited, especially with the increasing use of CTA. DUS can be time-consuming and operator specific, but the existing data regarding the technique deserve mention here. Bynoe et al.[29] studied a mixed population of 198 blunt and penetrating extremity trauma patients. All had a wound in proximity to a major vessel and underwent DUS. In cases in which DUS was inconclusive or the trauma surgeon thought more information was needed, arteriography was performed. DUS identified 22 major arterial injuries, 12 to the SFA. Only two injuries were missed (one diagnosed on angiography and the other during a surgical wound débridement); both were due to shotgun wounds. The sensitivity and specificity of DUS for the diagnosis of arterial injury were 95% and 98%, respectively. Bergstein et al.[30] performed a similar study in which 67 penetrating extremity trauma patients with soft signs of arterial injury or proximity underwent arteriography followed by DUS. Four arterial injuries were identified on angiography with only half also seen on DUS, making the sensitivity only 50% compared with a gold standard of arteriography. Finally, Gagne et al.[31] published a small study in which only four arterial injuries were prospectively identified, three discovered only by arteriography and one only by DUS, confirming the questionable reliability of DUS in the trauma setting. In this study, however, DUS was also compared with contrast venography for the detection of venous injuries. DUS identified seven injuries, four of which were missed by venography, which captured only one injury (to a calf vein) missed by DUS.

Although DUS is inexpensive and noninvasive, it is unreliable for the detection of arterial injuries in extremity trauma. CTA remains the most appropriate initial study for this purpose. DUS may have a role in the detection of occult venous injuries and should be considered an adjunctive imaging modality in extremity trauma. In addition, DUS may have a role in the surveillance of known injuries selected for nonoperative management (see later).

TREATMENT PRINCIPLES

Nonoperative Management

The presence of an arterial injury in a traumatized extremity does not necessarily mandate surgical therapy. When blunt and penetrating injuries to distal branches of the axillary and common femoral arteries are diagnosed with CTA, nonoperative management can be successful in up to 70% of cases.[32] Stain et al.[33] reported on 45 extremity arterial injuries noted on angiography and treated initially without surgical exploration. Injuries included small, non–flow-limiting intimal defects and flaps, small pseudoaneurysms, and arteriovenous fistulas. None produced distal ischemia or extravasation. Of these 45 injuries, 31 (69%) were proximal to the knee or elbow. None of the 45 progressed to require operative intervention after a mean of more than 5 weeks of follow-up.

Dennis et al.[34] presented a series of extremity trauma patients including 44 patients with an arterial injury identified on angiography at presentation and undergoing initial nonoperative management. Requirements included a lack of distal ischemia or extravasation and a defect smaller than 2 cm. Of the 44, 4 (9%) developed new or enlarging pseudoaneurysms within one month of injury and went on to repair. Additionally reported were 309 patients with injuries in proximity to a major vessel. These patients were evaluated without angiography and observed clinically. Four (1.3%) eventually developed hard signs of injury (all within 1 week) and had operative repair. No long-term limb morbidity resulted from their approach in either group.

These results confirm the lack of necessity for routine arteriography and suggest that nonoperative management of selected arterial injuries is reasonable, but a high index of suspicion for the possible development of pseudoaneurysm or ischemic complication is necessary during a period of close clinical follow-up. Injuries identified on imaging that may be considered for observation include those that produce no active hemorrhage or distal ischemia, such as small intimal tears or flaps, pseudoaneurysms, and arteriovenous fistulas. Serial surveillance with an appropriate imaging modality such as CTA or DUS is recommended; early repair might be more appropriate if prospects for follow-up are uncertain.

Endovascular Therapy

The use of endovascular techniques to treat vascular injuries has increased significantly over the past 2 decades. From 2000 to 2003, there was a nearly fourfold increase in the percentage of arterial injuries treated by endovascular means. This same period saw a greater than 30-fold increase in the use of stent-grafts to treat arterial trauma.[35] The growth in endovascular treatment has been less pronounced for extremity injuries than for axial arterial trauma, and endovascular therapy is currently applied more frequently in blunt than in penetrating trauma and in lower extremity than in upper extremity injuries. It appears to have similar or improved outcomes compared with open repair of extremity arterial injuries despite being applied in patients with a significant burden of associated injuries and medical comorbidities.[36,37]

Endovascular treatment is most appropriate when the morbidity difference between the open and endovascular procedures is greatest. This is most often the case in the setting of injuries to junctional vessels (such as the subclavian and iliac).[38] In such cases, the use of endovascular balloon occlusion for proximal vascular control may obviate the need for opening a body cavity. If the traumatic vascular lesion can be safely traversed with a guide wire, definitive endovascular treatment is possible in some cases.

Stent-grafts have been successfully deployed to treat arterial injuries manifesting with hemorrhage and occlusion.[39] The greatest experience is in the iliac and subclavian vessels, and reported short-term results are promising.[40,41] Catheter-directed embolization with coils and glue has been used to treat smaller vessels and seems particularly successful when it is used for the treatment of small pseudoaneurysms and arteriovenous fistulas of the crural and deep femoral branch arteries.[42,43]

With endovascular equipment and skills in increasingly ready supply, their broader application in the treatment of extremity vascular injuries seems inevitable. Enthusiasm for their use should be tempered by the fact that there are few to no long-term data available on the outcomes when these techniques are used "off-label" to treat such injuries. Every limb trauma patient is different, and the most appropriate treatment should be determined on a case-by-case basis through close communication between the trauma surgeon and endovascular provider. If an institution is to have the capability to apply endovascular techniques to emergently treat extremity trauma patients, it must be prepared with the ready availability at all hours of the equipment and expertise necessary to maximize the benefits of these techniques.

Open Surgical Management

Open surgical control and repair remain the mainstays of the management of most extremity vascular injuries. If possible, operations should be performed on a table amenable to fluoroscopic imaging to facilitate orthopedic fixation and on-table angiography if needed. The extremity should be prepared and draped widely to facilitate exposure of inflow and outflow vessels, typically circumferentially in the case of extremity injuries. If the need for a vein graft is anticipated, the proposed harvest site should be included in the prepared operative field. Conventional practice is to obtain saphenous vein grafts from uninjured extremities to preserve collateral venous drainage. This dogma is not supported by good-quality data, however, and it may be appropriate to harvest conduit from an injured extremity if there is no venous injury present or if the vessel to be harvested is well peripheral to the site of injury.

The general principles of establishing proximal and distal vascular control and restoring in-line flow to a suitable outflow bed are the same for the treatment of traumatic lesions as for any other vascular defect. Because traumatic vascular injuries frequently present with significant hemorrhage, the ability to expeditiously achieve vascular control is paramount. A tourniquet can be used to provide rapid control of inflow until surgical proximal arterial control can be obtained. To ensure adequate exposure for control and repair, incisions are typically made longitudinally, directly over the target vessel, proximal and distal to the injury. Once vascular control is achieved, incisions can be extended as needed to expose the zone of vascular injury. In some cases of extremity injury, control may need to be obtained proximal to the extremity itself. Such cases lend themselves well to the endovascular placement of an occlusion balloon to achieve proximal control. If this is not possible, upper extremity control may require infraclavicular or supraclavicular incisions to expose the subclavian vessels. Retroperitoneal or inguinal ligament–splitting incisions may be required for proximal control in the lower extremity. Many trauma patients may be unable to tolerate systemic anticoagulation because of ongoing hemorrhage or associated injuries. In these patients, local anticoagulation with heparinized saline injection directly into the injured vessel proximal and distal to the injury may be used.

Wide débridement of contaminated and nonviable tissue within the zone of vascular injury should be performed. During débridement, an assessment of the availability of healthy tissue to cover the vascular repair should be made; as such, coverage is essential to prevent desiccation and possible anastomotic breakdown or graft disruption. Tissue coverage may require coordination with other services operating on the injured extremity. The injured vessel should be débrided to healthy-appearing tissue before a final plan for vascular repair is made. Intimal injury can extend beyond what is appreciated by an injured vessel's outward appearance. Before heparinization and repair, inflow and outflow vessels should undergo gentle balloon catheter thrombectomy to confirm patency. A subjective assessment should be made of the bleeding forward and backward from the injured vessel, and if it is not thought to be adequate, a search for additional flow-compromising injuries should be undertaken.

In general, provided the patient's physiologic status will tolerate it, arterial injuries should undergo urgent surgical repair with the goal of restoring inline distal flow. In some cases, however, acute ligation of an injured extremity artery may be the most feasible acute option. Sometimes this may be done with a plan for formal revascularization when the patient's overall condition stabilizes. If an artery proximal to the elbow or knee

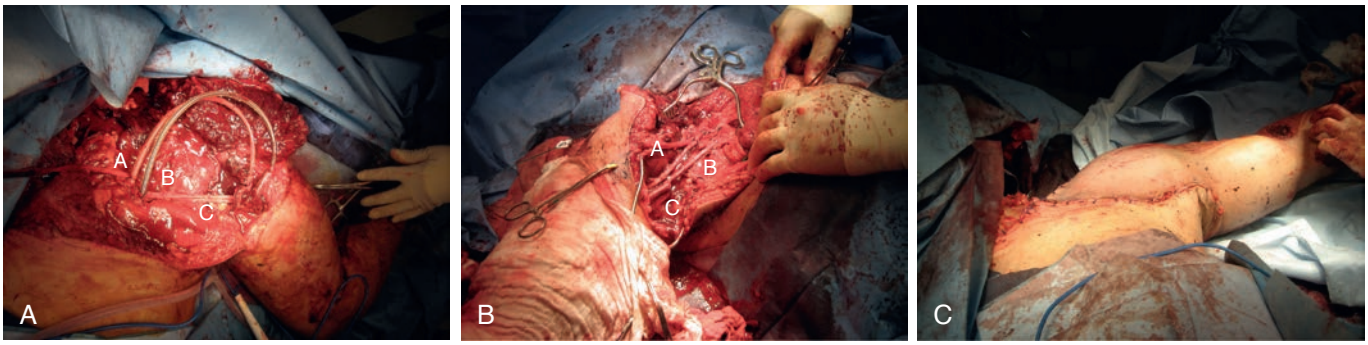

Figure 184.4 (A) Open scapulothoracic dissociation (torso to the left) before return to normal anatomic length with axillary arterial *(A)* and venous *(B)* shunts in place. Note brachial plexus component *(C)* on significant stretch before reduction. (B) After reduction, fixation, and interposition vein grafts to the axillary artery *(A)* and vein *(B)*, the brachial plexus *(C)* is returned to its typical anatomic position and tension. (C) Normal-appearing external shoulder anatomy is restored after skin closure.

is ligated, the extremity distal to the injury should be observed extremely closely for signs of developing ischemia, which should prompt immediate formal revascularization or shunting (or amputation if neither of these can be safely performed).[44,45]

Once the extent of the arterial injury is known, three options exist for repair. In some cases, a short injured segment can be resected circumferentially and enough of the vessel freed proximally and distally to perform a spatulated end-to-end anastomosis. In other cases, a single arteriotomy can be débrided and a patch angioplasty performed. If neither of these is feasible, an interposition graft of appropriate length is indicated. Results of vein grafts are good, with 30-day patency rates of around 90%. Most occlusions occur within the first week, suggesting technical problems as the etiology for graft failure.[46] All open traumatic wounds are considered contaminated, and the preferred conduit for repair of vascular injuries is autologous saphenous vein. Infections involving prosthetic grafts are notoriously difficult to manage, resulting in high rates of graft explantation and amputation. These issues are exacerbated when there is inadequate soft tissue graft coverage.[47,48] It is generally accepted that the poor long-term patency seen with prosthetic grafts used for chronic occlusive disease will manifest in trauma patients as well.[49] Feliciano et al.[48] reported an early (≤30 days) graft occlusion rate of more than 6% in a series of 175 extremity arterial prosthetic grafts, with an additional 6% of grafts occluding after 30 days. The prosthetic arterial grafts most at risk for thrombosis were placed in smaller vessels. Despite the perception of a high failure rate, the use of prosthetic conduits remains controversial, and no long-term patency data are available. A short-segment prosthetic graft may be considered to repair an uncontaminated (typically blunt) arterial injury to a proximal vessel such as the axillary or common femoral artery, where size match with the saphenous vein may be a problem.

Temporary Shunting

The civilian use of temporary shunts to expeditiously restore flow before definitive vascular repair has grown out of initial military surgical experiences with the technique in the Vietnam War.[50] The technique has gained wide acceptance as a temporizing measure allowing for distal perfusion during fracture stabilization before formal vascular repair or as an adjunct to damage control management of a patient unable to undergo definitive repair acutely (Fig. 184.4). In reports of shunts used to allow orthopedic fixation, arterial shunt dwell times have been in the range of 1 to 3 hours, with patency rates approaching 100% in the absence of the use of systemic anticoagulation.[51-53] Dwell times are predictably longer when shunts are placed as part of damage control management, typically ranging from 12 hours to over 24 hours, allowing time for resuscitation and physiologic stabilization before definitive vascular repair. Despite higher limb injury severity in such damage control patients, shunt patency and limb salvage results are equivalent to those seen when arteries are shunted to allow for orthopedic stabilization.[52,54] Although infrequently used, arterial shunts placed in the forearm and tibial vessels have poor patency (12% vs. 86% for proximal shunts), as presented in a recent military report.[55] Shunts placed in the venous system fare surprisingly well in terms of patency, despite the absence of systemic anticoagulation and dwell times of up to a few hours. In a combined review of two recent military reports, only a single episode of thrombosis was noted among 14 shunted vein injuries (93% patency).[55,56]

Venous Repair Versus Ligation

The decision whether to repair or to ligate major extremity venous injuries remains controversial. There has been no consistently reported association between major venous ligation and eventual amputation. Conventional wisdom has been that vein repairs are highly likely to acutely thrombose, a conclusion supported by data from Timberlake et al.,[57] who performed DUS on 138 patients with venous repairs. They found that between 24 and 96 hours from operation, all repairs had occluded. The high incidence of acute thrombosis of venous repairs is supported by data from Smith et al.,[58] who reported 45% occlusion rate at 72 hours. The occlusion of venous repairs may be transient, however, as they found that at 12 weeks, more than 85% of the vein repairs were patent.

The development of limb edema is seen as the primary potential adverse outcome when a major extremity venous injury

is ligated. The development of edema is more common when ligation is performed at the popliteal than at the femoral level, with transient swelling seen in up to 90% of ligated popliteal and 50% of ligated femoral injuries. Repair reduces the transient edema by about half, to 50% and 29%, respectively.[57] Nearly all patients, regardless of the status of the injured vein, experience near-complete resolution of edema by the time of or shortly after discharge from the hospital.[57,59,60] Edema is far less common after ligation of major upper extremity veins.

Venous thromboembolism is also a risk after major extremity venous injury, and the rate of deep venous thrombosis in patients undergoing major venous ligation appears to be approximately twice that of patients undergoing repair. There is no clear indication of whether the thrombi seen in this population are the result of the venous ligation, however, and the rates of pulmonary embolism are similar between patients undergoing ligation and repair.[61]

The decision to repair or to ligate a major extremity vein injury should be made in the context of the patient's overall physiologic condition. If it is safe to take the time required to repair an injury, it is reasonable to attempt to do so. End-to-end anastomosis, lateral suture venorrhaphy, patch venoplasty, and interposition grafting are all viable options for repair, depending on the anatomy of the injury. Ligation should be performed if the patient's condition will not tolerate the additional operative time. Regardless of whether ligation or repair is performed, a period of leg elevation and gentle compression can help reduce the incidence of postoperative edema and possibly eventual venous insufficiency.

SPECIFIC ARTERIAL INJURIES

Axillary Artery

Mechanism and Pattern

The axillary artery is predominantly injured in penetrating trauma,[44,62] with the proximal, middle, and distal divisions injured with similar frequency.[62] The artery is located in close proximity to the brachial plexus, and nerve injuries are seen in more than a third of patients sustaining axillary injury.[62,63]

Diagnostic Considerations

Deficiencies in distal pulses and frank ischemic changes are not universally seen in proximal upper extremity arterial injuries, and a deficit is appreciated in only about two thirds of patients with injury to the axillary artery.[44,64] A high clinical index of suspicion should be maintained when a patient has an injury in proximity to the course of the axillary artery, especially if there is evidence of a concomitant brachial plexus injury. Doppler indices and vascular imaging with CTA or angiography can be useful in making the diagnosis.

Surgical Considerations

Because the proximal portion of the vessel is relatively fixed and cannot be significantly mobilized longitudinally, injuries to the axillary artery are most commonly primarily repaired or treated with an interposition graft.[44,62,63] Owing to the proximal location of the axillary artery near the thoracic outlet, certain injuries in hemodynamically stable patients may be amenable to stent-graft treatment if the lesion can be safely traversed with a wire. The endovascular procedure can be performed antegrade by the femoral approach or retrograde by the ipsilateral brachial approach.[39-41,65]

Brachial Artery

Diagnostic Considerations

A pulse deficit is appreciated in three quarters of patients with an injury to the brachial artery.[44] The arterial injury is frequently associated with fractures of the humerus and dislocations of the elbow (especially in children), so a high clinical index of suspicion is warranted when these skeletal injuries are present.

Surgical Considerations

The brachial artery's course is generally straight, and the vessel can be extensively mobilized and can be repaired with an end-to-end anastomosis in up to 50% of cases; most of the remaining injuries are treated with an interposition graft.[20,44,66]

Radial and Ulnar Arteries

Diagnostic Considerations

Radial and ulnar artery injuries are manifested with corresponding pulse deficits more than 80% of the time and can be associated with significant soft tissue trauma.[20] Part of the diagnostic evaluation of a patient with suspected forearm arterial injury is a Doppler-based Allen test to confirm joint radial and ulnar contribution to the anastomoses of the palmar arches.

Surgical Considerations

If only one of the forearm arteries is injured and an Allen test reveals a patent palmar arch, the injured artery may be safely ligated. If the palmar arch is not patent in the absence of the contribution of the injured artery, the artery should be repaired. In instances in which both the radial and ulnar arteries are injured, preference should be given to repair of the ulnar artery, as it is most commonly the dominant contributor to the perfusion of the hand. The forearm arteries are commonly amenable to mobilization and end-to-end repair.

Femoral Arteries

Diagnostic Considerations

Clinically apparent distal ischemia or pulse deficit is noted in more than 90% of femoral arterial injuries.[45] Although hard signs of arterial injury are common, a high clinical index of suspicion should be maintained in cases of penetrating injury to the groin or proximal thigh. An injury to the PFA may not itself produce diminished distal perfusion, but such injuries can be manifested with an expanding thigh hematoma. A low threshold for the use of CTA or other vascular imaging modality should be maintained.

Surgical Considerations

The CFA is most commonly repaired with a short-segment interposition graft or a vein patch. Injuries to the CFA should be explored with circumferential dissection and control of the CFA and proximal SFA and PFA to ensure that a small back-wall injury is not missed (Fig. 184.5). The PFA can be ligated in an unstable patient, but it should be repaired if the patient's physiologic condition will tolerate because of the vessel's role in collateralization of the leg (Fig. 184.6). Injuries to branches of the PFA are frequently amenable to endovascular embolization.

The SFA is typically repaired with an interposition graft, but if sufficient length can be attained by longitudinal mobilization, end-to-end anastomosis can be performed.

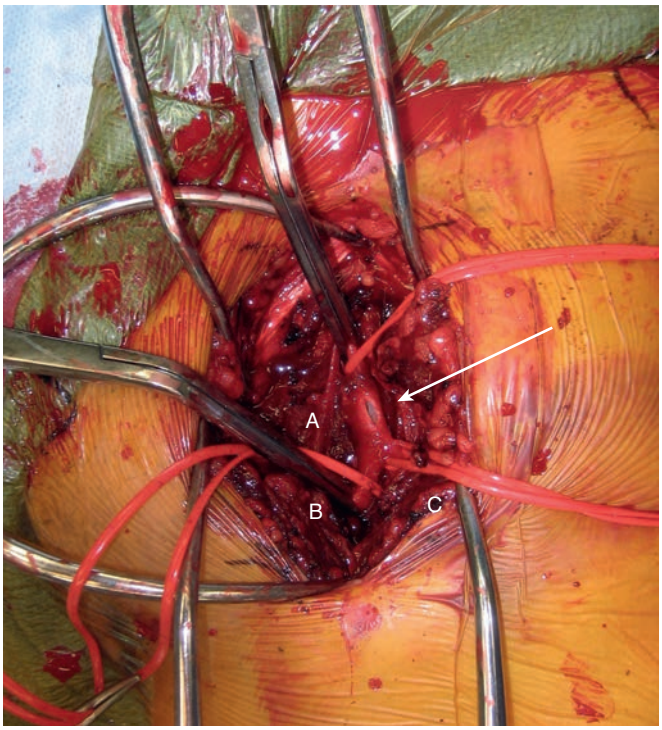

Figure 184.5 Stab wound to the common femoral artery (CFA). In addition to the traumatic anterior CFA laceration *(arrow)*, this vessel also had a smaller, full-thickness, posterior laceration. Note circumferential dissection and loop control of the CFA *(A)*, superficial femoral artery *(B)*, and proximal profunda femoris artery *(C)*. The posterior laceration was primarily repaired with interrupted sutures and the anterior laceration was repaired with a vein patch to prevent loss of luminal diameter.

Popliteal Artery

Diagnostic Considerations

Diminished or absent pulses are features of nearly all blunt and most penetrating popliteal injuries.[17] Because of the close association of popliteal injury with fractures and dislocations of the knee, an arterial injury should be suspected in patients with such skeletal injuries unless their physical examination findings and noninvasive evaluation are completely normal (Fig. 184.7).

Surgical Considerations

In nearly all instances, the most appropriate exposure of the injured popliteal artery is through separate medial above- and below-knee incisions. Although they do not allow direct access to the retrogeniculate popliteal artery, these incisions allow proximal and distal vascular control and extension to the SFA and crural arteries, and they permit a number of options for arterial repair. Medial exposure of the popliteal artery directly behind the knee should be avoided because the necessary division of the semimembranosus and semitendinosus tendons invites considerable morbidity. Rarely, a posterior approach to the popliteal may be used to treat an arterial injury that is known to be focal and behind the knee, but most injured patients cannot be safely placed in the required prone position, and it is frequently difficult to know the true extent of arterial injury preoperatively. Because of the relatively fixed location and nature of the exposure of the popliteal artery, primary anastomosis is not typically possible, and the majority of injuries require an interposition graft.[67]

Injury to the popliteal artery, especially when resulting from blunt trauma, carries the highest amputation rate of any arterial disruption of the lower or upper extremity.[5,10,19,68]

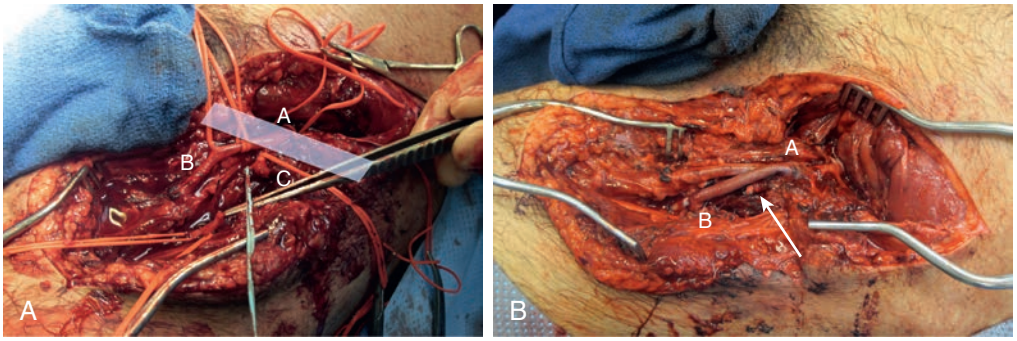

Figure 184.6 (A) Gunshot wound resulting in transection and segmental loss of the proximal profunda femoris artery. Control of the common femoral *(A)*, superficial femoral *(B)*, and proximal profunda femoris *(C)* arteries has been obtained. The distal profunda is at the forceps tip. The patient had a high femoral bifurcation, necessitating division of the inguinal ligament *(shaded box)* to achieve proximal control. (B) To preserve the most proximal profunda branches, repair was achieved through a common femoral *(A)* to profunda *(B)* interposition graft *(arrow)* with ligation of the proximal profunda stump *(arrow)*.

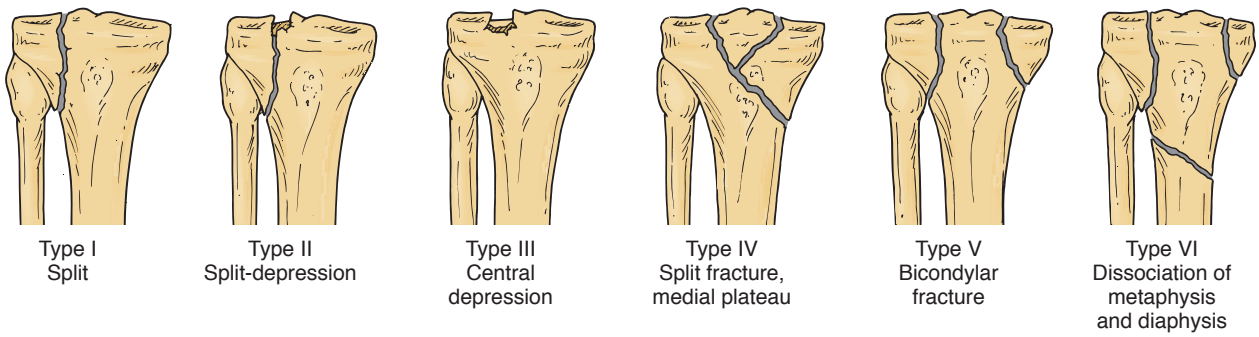

Figure 184.7 Schatzker classification of tibial plateau fractures. The type IV fracture pattern is associated with injury to the popliteal artery.

Although amputation rates have decreased in recent times, popliteal injuries should be reconstructed promptly and with great care, because failure to promptly restore adequate distal perfusion or to identify thrombosis in a repaired vessel may lead to limb loss. Clinical conditions predisposing to amputation in a large series of blunt popliteal injuries are presented in Table 184.2.

TABLE 184.2 Amputation Rates in Association With Perioperative Risk Factors in Blunt Popliteal Artery Trauma ($N = 100$)

Risk Factor	Present (%)	Absent (%)	*P* Value[a]
Severe soft tissue injury	13/31 (42)	2/69 (3)	<.0001
Deep soft tissue infection	9/17 (53)	6/83 (7)	<.0001
Preoperative ischemia	15/64 (23)	0/36 (0)	<.001
Preoperative delay >6 h	10/40 (25)	5/24 (21)	NS
Preoperative delay >12 h	2/14 (14)	13/50 (26)	NS
Systemic anticoagulation	6/71 (8)	9/29 (31)	<.01
Primary arterial repair	3/49 (6)	12/51 (24)	<.05
Palpable pedal pulse within 24 h	4/55 (7)	11/45 (24)	<.05
Trifurcation arterial injury	6/29 (21)	9/71 (13)	NS
Popliteal vein injury	6/29 (21)	9/71 (13)	NS
Ligation of venous injury	2/6 (33)	4/23 (17)	NS
Fasciotomy (operative or delayed)	11/61 (18)	4/39 (10)	NS
Delayed fasciotomy	1/4 (25)	14/96 (15)	NS
Preoperative compartment syndrome	2/17 (12)	13/83 (16)	NS

Tibial Arteries

Diagnostic Considerations

Most patients with tibial arterial injuries present with a pulse deficit and, if multiple arteries are involved, clinically apparent ischemic changes of the foot.[69-71] Arterial injury should be suspected in cases of high-energy trauma to the tibia, especially in patients with complex fracture patterns and significant soft tissue disruption.

Surgical Considerations

It is widely accepted that disruption of a single tibial artery does not require reconstruction. Very low amputation rates have been consistently reported when such isolated injuries are observed or ligated.[69-72] In cases of multiple arterial injuries or single injuries with clinically ischemic limbs, repair of at least one tibial vessel should be performed.[73] Standard surgical approaches to the tibial arteries should be used, and if calf fasciotomies have been or are to be performed, these exposures of the anterior and deep posterior compartments can be used to access the injured vessels. Most tibial artery injuries require interposition grafting; however, end-to-end anastomosis is possible if the injury is focal. Because some isolated tibial artery injuries are not clinically apparent on presentation, late pseudoaneurysms and arteriovenous fistulas can develop. These can frequently be treated by endovascular means.[43]

OTHER CONSIDERATIONS

Compartment Syndrome and Fasciotomy

For a detailed discussion of the pathophysiology and clinical features of compartment syndrome, refer to Chapter 102. The classically described diagnostic signs of the five *p*'s (pain with passive motion, pallor, poikilothermia, paresthesia, and pulselessness) represent late signs of compartment syndrome and are frequently absent or obscured in trauma patients because of distracting injuries and altered mental status. The true incidence of clinically relevant compartment syndrome after modern extremity vascular injury is unknown because of the widespread use of prophylactic fasciotomy. This practice has developed as it has become accepted that the development of compartment syndrome portends a poor limb outcome.[74,75]

Approximately 40% of patients with lower extremity arterial injury will receive a fasciotomy, with most of these performed within hours of initial revascularization. Performance of a

fasciotomy concomitant with or soon after lower extremity revascularization is associated with a fourfold reduction in eventual amputation and other complications.[76] Lower extremity fasciotomies are performed more commonly for penetrating than for blunt trauma and are most commonly performed when the popliteal artery is injured, followed closely by the femoral arteries. The performance of a fasciotomy is most strongly predicted by the presence of a fracture or dislocation, a vein or nerve injury, or multiple arterial injuries.[75,76]

In the upper extremity, compartment syndrome principally results from arterial injury proximal to the elbow, most frequently to the brachial artery. Approximately 20% of patients with brachial artery injuries will be diagnosed with compartment syndrome, and as with the lower extremity, the syndrome is more common in penetrating trauma. Multiple arterial injuries and fracture predict the development of upper extremity compartment syndrome, but unlike in the lower extremity, vein and nerve injuries do not.[74]

Early calf or forearm fasciotomy should be considered in all patients, with restoration of distal perfusion after ischemia resulting from trauma, especially if multiple fractures or arterial injuries are present. Fasciotomy will be of greater potential benefit with longer ischemic time. Thigh or upper arm fasciotomies should be considered for proximal arterial injuries, especially if there is a proximal venous occlusion and outflow is not restored. Although fasciotomies complicate wound management and may require additional operative procedures to include possible split-thickness skin grafting, their benefits, even when performed prophylactically, outweigh these risks.

Vascular Injury in the Mangled Extremity

Injured extremities with severe trauma to multiple tissue types (some combination of skin, muscle, nerve, and bone) present a difficult clinical problem. Such "mangled extremities" can present with one or more arterial injuries and the decision regarding whether to perform primary amputation or to attempt limb salvage has been a source of debate for decades. The Mangled Extremity Severity Score (MESS) has been devised as a decision aid (Box 184.2).

A MESS of 7 or higher correlates well with primary amputation of the upper[77,78] or lower[79,80] extremity. Ischemia is a component of the MESS, but the degree of bone loss and soft tissue disruption has greater bearing on the decision to perform primary amputation.[11,13] Neither the MESS nor any of the numerous other extremity injury scores accurately predict functional outcomes in severe limb trauma.[81-83] In addition, long-term functional status does not appear to be affected by limb amputation in a patient with severe lower extremity injury.[21,84]

Patients with mangled extremities and arterial injuries should undergo initial multidisciplinary consultation with the inclusion of a vascular surgeon. If an initial attempt at limb salvage is planned, vascular reconstruction should be performed, provided the graft or repair can be covered with viable tissue. In general, an attempt at initial limb salvage and early revascularization is appropriate. The need for reconstruction of arterial injuries should not be considered an indication for primary amputation, except in select instances, including cases of multiple-level or very long arterial injuries, requiring extensive reconstruction or physiologic compromise precluding the long reconstructive procedure. The general principle that a patient's life should not be sacrificed for the sake of an injured limb holds true in all cases. In cases of limbs with multiple tissue injuries, shunts can be used to temporize and allow early fracture stabilization or continued resuscitation (so-called vascular damage control), followed by vascular reconstruction when physiologic condition allows.

BOX 184.2 Mangled Extremity Severity Score

Skeletal/Soft Tissue Injury	
Low energy (stab; simple fracture; pistol gunshot wound)	1
Medium energy (open or multiple fractures, dislocation)	2
High energy (high-speed motor vehicle accident or rifle gunshot wound)	3
Very high energy (high-speed trauma + gross contamination)	4
Limb Ischemia	
Pulse reduced or absent but perfusion normal	1[a]
Pulseless; paresthesias, diminished capillary refill	2
Cool, paralyzed, insensate, numb	3[a]
Shock	
Systolic blood pressure always >90 mm Hg	0
Hypotensive transiently	1
Persistent hypotension	2
Age	
<30 years	0
30-50 years	1
>50 years	2

[a]Score doubled for ischemia >6 h.
Modified from Helfet DL, Howey T, Sanders R, Johansen K. Limb salvage versus amputation. Preliminary results of the Mangled Extremity Severity Score. *Clin Orthop Relat*. 1990; Res 256:80-86.

Intra-arterial Drug Injection

The accidental injection of therapeutic or illicit drugs into a peripheral artery is an uncommonly encountered but potentially devastating clinical phenomenon. The upper extremity is most commonly involved and the brachial is the most commonly injected artery. Injection is immediately followed by distal perfusion of the drug with an ensuing intense intra-arterial inflammatory response. Clinically, severe pain, often accompanied by edema, numbness, discoloration, cyanosis, or mottling of the skin, is seen as endothelial inflammation proceeds to microvascular thrombosis. These findings are most prominent distally. Pulses may be present at the wrist, but signals in the hand and digits are usually absent. The diagnosis of intra-arterial drug injection is primarily made clinically, but DUS can be used to ascertain patency of proximal arteries. Angiography can promote further thrombosis and is not generally recommended.

The treatment of intra-arterial drug injection is supportive, aiming to reduce inflammation and stasis and to prevent propagation of thrombosis. Revascularization is not considered

BOX 184.3 Suggested Therapeutic Regimen for Acute Intra-arterial Drug Injection

- Systemic intravenous anticoagulation with heparin
- Dexamethasone 4 mg intravenously every 6 h to reduce inflammation and to stabilize cellular membranes
- Dextran 40 intravenously at 20 mL/h to prevent platelet aggregation and thrombosis
- Appropriate pain control, including opiates as needed
- Elevation of the extremity to reduce edema
- Aggressive physical therapy to minimize contractures

a viable option because the primary pathophysiologic mechanism consists of distal microvascular thrombosis and resulting soft tissue damage. A suggested therapeutic regimen for acute intra-arterial drug injection is presented in Box 184.3.[85,86]

The treatment regimen is continued until the condition resolves or is fully stabilized, typically 3 to 7 days. Débridement of ischemic tissue is deferred pending clear demarcation. Long-term occupational therapy is frequently necessary to maximize the restoration of limb function. Various other treatments for intra-arterial drug injection have been reported, including the use of nerve blocks, local and systemic vasodilators, and thrombolytic agents. Experience with these modalities is confined to small groups of patients.[87] The role of thrombolytic therapy in the treatment of intra-arterial drug injection has yet to be defined.

Infectious sequelae can complicate cases of intra-arterial drug injection. Localized soft tissue infections resulting from injection with contaminated needles or superinfections of ischemic tissue should be treated by standard methods, with parenteral antibiotics and surgical drainage and débridement as necessary. Another potential infectious complication is the development of a mycotic aneurysm at the site of injection. This is manifested as a tender mass overlying a major vessel, but it is not always pulsatile. DUS or CT angiography can help make the diagnosis and can assist with operative planning (Fig. 184.8). The surgical treatment of mycotic aneurysms can be ligation and resection or arterial reconstruction. The clinical consequences of ligation without reconstruction should be considered, and ligation with delayed reconstruction if clinically apparent distal ischemia develops is an acceptable treatment. If reconstruction is attempted, autogenous conduit should be used if at all possible, and the anastomoses and graft bed should be in tissue planes uninvolved with infection. Frequently, graft courses will be extra-anatomic (i.e., obturator bypass, laterally tunneled femoral bypass). Grafts should be covered with viable muscle, and local flaps may be required. When operating on a patient with intra-arterial drug injection, the surgeon should maintain vigilance for broken needles within the soft tissue. Injury to the surgeon from these may result in the transmission of diseases such as human immunodeficiency virus infection and hepatitis if the patient is affected.[88]

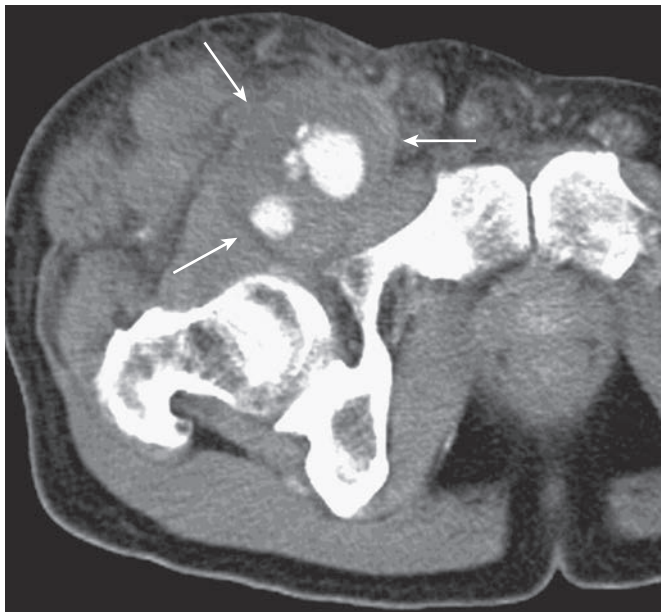

Figure 184.8 Computed tomographic angiography demonstrating a mycotic aneurysm *(arrows)* of the right femoral and external iliac arteries in a patient with a history of heroin injection into the right groin. Note thick aneurysm wall and multilobed morphology. (From Lee W, Mossop PJ, Little AF, et al. Infected (mycotic) aneurysms: spectrum of imaging appearances and management. *Radiographics*. 2008;28:1853-1868.)

Extremity Frostbite

The distal tissue necrosis seen in severe cold exposure injuries results from the combination of direct cellular destruction by freezing and thawing and severe peripheral vasospasm with resultant small-vessel thrombosis after rewarming. This combination of pathophysiologic factors frequently results in eventual irreversible necrosis necessitating partial digital amputation. Similar to intraarterial drug injection, the vascular problem manifested in frostbite primarily involves thrombosis within the digital arteries, capillaries, and venules and is not amenable to surgical treatment. Local, intraarterial, catheter-directed thrombolysis has been used as an adjunct to close observation, limb rewarming, and wound care, which are the mainstays of the treatment of extremities with severe frostbite. Bruen et al.[89] performed catheter-directed thrombolysis in six patients with extremity frostbite and distal ischemia. They noted an 80% decrease in eventual amputations versus historical controls not undergoing catheter-directed thrombolysis. Outcomes after catheter-directed thrombolysis were better if the procedure was performed within 24 hours of presentation.

In cases of acute frostbite, catheter-based diagnostic angiography of all distal extremities with clinically apparent ischemia (absent pulses, skin cyanosis) should be considered. If distal perfusion defects are present that are not solely due to vasospasm (i.e., persistent after vasodilator challenge with papaverine or nitroglycerin), intra-arterial catheter-directed thrombolysis with recombinant tissue plasminogen activator should be considered. Treatment is initiated through an infusion catheter placed in a proximal extremity vessel (typically the brachial, superficial femoral, or popliteal artery) and should be continued for up to 48 hours, with repeated diagnostic angiography performed at 8- to 12-hour intervals and catheter-directed thrombolysis discontinued when angiography reveals no residual perfusion

defects. Multiple extremities can be treated simultaneously through multiple arterial access points with the cumulative dose of tissue plasminogen activator administered (0.5 to 1.0 mg/h) divided between the affected extremities. Unfractionated heparin is administered at 500 units/h through each arterial sheath for the duration of treatment.

Upper extremity work-related injuries are a major societal problem in regard to disability, cost, and loss of work days. Occupational injuries affecting the shoulders, arms, and hands have been recognized for nearly 300 years and are generally categorized into injuries caused by accidents or injuries resulting from long-standing repetitive tasks.[1] Injuries in the latter category are due to small but additive amounts of tissue damage sustained from repetitive motions; they are known collectively as cumulative trauma disorders. According to 2011 data released by the US Bureau of Labor Statistics, injuries sustained from repetitive motion often result in longer duration of time away from work compared with other classes of injury.[2] Although most of these injuries affect the musculoskeletal system, injuries to arteries and veins are known to occur.[3] Work-related vascular injuries develop from excessive or exaggerated activity involving the shoulders, arms, or hands. Box 185.1 lists arterial disorders associated with occupational trauma.

MANUAL LABOR INJURIES

Hand-Arm Vibration Syndrome

The first cases of this injury were reported by Loriga in 1911 among Italian miners presenting with "dead finger."[4] Hamilton in 1918 made the connection between cold-induced blanching and numbness of the hands and use of pneumatic drills by stonecutters in Indiana.[5] Subsequent work by Taylor and Pelmear[6] and Ashe et al.[7] firmly established hand-arm vibration syndrome as a discrete clinical entity.

The disease has been referenced by many names, from the original dead finger to Raynaud of occupational origin, traumatic vasospastic disease, and vibration-induced white finger. The current designation hand-arm vibration syndrome (HAVS) was introduced to reflect that the extent of involvement is more of the upper extremity than just the digit. Regardless of the name,

Abstract

Occupational Vascular Problems Abstract

Upper extremity work-related injuries represent a society-level problem with regard to disability, cost, and loss of work days. Repetitive motions and long-term exposure to vibration, cold, and trauma can cause tissue damage and vascular injury resulting in long-term injury and disability. This chapter serves to describe the etiology, presentation, diagnosis, and management of upper extremity occupational vascular disorders.

Keywords

Raynaud syndrome
hand ischemia
digital ischemia
vibration injury
exposure injury

BOX 185.1 Arterial Disorders Associated With Occupational or Recreational Activities

Manual Labor

Hand-arm vibration syndrome
Hypothenar hammer syndrome

Exposure

Acro-osteolysis
Electrical burns
Extreme thermal injuries

Athletic

Chronic hand ischemia
Quadrilateral space syndrome
Humeral head compression of the axillary artery
Thoracic outlet syndrome

the common initial symptoms are those of Raynaud phenomenon secondary to prolonged use of vibrating mechanical tools.

Clinical Findings and Risk Factors

The Taylor and Pelmear staging system is presented in Table 185.1.[6] In the early stages, vibration injury may be manifested as slight tingling and numbness. Later, the tips of one or more fingers experience attacks of blanching, usually precipitated by cold. With continued progression, the affected area increases in size, and the blanching extends to the entire finger. Attacks of white finger typically last approximately 1 hour and terminate with reactive hyperemia (red flush) and often considerable pain. Prolonged exposure may induce bluish black cyanosis in the affected fingers. Only approximately 1% of cases progress to ulceration or gangrene.[8]

Vibrating handheld machines (e.g., pneumatic hammers and drills, grinders, and chain saws) have been implicated in hand-arm vibration syndrome. Such injury potential is not restricted to a few types of tools but applies to a variety of situations in which workers' hands are subjected to transmission of vibration energy.[9] There appears to be a linear relationship between the acceleration exposure dose (amount of acceleration and years of exposure) and the onset and severity of hand-arm vibration syndrome.[10]

The exact mechanism of injury is unknown. The frequency and intensity of vibration affect the extent of damage to the endothelium.[11] Local platelet adhesion seems to be an important factor in arterial occlusion. It has been shown that sympathetic hyperactivity, in combination with local factors such as vibration-induced hyperresponsiveness of the digital vessels to cold, may be responsible for the finger-blanching attacks.[12] In those with exposure to vibration injury, appearance of symptoms has also been correlated to smoking status.[13] Lower levels of serotonin, as well as polymorphism variants of the HTR1B, have also been shown to increase susceptibility to symptoms.[14]

Diagnosis

Key features in the history include use of vibrating tools and symptoms of Raynaud phenomenon. For a vasospastic condition, the most promising single objective test is cold provocation and recording of the time until digital temperature recovers (see Chapter 20). Digital artery occlusion is best detected by recording the systolic pressure of the affected fingers with transcutaneous Doppler ultrasound[15-17] or duplex scanning.[18] In advanced disease, arteriography is helpful. Barker and Hines[19] documented arterial occlusion by brachial arteriography in workers who complained of hand blanching and attacks of numbness. Other authors have reported on the use of arteriography in this injury.[20-22] Use of MRA is described by Poole and Cleveland to differentiate HAVS from hypothenar hammer syndrome.[23]

Arteriographic changes in hand-arm vibration syndrome can include multiple segmental occlusions of the digits and a corkscrew configuration of vessels in the hands.[22] The extent of digital artery occlusion appears dependent on the frequency and duration of exposure.[24] Of 80 workers (chippers) with hand-arm vibration syndrome investigated at the Blood Flow Laboratory at Northwestern University, 25 (31%) exhibited a significant reduction in systolic pressure in one or more digits.[25] In 6 of the 25 workers, arteriography showed digital artery occlusion (Fig. 185.1). Incompleteness of the palmar arch was seen not only in the symptomatic hand but also in the contralateral, asymptomatic one. Raynaud phenomenon was present in 73 of 80 workers (91%). Abnormal cold response was observed in 53% of these workers (Fig. 185.2).

TABLE 185.1 Stages of Hand-Arm Vibration Syndrome

Stage	Condition of Digits	Work and Social Interference
0	Vibration exposure but no signs or symptoms	No complaints
0T	Intermittent tingling	No interference with activities
0N	Intermittent numbness	No interference with activities
1	Blanching of 1 or more fingertips, with or without tingling and numbness	No interference with activities
2	Blanching of 1 or more fingers with numbness, usually in winter	Slight interference with home and social activities; no interference with work
3	Extensive blanching; frequent episodes in summer and winter	Definite interference at work, at home, and with social activities; restriction of hobbies
4	Same as stage 3: extensive blanching, most fingers involved, frequent episodes in summer and winter	Same as stage 3, but occupation changed to avoid further vibration exposure because of the severity of signs and symptoms

Modified from Taylor W, Pelmear PL, eds. *Vibration White Finger in Industry.* New York: Academic Press; 1975.

Figure 185.1 Arteriogram of the hand in a vibratory tool worker. Occlusion of the digital arteries *(arrow)* is apparent.

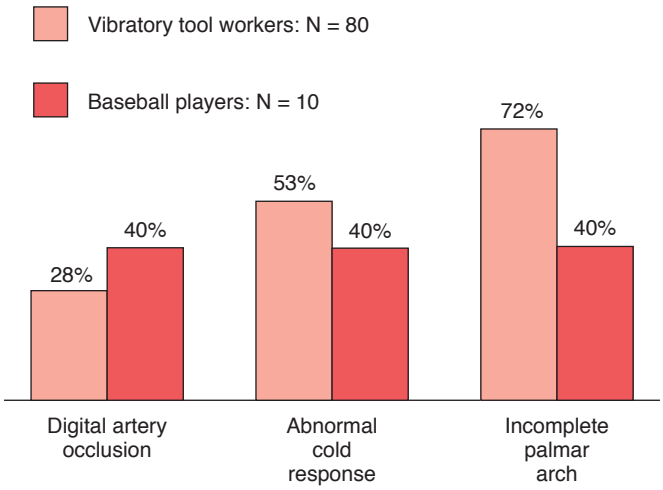

Figure 185.2 Incidence of digital artery occlusion, abnormal cold response, and incomplete palmar arch by Doppler examination in vibratory tool workers and baseball players. (From Bartel P, Blackburn D, Peterson L, et al. The value of non-invasive tests in occupational trauma of the hands and fingers. *Bruit*. 1984;8:15.)

Treatment and Prevention

With onset of neurovascular symptoms that interfere with social or work activities, the initial treatment is discontinuation of use of vibratory tools.[10] In advanced cases a calcium channel blocker such as nifedipine (30-120 mg daily) may be useful. Calcium antagonists inhibit the response of arterial smooth muscle to norepinephrine and have been reported to be

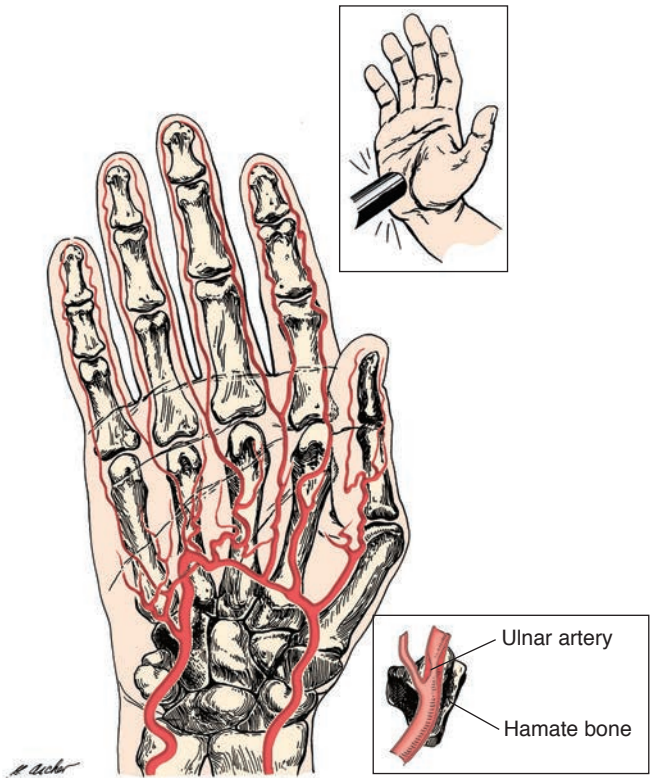

Figure 185.3 Mechanism of ulnar artery injury *(upper inset)* in a patient with hypothenar hammer syndrome. The terminal branch of the ulnar artery is vulnerable to injury because of its proximity to the hamate bone *(lower inset)*.

effective.[26] Intravenous infusion of a prostanoid (prostaglandin E1, prostacyclin, or iloprost) is usually reserved for patients with digital gangrene.[27] Surgical treatment, such as cervical sympathectomy or digital sympathectomy, is rarely needed.

Prevention is likely to be more effective than treatment. Personal protective equipment, such as gloves that limit exposure to cold and dampen transmission of vibration, should be used. Standards that limit the dose and duration of exposure to vibration have been set in place for factories and workplaces in the United States and internationally.[10]

Hypothenar Hammer Syndrome

Etiology and Incidence

The anatomy of the ulnar artery at the hypothenar eminence makes it vulnerable to injury with repetitive use of the palm of the hand in activities that involve pushing, pounding, or twisting. The ulnar artery and nerve travel in a tunnel known as Guyon canal that is bound by the pisiform and hamate bones. In this region, the ulnar artery is superficial and covered only by skin, subcutaneous tissue, and the palmaris brevis muscle (Fig. 185.3). Use of the palm as a hammer compresses the artery against the hook of the hamate bone, which acts as an anvil.

Von Rosen (1934)[28] and Guttani (1772)[29] published the original reports of the disease, but it was Conn et al.[30] who first recognized the anatomic mechanism of injury and coined the term *hypothenar hammer syndrome*. Mechanics, factory

workers, carpenters, masons, and any laborers who habitually use their hands as a hammer are at risk for the disease.[31-33]

The incidence of this rare entity is not precisely known because it is likely underrecognized. In Little and Ferguson's study of 79 mechanics, 14% had evidence of ulnar artery occlusion but none had symptoms severe enough to seek medical attention.[31] Studies focusing on cases of hypothenar hammer syndrome among referrals to tertiary centers for hand ischemia have found an incidence of 1.1% to 1.6%.[33,34]

The type of arterial abnormality observed often depends on the nature of the vessel injury but includes thrombotic occlusion, aneurysm formation, or both. Vasospasm and damage to the intima can result in platelet aggregation and thrombus formation.[35] Damage to the media can lead to aneurysmal degeneration of the artery (Fig. 185.4), although this occurs less frequently. Thrombus formation can also occur within the aneurysm itself and lead to distal embolization.

Research by Ferris et al.[34] demonstrated that, in addition to vascular damage from repetitive trauma, underlying vessel abnormalities may also be responsible. Histologic examination of 19 resected ulnar arteries showed hyperplastic proliferation of the intima or media and disruption of the internal elastic lamina suggestive of fibromuscular dysplasia. In 13 patients for whom bilateral angiograms were available, 12 of 13 (92%) showed an abnormality in the contralateral asymptomatic ulnar artery. On the basis of this evidence, they proposed that the etiology of hypothenar hammer syndrome depends on the presence of underlying ulnar artery fibromuscular dysplasia with superimposed repetitive palmar trauma.

Figure 185.4 Arteriogram of the hand of a carpenter. Note the aneurysm of the ulnar artery *(arrow)* caused by repetitive trauma from using the hand as a hammer.

Clinical Findings and Diagnosis

Patients typically present with Raynaud phenomenon. However, several key features distinguish hypothenar hammer syndrome from similar syndromes.[35] There is a preponderance of male smokers with a concomitant history of repetitive trauma to the hand.[33] The distribution is asymmetrical, often involving only the dominant upper extremity. The cyanosis and pallor phases can occur, but the hyperemic redness is usually lacking.[32] The digits affected tend to be the ulnar three fingers, with a distinct lack of involvement of the thumb.[32,34]

Physical examination may reveal cool or mottled digits; severe cases present with ischemic ulcers. A callus may be present over the hypothenar eminence. The result of Allen test is often positive, indicating ulnar artery occlusion. On occasion, an aneurysm is observed as a pulsatile mass in the hypothenar eminence.

Noninvasive imaging studies such as duplex ultrasound and contrast-enhanced computed tomography or magnetic resonance imaging have been used to make the diagnosis of hypothenar hammer syndrome.[36-38] However, the "gold standard" imaging modality in hypothenar hammer syndrome remains invasive arteriography. Arteriography is extremely useful in diagnosis and planning of surgical treatment because it defines the type of vascular lesion (spasm, aneurysm, occlusion), shows the site and extent, and identifies the anatomy of the palmar arch and significant collateral vessels. A corkscrew pattern is typically observed in affected vessels.[34] Regardless of which imaging modality is used, proximal arterial segments should be included in the examination to rule out upstream sources of embolization.

Treatment

The majority of patients with hypothenar hammer syndrome will improve with nonsurgical interventions.[33] Conservative measures include smoking cessation and hand protection involving avoidance of exposure to cold environments and avoidance of further trauma. Medical therapy consists of calcium channel blockers and antiplatelet drugs. Anticoagulation has been used in cases of digital necrosis.

Surgical therapy is reserved for severe cases of digital ischemia or the presence of an aneurysm. Simple ligation of an aneurysm can be performed if there is adequate collateral circulation. More often, surgical intervention requires resection with primary reconstruction or vein graft interposition. One study suggests the use of arterial interposition graft as well.[39] Several large case series report that a majority of patients have improvement in symptoms of hand ischemia after reconstruction and that long-term results are satisfactory.[34,40-42]

EXPOSURE INJURIES

Occupational Acro-Osteolysis

Wilson et al.[43] first described this disease in workers exposed to polyvinyl chloride. Many of these workers experienced ischemic symptoms in the hand, with resorption of the distal phalangeal tufts, similar to that seen with scleroderma. The

dominant initial symptoms are those of Raynaud syndrome. A few reports of angiography in this syndrome document damage to the digital arteries.[44-46] Findings include multiple stenoses and occlusions of the digital arteries along with nonspecific hypervascularity adjacent to the areas of bone resorption. The reason for the hypervascularity is not clear, but it may be related to stasis of contrast medium in digital pulp arteries secondary to shortening and retraction of the fingers. Some of these digits were clubbed, a finding that has also been associated with hypervascularity in the fingertips. Treatment is supportive.

Electrical Burns

Electrical energy inflicts tissue destruction in relation to the voltage applied. Currents less than 1000 V cause injuries limited to the immediate underlying skin and soft tissue. High voltage (>1000 V) usually causes extensive damage as the current travels from the point of entry to the point of exit. No tissue is immune to the devastating effects of high-voltage injury, and arterial injury may occur. The upper extremity, especially the hand, is involved more often than are other parts of the body because of its grasping function. The arterial injury is often manifested by arterial necrosis with thrombus or bleeding, and gangrene of the digits occasionally develops.

Bookstein[44] described the angiographic changes in the upper extremity after electrical injury, including extensive occlusion of the ulnar and digital arteries and thrombosis of the radial artery. Arterial spasm may also be present. Later, damage to the media may cause aneurysm formation. Fig. 185.5 shows a brachial artery aneurysm in a patient who had sustained electrical burns 9 months earlier. Treatment and salvage of the upper extremity depend on the associated soft tissue and bone injuries.[47]

Figure 185.5 Aneurysm of the brachial artery in an electrician who had sustained a high-voltage electrical burn 9 months previously.

Reconstruction with free flap due to local vascular damage has been described.[48] Occlusion of a major artery documented by arteriography requires bypass grafting, and good results have been reported.[49]

Extreme Thermal Injuries

Vasomotor disturbances in the hands of individuals exposed to extreme chronic thermal trauma are typically manifested as Raynaud syndrome. Workers at highest risk for thermal injuries are those in a profession in which their hands are subjected to chronic exposure to cold, such as slaughterhouses, canning factories, and fisheries.[50,51] Epidemiologic studies examining this dilemma are limited. Swedish military trainees exposed to extreme cold for up to 14 months were found to have reduced sensation to temperature changes as well as vibrotactile stimulus; however, there were no alterations in the finger systolic blood pressure.[52] These symptoms were documented to be present by sensory testing at 4 months; however, symptoms such as cold intolerance and white fingers were present 4 years after initial injury.[53] The action of alternating ice-cold and hot exposure, use of plastic gloves in cold exposure, and long-term exposure to cold seem to be identifiable risk factors. Treatment is supportive.

ATHLETIC INJURIES

Athletes, particularly professionals who engage in strenuous or exaggerated hand or shoulder activity, may be susceptible to upper extremity ischemia as a result of arterial injury. Hand ischemia is often manifested as Raynaud syndrome, symptoms of sudden arterial occlusion, or embolization to the digits. Injury can occur anywhere along the course of the upper extremity from the subclavian artery to the digital vessels. Recognized syndromes occur anatomically at the thoracic outlet, the quadrilateral space, and the humeral head and in the hand. The exact incidences of these syndromes are unknown. The majority of reported arterial injuries in the elite athlete involve baseball players; however, vascular injury has been reported in such sports as karate, volleyball, handball, Frisbee, lacrosse, golf, weightlifting, and butterfly swimming.[54,55]

Hand Ischemia

Clinical Findings and Risk Factors

The mechanisms of hand ischemia fall into two main categories: direct digital artery injury and embolization from a proximal source in the upper extremity. Hand activity in any sport can cause blunt-force injury to the arteries[56]; however, direct digital arterial trauma is encountered more often in handball players, baseball catchers, and practitioners of karate. Fig. 185.6 illustrates occlusion of the palmar arch in a Frisbee player; ischemia of all fingers occurred suddenly after he caught the Frisbee. It has been suggested that handball players with more than 200 hours of accumulated playing time are at greater risk for symptomatic alterations in perfusion.[57,58] In a study of Basque handball players, 57% of those who play, 77% of federated players in the senior category, and 87% of professionals sustain injury to the arteries

Figure 185.6 Occlusion of the palmar arch in a Frisbee player *(arrow)*. Because of this injury, there is poor filling of contrast medium in the second, third, fourth, and fifth fingers.

of the hand and fingers.[59] In a study of beach volleyball players, both time spent playing and female gender were risk factors for developing hand ischemia symptoms.[60]

Baseball players, particularly catchers because of the tremendous and frequent impact of the baseball, are predisposed to the development of chronic hand ischemia. Many catchers exhibit Raynaud symptoms, especially in the off-season when they engage in outdoor activity in cool autumn or winter weather. Lowrey[61] reported decreased digital perfusion to the index finger of the glove hand in 13 of 22 baseball catchers examined by Doppler flow and the Allen test. Of 10 professional catchers studied in that author's laboratory, 40% had evidence of digital artery occlusion.[61]

Another form of hand ischemia occasionally observed in baseball pitchers is compression of the digital artery by Cleland ligament. These ligamentous structures are found on the palmar surface of the digits and span from the phalanx to the subcutaneous tissue (Fig. 185.7). The proposed mechanism is compression of the digital vessels with hyperextension of the proximal interphalangeal joints.

Treatment

Treatment of hand ischemia depends on the clinical findings. With acute injury, a conservative approach involving intravenous infusion of dextran and pain control is in order. Medical therapy for digital ischemia includes purine derivatives such as pentoxyfylline, calcium channel blockers, and analgesics for pain control.[59] Botulinum toxin (Botox) injection has emerged as an alternative to surgical intervention for digital ischemia due to vasospasm. In case series, Botox injection into the neurovascular bundle of the fingers results in 75% to 100% improvement of pain and healing of digital ulceration in 48% of patients.[62] Surgical intervention is indicated for severe symptoms not alleviated by conservative management. Digital periarterial sympathectomy was shown to be successful in a cohort of handball players with severe symptoms.[59] Release of Cleland ligament has been successful in relieving digital artery compression in baseball pitchers as well.[63] Preventing injury is important and can be accomplished by the use of gloves with padding and other protective devices.[61]

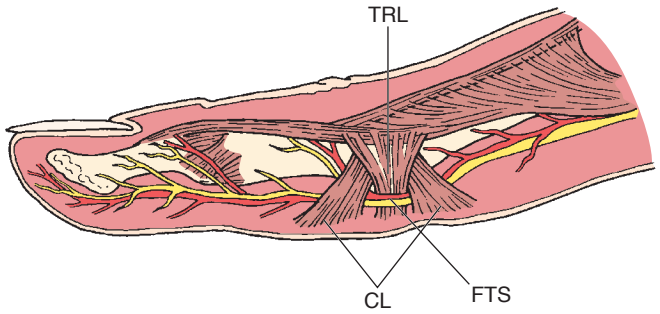

Figure 185.7 With the proximal interphalangeal joint in hyperextension, Cleland ligament may compress and occlude the vascular supply to the fingertip. *CL,* Cleland's ligament; *FTS,* flexor tendon sheath; *TRL,* transverse retinacular ligament.

Quadrilateral Space Syndrome

The quadrilateral space is defined as the area bordered by the teres minor superiorly, the humeral shaft laterally, the teres major inferiorly, and the long head of the triceps muscle medially (Fig. 185.8).[64] Found within this space are the posterior humeral circumflex artery and the axillary nerve.

Cahill and Palmer[65] first reported in 1983 the diagnosis and surgical treatment of 18 patients with this entity. Compression of the posterior humeral circumflex artery within this space occurs with the arm in the "cocked" position (abduction and external rotation). Chronic compression and trauma to this artery in overhand motion athletes, particularly pitchers and volleyball players, can lead to aneurysmal dilatation or occlusion (Fig. 185.9). Aneurysms in this location are prone to distal embolization in the hand.[66,67]

Experience with nine patients at the Mayo Clinic suggests a new classification of quadrilateral space syndrome into vascular and neurogenic etiologies. Vascular quadrilateral space syndrome (vQSS) is caused by repetitive mechanical trauma to the posterior circumflex humeral artery resulting in thrombosis and/or aneurysmal degeneration leading to distal embolization. vQSS is most often seen in overhead athletes. Neurogenic QSS (nQSS) is caused by fixed structural impaction of the quadrilateral space by fibrous bands or space-occupying lesions. This occurs from

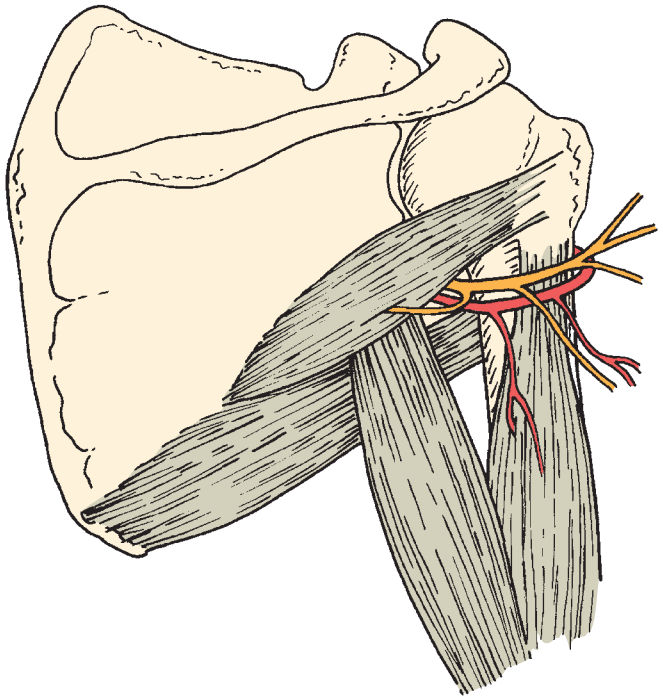

Figure 185.8 The posterior humeral circumflex artery and axillary nerve traverse the interval of the quadrilateral space.

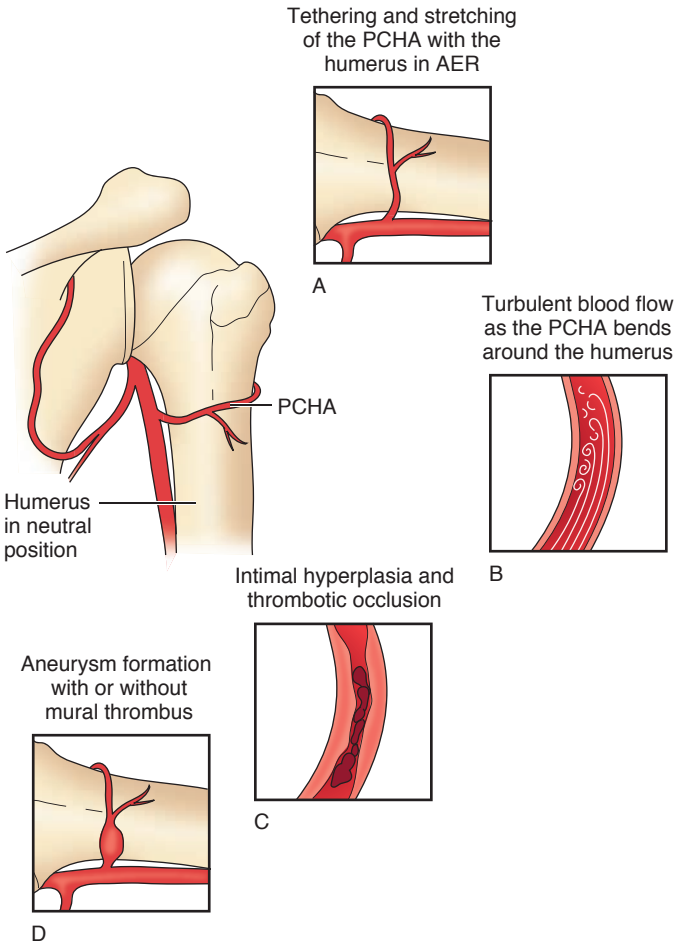

Figure 185.9 Proposed mechanism for posterior circumflex humeral artery degeneration and thrombosis: (A) The posterior circumflex humeral artery stretches around the neck of the humerous similar to a stretched rubber band leading to intimal injury and weakening of the vessel wall. (B) The repetitive pulley movement likely leads to turbulent blood flow within the bend around the humeral neck. (C) These changes lead to intimal hyperplasias, thrombotic occlusion, and (D) aneurysmal formation. (From Brown SAN, Doolittle DA, Bohanon CJ, et al. Quadrilateral space syndrome: the Mayo Clinic experience with a new classification system and case series. *Mayo Clin Proc*. 2015;90(3):362–394.)

repetitive microtrauma to connective tissue in the quadrilateral space and can be seen in recreational athletes, such as swimmers, or in occupations requiring some overhead movement. Presentation can include muscle atrophy, paresis, paresthesia, poorly localized shoulder pain, or tenderness with palpation of the quadrilateral space.[68]

For vQSS, thrombolytic therapies may be used initially to dissolve the distal emboli, but surgery to treat the aneurysm should then be addressed. Surgical treatment of aneurysms in this location involves ligation of the posterior humeral circumflex artery.[69] The anterior and posterior humeral circumflex arteries provide blood supply to the humeral head, and at least one of the two vessels must be preserved or repaired to prevent avascular necrosis. Many athletes return to practice after operation, and surgical treatment may be supplemented with 3 to 6 months of anticoagulation.[68]

Treatment of nQSS can initially be conservative with oral antiinflammatory medications, physical therapy, and limitation of activities; however, surgical decompression involving neurolysis and excision of fibrous bands or other space-occupying lesions often allows patients to return to full activity without pain or limitation after several weeks.[68]

Humeral Head Compression of the Axillary Artery

Lord and Rosati[70] first reported compression of the third portion of the axillary artery by the head of the humerus. With overhead throwing or striking motions in which the arm is abducted and externally rotated, there is downward compression of the humeral head against the axillary artery.[66,71] Sonographic studies have demonstrated the impedance of flow through the axillary artery by the humeral head with these overhand motions.[72]

Symptoms typically include arm fatigue and loss of pitch velocity after several innings. Finger numbness, Raynaud syndrome, and cutaneous embolization can be seen as well. Evaluation includes duplex studies and arteriography with the arm at rest and in the provocative position.

Treatment is based on extent of injury. For those with compression of the artery alone, modification of throwing motion has resulted in improvement of symptoms. Saphenous vein patch angioplasty has been used for those whose symptoms do not improve.[73,74] In patients with structural injury to the vessel, resection with saphenous vein bypass has been performed either anatomically tunneled or extraanatomically above the pectoralis minor. Long-term results are good, and many of the athletes treated at major centers are able to return to competition after rehabilitation.[74-76]

Thoracic Outlet Syndrome

Athletes who engage in overextended shoulder motion, such as baseball pitchers, butterfly swimmers, weightlifters, and oarsmen, are potential candidates for thoracic outlet compression. Although not as common as neurogenic and venous thoracic outlet syndrome, injuries to the subclavian artery have been reported in these athletes. Because a comprehensive review of thoracic outlet syndrome is provided elsewhere (see Chapters 120-124), only a brief discussion as it relates to athletic activities is given here.

Clinical Findings and Risk Factors

Compression of the subclavian or axillary artery can occur at the scalene muscles, costoclavicular space, or pectoralis minor muscle. A significant portion of cases of arterial thoracic outlet syndrome are due to underlying bone abnormalities, such as a cervical rib or anomalous first rib; but in athletes, hypertrophy of the scalene muscles or pectoralis minor muscles can lead to symptoms as well.[74] With chronic compression and vessel wall damage, a spectrum of disease can develop, including thromboembolism, occlusive disease, and aneurysm formation.

Although arterial thoracic outlet syndrome has been recognized for more than 2 centuries, the association with elite athletes has only been recent. Tullos et al.[77] in 1972 reported an axillary artery thrombus secondary to compression by the pectoralis minor in a major league pitcher. In 1978 Strukel and Garrick[78] reported on three competitive baseball pitchers with thoracic outlet compression. However, until the 1986 report of Fields et al.[79] on athletic injury in the thoracic outlet, the injury had received little attention. In their fascinating report, they describe a major league pitcher who suffered a catastrophic stroke resulting from subclavian artery thrombosis with proximal clot propagation.

Symptoms are similar to those previously described in humeral head compression of the axillary artery and include arm fatigue, loss of pitch velocity, finger numbness, Raynaud syndrome, and cutaneous embolization. It is often difficult to make the diagnosis, and evaluation by an orthopedic surgeon to rule out musculoskeletal abnormalities is useful. Duplex scanning and transcutaneous Doppler studies with the athlete in the pitching position help to detect compression of the subclavian or axillary artery. A definitive diagnosis is established by arteriography with positional exposure (Fig. 185.10).

Treatment

Treatment depends on the extent of injury. Nonbone compression alone can be treated by division of the offending muscle or tendon.[73] If an anomalous first rib or cervical rib is the culprit, a transaxillary approach can be used for decompression. If the subclavian artery requires reconstruction because of severe occlusive disease or aneurysmal disease, combined supraclavicular and infraclavicular incisions provide better exposure. Saphenous vein is the preferred conduit for bypass, although prosthetic grafts or the femoral vein can also be used.[74,80] Long-term patency rates are good, approaching 90% to 100%. The ability to return to competition after repair is not well documented.

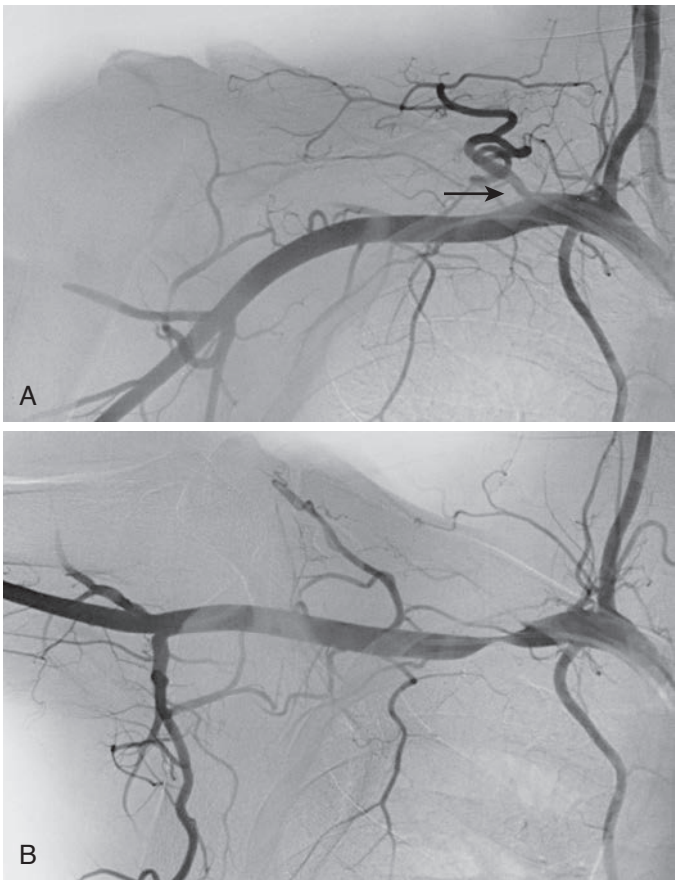

Figure 185.10 (A) Arteriogram of the right subclavian artery including the thyrocervical trunk *(arrow)* in a professional baseball pitcher. No injury is seen when the arm is placed in neutral position. (B) There is compression of the subclavian artery and occlusion of the thyrocervical trunk when the arm is placed in the pitching position (hyperabduction).

INTRODUCTION

Although conditions afflicting the extracardiac vascular system during infancy and childhood have been described for well over two centuries, a comprehensive literature dedicated to the management of pediatric vascular surgery patients remains lacking. Despite the presence of a number of textbooks devoted to the focused topic of pediatric cardiac surgery, a unified resource collating common themes and describing surgical techniques and principles does not exist for vascular surgery of children and the young adult. This can partly be explained by the range of vascular surgery conditions encountered in the modern era of pediatric surgery and by the diversity of providers who render treatment in this therapeutic area. Beyond pediatric surgeons with expertise in advanced vascular surgery reconstruction, adult vascular surgeons, pediatric and adult cardiothoracic surgeons, transplant surgeons, urologists, plastic surgeons, and adult general surgeons may all at one time or another operate on the blood vessels of pediatric patients. It is our hope in this introductory chapter to provide a broad overview of concepts and techniques that are particularly relevant to the pediatric population and that may prove useful to those who, either rarely or frequently, may be called upon to treat the vascular problems of this unique age group.

HISTORICAL BACKGROUND

One might trace the origins of pediatric vascular surgery to the 16th century when Guido Guidi first described a congenital vascular malformation after observing pulsatile varices protruding from a young man's scalp.[1] Giovanni Morgagni, a precocious Italian anatomist and a pioneer in the development of pediatric surgery, was instrumental in further expanding this early experience with vascular anomalies. His original description of coarctation of the thoracic aorta in 1760 was just one of his many original discoveries.[2] Sixty years later, August Meckel reported the associated collateral circulation and rib erosion that is seen in this condition.[3] In 1835 Schlessinger was the first to discover that aortic coarctation is not limited to the aortic isthmus[4] and, later in the same century, Pierre-Carl Pontain reported on arterial hypertension as a pathophysiologic consequence of coarctation.[5] Although much less frequently encountered, constriction of the subisthmic aorta was noted by Schlessinger during his autopsy of a 15-year-old girl whose distal thoracic aorta was nearly obliterated.[6] Quain reported a similar malady of the abdominal aorta in a 50-year-old man in 1847.[5] The first clinical recognition of renovascular hypertension in a child was in 1938 by Wyland Leadbetter and Carl Burkland.[7] They further noted that removal of the child's kidney,

which had become ischemic from fibromuscular dysplasia, corrected the hypertension. These are just a few of the myriad discoveries that have provided a framework for our current understanding of many pediatric vascular disorders.

For many years, operative repair of vessels in infants was deemed too hazardous to undertake.[8] Thomas Starzl overcame this barrier in July 1967 with his pioneering efforts to complete the first successful pediatric liver transplant. This operation, carried out on a 19-month-old child with a large hepatoma necessitating multiple vascular anastomoses, was a major milestone in pediatric vascular surgery.[9] Further technical advances were developed by Dean, Stanley, and Fry in their landmark work on pediatric patients with renovascular hypertension.[10,11] Over the past 3 to 4 decades, pediatric, cardiac, and vascular surgeons have continued to accrue significant clinical and technical experience that has translated into more consistent results and allowed more sophisticated vascular reconstructions to be undertaken in infants and children.

BASIC PRINCIPLES

William Ladd and Robert Gross are often cited as the founders of pediatric surgery, and much of the current-day training of pediatric surgeons can be traced to these two men and their many pioneering contributions. Publication of their textbook *Abdominal Surgery of Infancy and Childhood* in 1941 was instrumental in establishing pediatric surgery as a unique and independent surgical subspecialty.[12] This text emphasized the paramount importance of gentle tissue handling, one of William Halsted's fundamental surgical principles, when operating on children. Although there are many similarities between children and adults regarding surgical management and operative technique, there are also a number of important differences that warrant highlighting. These range from fluid management and anesthetic concerns to issues related to the future growth of organs and their surrounding critical elements. From a vascular surgical standpoint, one must take into consideration that as an infant or child grows, the demands on blood vessels will also increase.

Timing of Surgery

If clinically permissible, vascular reconstruction in small infants should be delayed to allow for further development as reconstructing vessels less than 2 mm in diameter is technically challenging and has been associated with comparatively inferior results. For example, deferring renal revascularization in children with renovascular hypertension until the child is at least 3 years old has been shown to increase the likelihood of a successful outcome.[13] Fortunately, the incidence of neonatal hypertension is quite low, ranging from 0.2% to 2%,[14] and prolonging the use of antihypertensive medications in an effort to delay surgery has not been associated with significant long-term adverse effects.[15] However, occasionally, it can prove challenging to control high blood pressure in an infant, given the variable onset and duration of oral antihypertensive medications as well as unpredictable responses to these agents. Persistent, uncontrolled hypertension in these young patients can lead to congestive heart failure and cardiogenic shock, which may compel surgical reconstruction of the renal arteries regardless of the child's age. Although the preference is to defer surgical repair until the patient is of appropriate age and size, renal artery reconstruction has been safely performed in the very young; the University of Michigan has described their successful treatment of a 3-month-old, 4700-g baby with bilateral renal artery occlusions.[13]

In contrast, the recommendation to delay the surgical correction of renovascular hypertension, early repair of thoracic coarctation is typically advised, given low reported perioperative mortality rates and a relatively low risk of reintervention or recurrent coarctation following reconstruction.[16] More importantly, early repair minimizes the incidence of vascular dysfunction and persistent hypertension.[17]

Anticoagulant and Antiplatelet Agents

The management of antithrombotic therapy in children has both similarities and important differences from that in adults. The major distinctions in the pediatric population relate to their dynamic and evolving coagulation system, age-dependent distribution and clearance of antithrombotic drugs, limited vascular access and the impact of this on monitoring efforts, the limited availability of medications in liquid formulations, dietary differences complicating oral vitamin K antagonists (VKAs), and general compliance issues.[18]

Unfractionated heparin has been used safely in children for decades. As in adults, heparin is typically systemically administered intraoperatively when vessels are temporarily clamped. A bolus dose of 75 to 100 units/kg results in a therapeutic activated partial thromboplastin time (aPTT) in 90% of children.[18] However, this percentage may in fact be an overestimation because aPTT therapeutic ranges are calculated using adult plasma and aPTTs are slightly elevated at baseline in young children. As such, the therapeutic range in a neonate correlates to a reduced relative increment in aPTT compared with adults; as a result, aPTT values correctly predict therapeutic heparin concentrations only 70% of the time.[19] Consequently, maintenance doses are age dependent, with infants requiring an increased hourly dose (28 units/kg per hour) compared with children older than 1 year of age (20 units/kg per hour).

Protamine sulfate can be safely given to reverse heparin intraoperative anticoagulation in the pediatric population. It is typically administered at a rate of 1.0 mg/100 units of heparin received. Given that neonates and young children have a more rapid clearance of heparin compared with adults, protamine is typically not administered in these age groups.[13,18] Avoiding protamine administration and allowing heparin to wear off over the early postoperative period confers an additional theoretical benefit of minimizing thrombotic events in particularly small-caliber blood vessels.

Similar to adults, postoperative anticoagulation regimens in children have evolved over the past decade. This is due to both difficulties inherent to the use of VKAs and the advent of newer agents such as low-molecular-weight heparin (LMWH) and novel oral anticoagulants (NOACs). VKAs can be particularly

problematic in newborns, given their decreased levels of vitamin K–dependent coagulation factors. The fact that VKAs are available only in tablet form, and that vitamin K is nearly absent from breast milk but typically present in infant formula, further complicates their use.[20] LMWH has now become the preoperative and postoperative anticoagulant agent of choice in the pediatric population. This class of drugs is appealing, given a decreased need for monitoring compared with VKAs, minimal drug-drug interactions, and a reduced risk of heparin-induced thrombocytopenia.[21] However, LMWH has considerable dose variability in children, which can result in fluctuations in antithrombin levels. In addition, the general unpopularity of frequent cutaneous injections obligated by LMWH therapy has led some centers to begin trialing NOACs. Although quite promising, the data on the use of NOACs in children remains limited at present and their appropriate role in this population remains to be defined.[22]

Antiplatelet drugs have been used for decades in children. If reconstructing very small vessels, aspirin is typically administered intraoperatively through a nasogastric tube to minimize the chance of thrombus formation at anastomotic sites.[13] Doses ranging from 1 to 5 mg/kg have been deemed safe.[18] Reye syndrome is rare in this setting because its association with aspirin is at much higher dosage levels (>40 mg/kg).[23] Clopidogrel has been used more frequently in recent years, particularly in children with heart disease. One randomized trial indicated that clopidogrel at a dose of 0.2 mg/kg per day was efficacious in young children.[24]

Pediatric Anesthesia and Perioperative Care

The subspecialty of pediatric anesthesia owes much of its foundation and progress to M. Digby Leigh, who published the first dedicated text on the discipline in 1947.[25] Although the full breadth of content pioneered by Leigh and further developed by subsequent generations of pediatric anesthesiologists is well beyond the scope of this chapter, there are several basic principles worth mentioning.

First, given that a neonate's ability to main normothermia is inadequate, the operating room environment should be optimized to minimize a baby's heat loss. As part of this effort, the ambient room temperature should be maintained between 23°C and 25°C (80°F and 85°F), inhaled gases should be warmed and humidified, fluids should be delivered via a warming device, and a forced warm air delivery device or warming blanket should be used. Second, given the obvious size differences between young children and adults, a full complement of appropriately sized anesthesia-related equipment and devices (pulse oximeter probes, facemasks, tracheal tubes, suction catheters, laryngoscope blades, etc.) must be readily available.

A critical component of anesthesia administration to infants and young children is expertise in airway management. This skill set requires a detailed knowledge of the developmental anatomy and physiology of the pediatric skull, nose, and upper airway. Equally as important to safely performing facemask ventilation, laryngoscopy, and subsequent tracheal intubation is the ability to effectively address postoperative airway complications, some unique to the pediatric population. Laryngospasm, hypoxemia, croup, and aspiration are among the respiratory events that are responsible for nearly 50% of pediatric anesthesia complications.[26] In contrast to adults, the usual method of inducing anesthesia in children is with inhalational agents, typically nitrous oxide followed by sevoflurane. Upon emergence from anesthesia, the child is typically placed in the "recovery position" (lateral decubitus) because it promotes airway patency and is helpful should the child develop emesis. This latter complication is not trivial because postoperative nausea and vomiting are significantly more common in children than adults and, among other negative consequences, can delay discharge from the recovery room. In addition to proper positioning in the lateral recovery position to minimize the aspiration risk, children are often prophylactically administered an antiemetic along with dexamethasone, which can minimize both tracheal edema and postoperative vomiting.[27]

BASIC VASCULAR TECHNIQUES

As in the adult world, there are multiple elements that comprise any successful pediatric vascular surgery operation. Proper patient positioning, adequate exposure and lighting, optimal incision location and size, safe and effective clamp selection and placement, appropriate suture material and conduit choice, and technically sound anastomoses are all important for a positive outcome. Of course, the aforementioned factors are all of secondary significance behind selecting the correct procedure from the onset.

Vascular Instruments and Retractors

In general, vascular instruments used during pediatric reconstructions are similar to those typically used in the adult realm. However, small versions of forceps, clamps, Castroviejo needle holders, scissors, and other specialty instruments are available and can be helpful in manipulating smaller-sized pediatric blood vessels. For example, "baby" Jacobson or Potts bulldog clamps are useful atraumatic vascular clamps, and Yasargil or Heifitz clips can be particularly beneficial for small or fragile vessels at risk for tearing or prone to spasm. Delicate handling of tissue with Debakey and fine Gerald forceps is advised. Metzenbaum, Stevens tenotomy, and Potts or Dietrich scissors are useful for dissecting vessels as well as extending arteriotomies.

With regard to retractor systems, both self-retaining and handheld instruments are used much like in adult surgery. For abdominal procedures, typically a Thompson Pediatric Abdominal System (Thompson Surgical Instruments, Traverse City, Michigan) is used because its selection of lower-profile blades with variable depths and widths affords considerable versatility in young patients (Fig. 186.1). For the extremities and neck, Weitlaner retractors, which come in various sizes, are most commonly used.

Vascular Exposure and Clamping

Information relating to specific vascular exposures is beyond the scope of this chapter and will be described elsewhere in

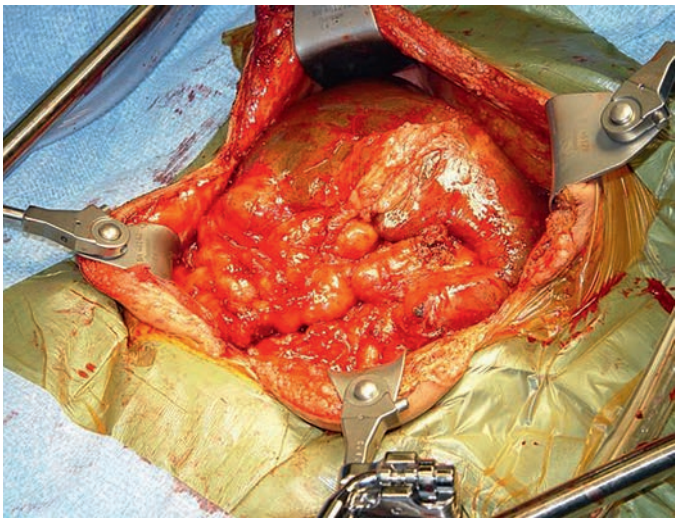

Figure 186.1 A Thompson Pediatric Abdominal Retractor System (Thompson Surgical Instruments, Traverse City, Michigan), due to its lower profile blades with variable depths and widths, provides excellent exposure to the abdominal contents in young patients.

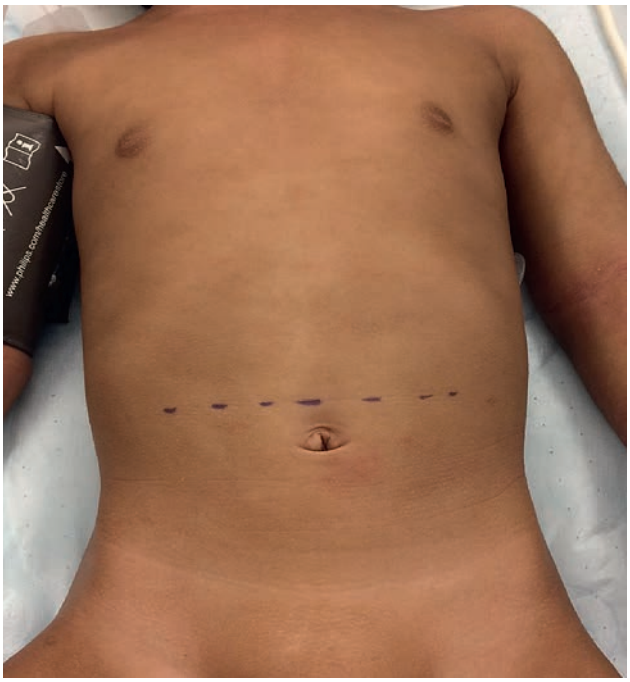

Figure 186.2 Proposed location of a transverse abdominal incision in a young child, which can provide better exposure of the abdominal aorta and viscera given the barrel-shaped nature of the abdomen.

this textbook. In general, exposure of the relevant blood vessels should be done in the most direct route possible and with the least amount of tissue manipulation. Broadly prepping the patient is recommended in the event that more complex exposure or vascular control than originally anticipated becomes necessary. Anatomic landmarks and key structures should guide the surgeon's incision and subsequent dissection. In the absence of a palpable pulse to further direct the course of the dissection, a Doppler probe should be used in the effort to avoid unnecessary tissue disruption and the creation of tissue flaps that may negatively impact wound healing. Given that the abdomen of young child is barrel shaped, a transverse incision often provides better exposure to the abdominal viscera and the abdominal aorta and its major branches than a midline incision (Fig. 186.2). There is also evidence that a transverse incision is less likely to develop fascial dehiscence compared with a vertical incision in children less than 1 year of age.[28]

Gentle handling of tissues is paramount in the effort to avoid vessel disruption, hematoma formation, and other bleeding complications. Particular caution should be undertaken in patients with known connective tissue disorder or in the setting of infected or dissected vessels. The clinical and anatomic scenario at hand should guide selection of appropriate clamp type and size. Applying clamps in a side-biting fashion should generally be avoided given the small caliber of pediatric vessels and the increased risk of "back-wall" suture placement with subsequent vessel thrombosis.

Arteriotomy Closure

Primary closure of an arteriotomy or venotomy in a pediatric patient is the simplest and most expedient means of arterial or venous reconstruction. However, given the small caliber of pediatric vessels and their need for future growth, primary closure can result in luminal narrowing with a hemodynamically significant stenosis. As such, similar to the situation with adult vascular reconstructions, judgment must be used in determining the safety and appropriateness of closing a given vessel primarily versus using a patch closure that may be necessary to ensure an adequate luminal size. Although a patch repair in adults is typically undertaken by beginning a running suture at each apex, some have advocated for an interrupted suture technique in children (see Figs. 59.39 and 59.40); such a strategy will theoretically better accommodate native vessel growth and luminal expansion over time. Similarly, the patch size should be made sufficiently large so as to not cause vessel constriction over time as the child grows. In one report of pediatric trauma patients less than 10 years of age and with a vascular injury, patch repair was the most common operative management strategy, being used 3 times more frequently than bypass grafting (28% vs. 9.6%).[29]

Arterial Replacement and Bypass Procedures

Several different techniques can be used to address young patients afflicted with aneurysmal degeneration or arterial occlusive disease. Although relatively infrequently encountered in children, connective tissue disorders, tuberous sclerosis, vessel infection, inflammatory middle aortic syndrome, and trauma are all examples of clinical conditions that may necessitate a major vascular reconstruction. Replacement of the diseased vessel with a bypass procedure is the most commonly performed revascularization procedure in these settings. Depending on the extent of vessel involvement, segmental resection and reconstruction with vessel reimplantation or primary end-to-end reanastomosis are additional options. Reimplantation has been used in the

Figure 186.3 Ostial stenosis of the left renal artery in a 4-year-old girl with renovascular hypertension. (From Stanley JC, Criado E, Upchurch GR Jr, Brophy PD, Cho KJ, Rectenwald JE. Figure 186.4 Bilateral renal artery–aortic implantations in a 7-year-old boy. Note the capacious aortic anastomoses from spatulation of the renal arteries. (From Stanley JC, Criado E, Upchurch GR Jr, Brophy PD, Cho KJ, Rectenwald JE. Pediatric renovascular hypertension: 132 primary and 30 secondary operations in 97 children. *J Vasc Surg.* 2006;44(6):1219-1228.)

surgical management of peripheral aneurysms, as well as for children with renovascular hypertension. This latter clinical entity typically develops from renal artery stenosis as a result of progressive medial dysplasia and intimal fibroplasia. The anatomic pattern where disease is limited to the renal ostia is particularly conducive to repair with renal artery implantation (Fig. 186.3). In a series of 97 children treated surgically for renovascular hypertension at the University of Michigan, reimplantation of the renal artery was the most common means of repair, being performed in 45% of procedures.[13] With this technique, the anterior and posterior aspects of the transected renal artery should be spatulated to ensure creation of a generous anastomosis. Typically, the renal artery is reimplanted onto the aorta; although infrequent, the iliac artery can be used if performing a renal autotransplantation. An aortic punch device can be helpful in fashioning a desired oval aortotomy that is at least twice the diameter of the renal artery. A tendency toward oversizing the aortotomy in this manner will decrease the chance of developing an anastomotic stricture over time (Fig. 186.4). As noted previously, an interrupted suture technique should be considered for the anastomosis unless the patient is a mature adolescent with normal-sized vessels. Medial mobilization of the kidney may be necessary to ensure the anastomosis is free of tension.

Peripheral aneurysms can often be treated by resection and primary end-to-end reanastomosis. This technique has been used for aneurysms of the renal, splanchnic, brachial, femoral, and popliteal arteries.[30] When using this technique, both vessel ends should be spatulated to increase the anastomotic circumference (see Fig. 139.41).

Reconstruction with a bypass or interposition graft adds complexity to the procedure, given the need for an additional anastomosis and important issues related to conduit selection. The most common indications for performing an arterial bypass or interposition graft in the extremity of a child are peripheral aneurysms and trauma. Traumatic causes include both blunt injury and iatrogenic injury, such as arterial disruption or thrombosis associated with percutaneous access or catheter placement. Abdominal aortic coarctation, also referred to as midaortic syndrome, and renovascular hypertension due to renal artery stenosis, on the other hand, are the most frequent indications for bypass grafting originating from the descending thoracic or abdominal aorta.

Children with abdominal aortic coarctation typically develop aortic narrowing in a supraceliac location and present during the first or second decade of life with refractory hypertension (Fig. 186.5A). Up to 80% of these children have coexisting splanchnic or renal artery occlusive disease. In rare cases the degree of obstruction can result in symptomatic mesenteric ischemia.[31] In the largest series to date of 53 children surgically treated for midaortic syndrome, Stanley and colleagues corrected the developmental narrowing with either a thoracoabdominal bypass graft ($n = 26$) or an interposition aortoaortic graft ($n = 3$).[32] Notably, more than half of the bypass procedures necessitated a concomitant renal or splanchnic revascularization procedure (see Fig. 186.5B). The conduit of choice for thoracoabdominal bypass grafting in this series was expanded PTFE because it was believed to be less likely to undergo postimplantation dilatation compared with Dacron. It is important that the graft be oversized in relation to the aortic diameter at the time of implantation to avoid the development of critical stenoses with future aortic growth. As such, 8- to 12-mm grafts, 12- to 16-mm grafts, and 14- to 20-mm grafts are recommended for use in young children, early adolescents, and late adolescents/adults, respectively. In contrast to graft diameter, the length of the graft is not as important as there is minimal longitudinal aortic growth after the age of 10. Although the long-term overall

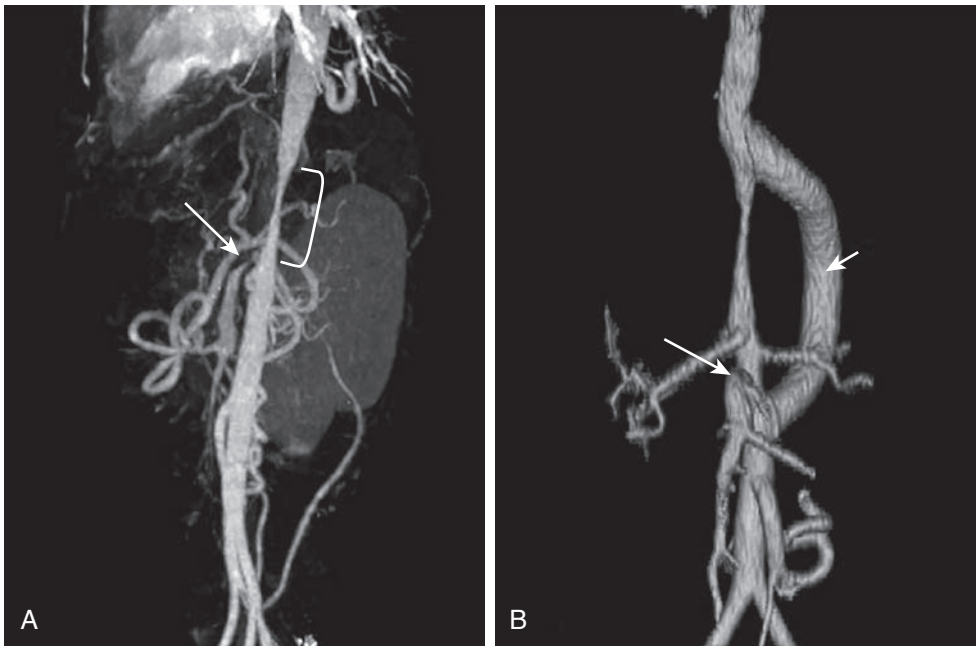

Figure 186.5 A, Midaortic syndrome *(bracket)* with superior mesenteric artery stenosis *(arrow)*. B, Thoracoabdominal bypass *(large arrow)* with aortic implantation of superior mesenteric artery *(small arrow)*. (From Stanley JC, Criado E, Eliason JL, Upchurch GR Jr, Berguer R, Rectenwald JE. Abdominal aortic coarctation: surgical treatment of 53 patients with a thoracoabdominal bypass, patch aortoplasty, or interposition aortoaortic graft. *J Vasc Surg*. 2008;48(5):1073-1082.)

graft patency was excellent in Stanley's series (97% at 5 years), lifelong surveillance is necessary to ensure that reoperation for graft outgrowth, anastomotic stenosis, or failed visceral artery reconstruction is not required.[32]

The use of a prosthetic conduit in children is traditionally limited to major aortic reconstructions. Autogenous conduit, namely the great saphenous vein (GSV), is preferred for visceral and peripheral reconstructions. It is important to be aware that GSV grafts can undergo late expansion and even aneurysmal degeneration, especially if the vein is unsupported when used in young children. A review of 100 aortorenal grafts created with GSV revealed that 16% developed late aneurysmal dilatation or stenosis.[33] In a more recent series of 16 lower extremity bypass procedures undertaken with GSV in children, the vein grafts proved more durable, with only 11% demonstrating expansion over a 10-year follow-up period.[34] Given the risks of late weakening and aneurysmal degeneration, some advocate for supporting GSV grafts originating from the abdominal or pelvic vessels in a Dacron mesh wrap. Alternatively, some prefer to use the internal iliac artery as a conduit when originating a bypass from the aorta or iliac vessels because it offers greater long-term durability compared with GSV.[13] A novel and quite creative technique using the principles of tissue expansion has recently been developed for children with midaortic syndrome that can obviate the need for any of the aforementioned conduits.[35] By periodically inflating a tissue expander implanted posterior to the distal aorta over time, longitudinal growth of the distal aorta and iliac vessels is promoted, ultimately allowing for resection of the diseased segment of aorta and reconstruction with a primary end-to-end anastomosis (Fig. 186.6).

Endovascular

Paralleling the tremendous improvements in endovascular technology seen in adult cardiovascular care, recent technical advances have now made it possible to perform complex percutaneous arterial and venous interventions in infants and children. There are several fundamental differences in technique between adults and children with regard to contrast angiography. In general, contrast volume should not exceed 4 to 5 mL/kg in neonates or 6 to 8 mL/kg in infants. A hand injection technique, rather than power injection, is generally preferred when the patient is less than 15 kg to maximize control of the arterial bed opacification and minimize contrast reflux or excessive injection rates. Power injectors can safely be used in children weighing more than 15 kg, although the injection parameters are typically reduced to half the adult rates.[36] Systemic heparinization is usually administered following arterial access in children less than 15 kg to prevent femoral artery thrombosis. Access is usually gained with ultrasound guidance using a 21-gauge access needle and an 0.018-inch micropuncture wire.[37] A 3- to 5-Fr vascular sheath can then be placed for diagnostic and/or therapeutic interventions. An array of dedicated pediatric-length catheters has been developed to facilitate cannulation of the artery or vein of interest.

Complications related to percutaneous arterial access are generally uncommon, but their frequency can approach 10% in children younger than 1 year of age.[36] The most frequently reported complications include hematoma, dissection, thrombosis, pseudoaneurysms, and arteriovenous fistula. Vessel thrombosis as a result of vasospasm is of particular concern in

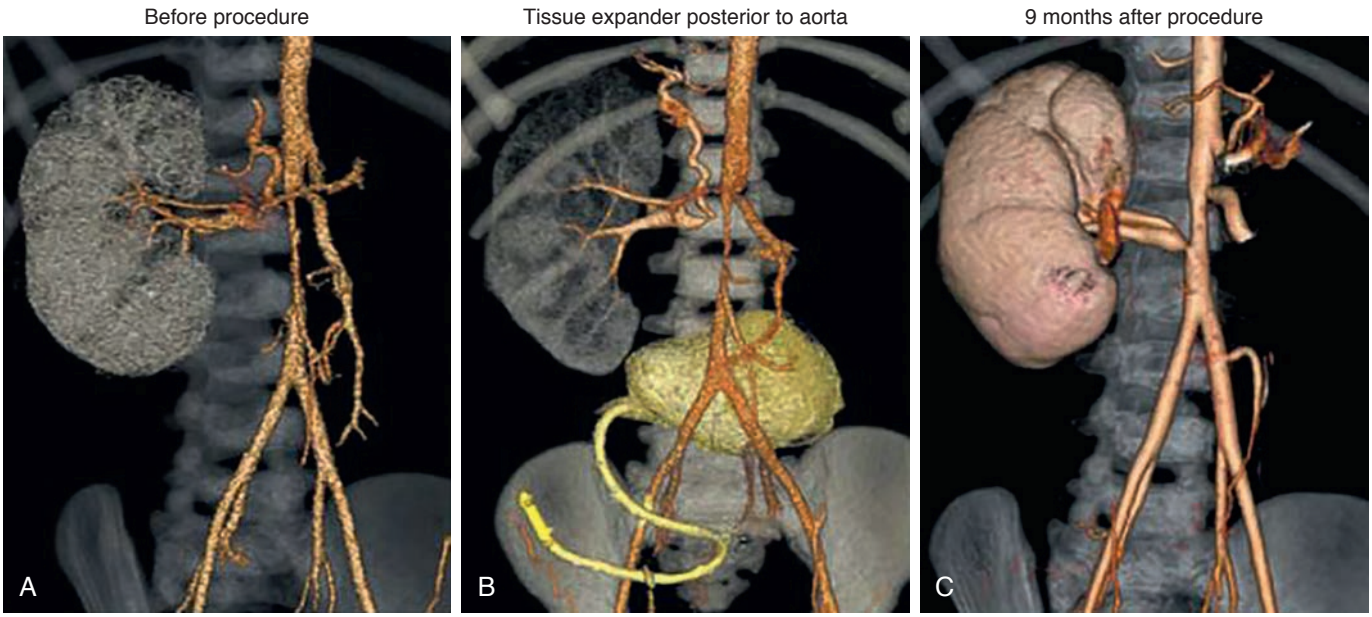

Figure 186.6 (A) Frontal angiographic view of 3-year-old girl with midaortic syndrome. (B) Placement of retroaortic tissue expander prior to aortic surgery. (C) Removal of tissue expander followed by primary aortic reconstruction. (From Kim HB, Vakili K, Modi BP, et al. A novel treatment for the midaortic syndrome. *N Engl J Med*. 2012;367(24):2361-2362.)

small patients (<15 kg); incidence rates as high as 16% have been reported.[38] Prophylactic intraarterial nitroglycerin (1 to 3 μg/kg) can be administered to help prevent this complication in small children.[36]

Percutaneous balloon angioplasty has been used as a treatment for children with renovascular hypertension for more than 20 years, with varying degrees of success. In one series of 33 patients, Shroff and colleagues achieved blood pressure control in only 54%, and 37% of the patients developed restenosis.[39] It is recommended to avoid placing stents in pediatric renal arteries unless there is significant elastic recoil after angioplasty or a postangioplasty dissection is identified. Hepatic artery stenosis can develop in up to 20% of pediatric liver transplant recipients,[40] and these lesions can also be successfully treated with percutaneous angioplasty techniques. Typically, balloons between 2 and 6 mm in diameter are used, and the associated complications include acute vessel dissection, vasospasm, and thrombosis.[41] The literature on this technique is limited to several case series, and currently no long-term data are available. Although balloon angioplasty of aortic coarctation in pediatric patients has been a safe and effective treatment option since the 1980s, its durability remains in question. In a series of 67 neonates and children with coarctation treated by endovascular means, 25% developed recoarctation requiring reintervention and 5% developed an aneurysm at the angioplasty site at long-term follow-up (median, 5 years).[42]

Much like in adults, endovascular procedural success in children will likely continue to improve as the associated technology becomes further advanced over time. This treatment modality will likely confer the benefit of decreased perioperative morbidity at the potential expense of lower longer-term durability, a trade-off that parallels the adult experience with endovascular surgery.

Aortic and Arterial Aneurysms in the Pediatric Population

DAWN M. COLEMAN, JONATHAN L. ELIASON, and JAMES C. STANLEY

AORTIC ANEURYSMS 2439
NONAORTIC ARTERIAL ANEURYSMS 2442
SUMMARY 2447

Pediatric arterial aneurysms include many rare and heterogeneic diseases. Etiologies vary widely among the different types of aneurysms, with infection, inflammation, genetic disorders, and trauma being most common (Table 187.1). Aneurysms in children, with few exceptions, should be considered dangerous. Although optimal management strategies and established criteria for operative treatment remain ill defined, rupture and thrombosis are reported frequently enough to justify early intervention in most cases. Unfortunately, children having a systemic process responsible for their aneurysm carry the highest chance of rupture, but they are also at greatest operative risk. Many surgical procedures in the treatment of these aneurysms are complex, and management strategies based upon the specific arterial bed involved deserve individual review.

AORTIC ANEURYSMS

Aortic aneurysms are classically defined as enlargement (dilation) of the aorta's diameter greater than 1.5 times normal. Diagnosis of a pediatric aortic aneurysm requires a careful consideration of location and aortic size, for which standards are not well established. However, a contemporary retrospective series analyzed the results from 88 thoracic and 110 abdominal contrast material-enhanced computed tomographic examinations in children without known cardiovascular disease and determined a range of normal "effective diameters" of the aorta and common iliac arteries at multiple levels.[1] Aortic diameters exceeding the "normal" range were considered aneurysmal.

Etiologies of pediatric aortic aneurysm are quite diverse. Infectious aneurysms in the past accounted for nearly one-third of pediatric aortic aneurysms but are less commonly encountered in contemporary times, most often associated with umbilical artery catheterization.[2] Infectious aneurysms are typically saccular and may involve the thoracic aorta, abdominal aorta, and iliac vessels (Fig. 187.1). *Staphylococcus aureus* and *albus* are predominant organisms responsible for these infections. These aneurysms present most commonly during the first 2 years of life. In such cases, it is critical for infection to be quiescent if a prosthetic conduit is to be used for the aortic repair. Unfortunately, such an option does not exist in the face of many acutely expanding or ruptured infected aortic aneurysms. Noniatrogenic periaortic infections are also recognized as a rare cause of childhood aortic aneurysms.

Inflammatory aortic aneurysms are uncommon, being most often attributed to Takayasu aortoarteritis and in rare instances to Kawasaki disease, Behçet disease, and systemic lupus erythematosus.[3] While Takayasu aortitis more commonly results in aortic stenoses, related aneurysms do occur, typically involving the thoracic aorta.[4] They affect older children and adolescents.

Kawasaki disease (mucocutaneous lymph node syndrome) is characterized by a febrile state typically in young children having erythematous extremities, fingertip desquamation, conjunctivitis, and lymphadenopathy. The disease more commonly affects the abdominal segment of the aorta, usually during the first year of life. A critical component of Kawasaki disease is coronary artery aneurysm, affecting approximately a fifth of children with

Abstract

Pediatric arterial aneurysms are rare and heterogeneous. Aneurysms in children, with few exceptions, should be considered hazardous and while optimal management strategies and established criteria for operative treatment remain ill defined, rupture and thrombosis are reported frequently enough to justify early intervention in most cases. Individualized surgical treatment is often complex and must consider patient age and anatomic factors; these reconstructions may be undertaken with negligible perioperative morbidity and mortality. Given the predicted long life expectancy of most children affected with these aneurysms, the treatment must be thoughtfully planned and executed for durability and long-term follow-up is mandatory.

TABLE 187.1 Pediatric Aneurysms

Etiology	Principal Artery Affected	Histologic and Morphologic Character	Clinical Characteristics
I: Infection	Aorta, iliac arteries	Acute inflammatory infiltrates present initially, then chronic inflammation and fibrotic changes; saccular aneurysms	Umbilical artery catheterization, endocarditis, predisposing factors; fever, systemic infectious symptoms; untreated aneurysms often progress to rupture
II: Aortitis Takayasu disease	Aorta	Chronic inflammation with giant cells, vessel wall necrosis; saccular aneurysms	Signs and symptoms more often relate to stenotic disease than aneurysms, with the latter often remaining asymptomatic
III: Arteritis Behçet disease Systemic lupus Kawasaki disease Periarteritis nodosa	Renal, splanchnic, axillobrachial, iliofemoral arteries (Kawasaki: coronary arteries)	Chronic panmural inflammation and degeneration, late fibrosis; multiple small saccular aneurysms	Usually asymptomatic but may cause hematuria, perirenal hematomas or death with rupture (lupus, periarteritis nodosa); myocardial infarction or tamponade (Kawasaki), aneurysm thrombosis more common than rupture
IV: Genetic Arterial tortuosity Cutaneous Laxa syndrome Ehlers-Danlos syndrome Marfan syndrome Loeys-Dietz syndrome Tuberous sclerosis	Aorta, muscular arteries	Medial elastic tissue disorganization, mucinous deposits (cystic medial necrosis); solitary fusiform and saccular aneurysms	Aortic rupture or dissection relatively common; arteriography and vascular reconstructions may be hazardous in the face of active disease
V: Developmental: Idiopathic	Aorta, renal, iliofemoral arteries	Medial thinning and fibroplasia; solitary and multiple saccular aneurysms affecting arterial bifurcations most often	Usually asymptomatic; extremity aneurysms often present as painless, pulsatile mass
VI: Traumatic: Extravascular	Aorta, extremity arteries	Disruption of usually three layers of artery (pseudoaneurysm), thrombosis of small aneurysms Common; saccular aneurysms	Protean manifestations; aortic aneurysms often rupture; peripheral lesions often asymptomatic

an attending risk of acute thrombosis. Aneurysm regression with immunosuppression is well described in this disease, and reconstructions should be avoided in the face of active disease at the risk of anastomotic disruption or stenosis.[5]

A number of genetic diseases have been associated with the development of pediatric aortic aneurysms. The most common ones deserve comment. Tuberous sclerosis is an autosomal dominant disorder characterized by complex multiorgan involvement affecting the brain, retina, kidneys, heart, and skin, with vascular manifestations occurring less often. Hamartomas in multiple organ systems are a common feature, and central nervous system involvement occurs often with associated seizures and mental retardation. The vascular complications of this entity tend to occur in younger children. The abdominal and thoracic aorta are more commonly affected than peripheral arteries (Fig. 187.2). Nearly two dozen pediatric aortic aneurysms attributed to tuberous sclerosis have been reported.[6-8] Instances of rupture and death have been reported in both infancy and childhood.[6] Although the pathogenesis of the vasculopathy remains unclear, there is evidence for dysplastic and degenerative changes within the arterial wall and a loss of heterozygosity involving genes *TSC1* and *TSC2*.[6,9,10]

Ehlers-Danlos, Marfan, Loeys-Dietz, arterial tortuosity, and cutaneous laxa syndromes are more often associated with aortic root and thoracic aortic aneurysms or dissections in older children. Vascular (type IV) Ehlers-Danlos syndrome is an autosomal dominant disease resulting from a defect in the *COL3A1* gene responsible for type III collagen. The syndrome is associated with spontaneous rupture of hollow viscera, as well as large arteries such as the aorta. Aortic lesions are not rare in this syndrome.[11] An earlier report noted that of 132 vascular complications encountered in 24 patients, 17 had thoracic or abdominal aortic aneurysms, dissections, or ruptures.[12] Vascular repair in these patients may be hazardous because the arteries are extremely fragile, and reconstructions should be undertaken with extreme caution.

Marfan syndrome is due to an autosomal dominant disease resulting from a defect in the *FBN1* gene which leads to abnormal collagen cross-linking. Dilation of the aortic root, which may progress to aneurysmal degeneration, is a hallmark vascular feature of this syndrome. Although infantile disease is rare and children are less commonly affected than adults, it is noteworthy that 50% to 83% of children with Marfan syndrome exhibit aortic dilation, including 20% having aortic aneurysms. Neonatal

Figure 187.1 Infectious 2.2-cm infrarenal abdominal aortic aneurysm *(arrow)* and a 1.3-cm right iliac artery aneurysm *(arrow)* in a 2-week-old associated with umbilical catheterization and sepsis (computed tomography angiography).[2]

Figure 187.2 Multiple saccular aneurysms along the anteromedial aspect of the descending thoracic aorta in a 5-year-old with tuberous sclerosis.

Marfan syndrome, resulting primarily from de novo mutations, is a particularly severe and rapidly progressive phenotype of this genetic disease.[13-15]

Loeys-Dietz syndrome is an autosomal dominant connective tissue disorder resulting from a defect in the TGF-β pathway that causes abnormal pathway signaling, tissue friability, craniofacial abnormalities, and a characteristic panvasculopathy.[16,17] The vascular phenotype is characterized mainly by descending thoracic aortic and peripheral aneurysms, arterial tortuosity, and dissections. Progressive aneurysmal expansion and rupture are commonplace with this syndrome and operative therapy is pursued earlier rather than later in most cases. Beta-blocker and angiotensin II type I receptor blocker (ARB) therapy should be considered for both Marfan and Loeys-Dietz patients, to potentially reduce progressive aortic root dilation.[18,19]

Frequently no identifiable etiology can be ascribed to pediatric aortic aneurysms. These aneurysms are considered as idiopathic, as well as developmental or congenital, in origin. In cases of thoracic aortic aneurysms that do not meet criteria for Marfan or Loeys-Dietz syndromes ("nonsyndromic"), there are data to suggest that acceptance of a global phenotype is useful to stratify risk and guide clinical interventions, including pharmacologic means to lessen the rate of aneurysmal progression.[20] It is noteworthy that children having systemic, noncardiovascular features involving the craniofacial, ocular, or cutaneous tissues have aneurysms associated with more rapid enlargement.

In other children, these aneurysms may be attributed to post-stenotic turbulent flow causing aortic dilation. Such aneurysms are most often observed in children with thoracic isthmic coarctations or abdominal narrowings caused by abnormal fusion of the embryonic dorsal aortas during the fourth week of fetal development. In as much as concurrent peripheral aneurysms are common in these cases, it is likely that an unknown genetic defect, yet to be identified, that results in a major fault in the vessel wall formation.

Surgical interventions for aortic aneurysms in children include aneurysmectomy with interposition graft reconstructions, nonanatomic aorto-aortic bypasses, and closed or open aneurysmorrhaphy in selected children.[2] These reconstructions are often complex, given the frequency of splanchnic or renal artery branches originating from the aneurysms.

Aneurysmectomy with interposition graft aortic reconstruction is the most direct means of treating pediatric abdominal aortic aneurysms limited to the infrarenal aorta (Fig. 187.3).[2] The largest diameter graft that can safely be implanted should be used, but not one so large that slow flow along the grafts inner surface results in the accumulation of excess thrombus with the potential for thromboembolism. Large grafts placed in older children and adolescents allow for sufficient blood flow as adulthood is reached, and in infants and younger children a large conduit will permit further growth prior to the predicted need for reoperation as the child outgrows the initial reconstruction. In general, this translates to 6- to 10-mm grafts in newborns and small infants, 10- to 12-mm grafts in larger infants, 12- to 14-mm grafts in young children, and 14- to 20-mm grafts in older children and adolescents. Teflon (expanded polytetrafluoroethylene [ePTFE]) prostheses are favored over

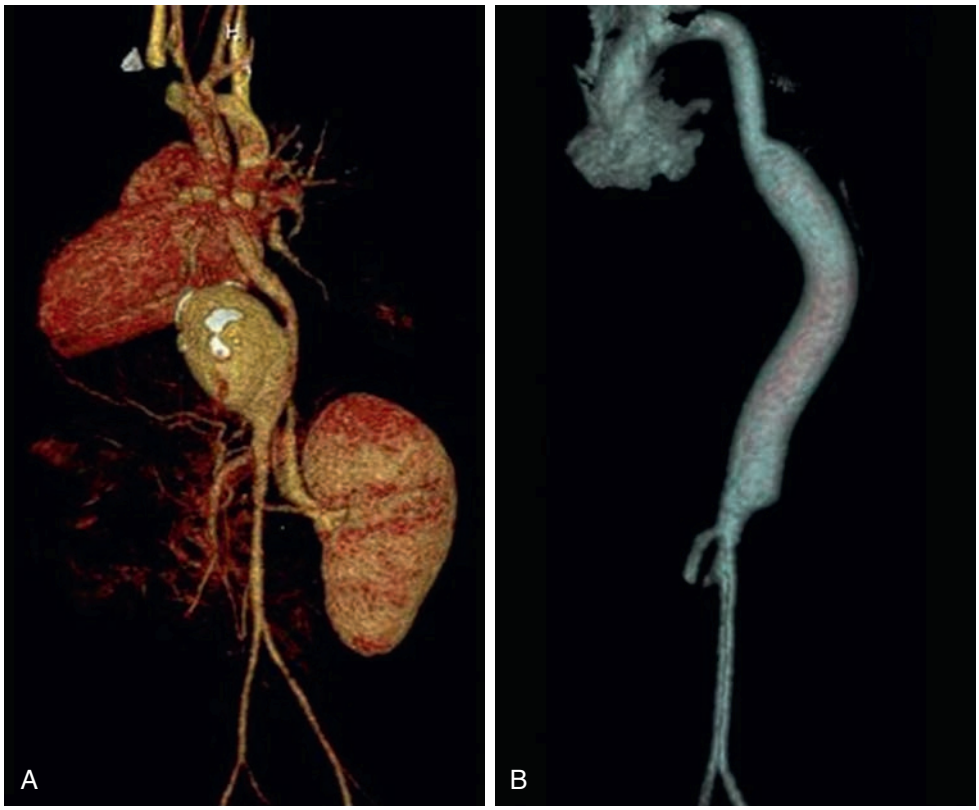

Figure 187.3 (A) Saccular 3.5-cm supraceliac mycotic aneurysm in a 20-month-old associated with infected umbilical artery catheterization (computed tomography angiography). (B) Magnetic resonance angiography following aneurysmectomy and repair with interposition 12-mm expanded polytetrafluoroethylene.[2]

woven or knitted Dacron (polyethylene terephthalate) due to the inherent postimplantation dilation of the latter conduits. Cryopreserved homografts may be an appropriate conduit in select children, although their long-term durability has not been established.[6,21]

Aneurysmectomy with nonanatomic aortic reconstructions in the form of thoracoabdominal or abdominal aorto-aortic and aorto-iliac bypasses are undertaken most often when splanchnic or renal arteries have their origins from the aneurysm itself, mandating their revascularization (Fig. 187.4).[2] Usually, the aortic reconstructions are undertaken first, before reconstructions of the branch arteries. This provides continuous flow to the pelvic and lower extremity tissues during respective splanchnic and renal artery reconstructions, and eventual aneurysmectomy.

The role of closed or open aneurysmorrhaphy in treating pediatric abdominal aortic aneurysms is ill defined.[2] Nevertheless, if the underlying basis of the aortic dilation can be eliminated, such as with post-stenotic aneurysms, the inexorable progression of aortic expansion following aneurysmorrhaphy may not occur. This assumes the residual aortic wall will remain stable. Although the latter may be reasonable, no long-term data exist to confirm such. Closed aneurysmorrhaphy is performed most often in treating small fusiform aortic aneurysms. Two specific circumstances negate the safe performance of closed aneurysmorrhaphy: (1) the first being the presence of thrombus or loose fibrinous debris lining the aneurysm sac, and (2) the second being an exceedingly large aneurysm in which the plicated wall would be difficult to collapse. In the latter setting, an open aneurysmorrhaphy with excision of a portion of the wall would be more appropriate (Fig. 187.5).

Endovascular aneurysm repair (EVAR) has a limited role in the definitive management of most pediatric abdominal aortic aneurysms. An exception to this tenet is the treatment of traumatic pseudoaneurysms in older adolescents in whom further aortic growth is unlikely, or in those emergent circumstances of an aortic disruption. Thoracic endovascular aneurysm repair (TEVAR) for thoracic aneurysm in select patients of appropriate age and size may be also appropriate, although caution exists in children with a progressive arteriopathy.

Surgical treatment of abdominal aortic aneurysms is successful in more than 90% of infants and young children.[2] This involves complex operative techniques that must take into account the child's growth potential, the aneurysm location and whether the splanchnic and renal arteries are involved. Regardless of the intervention undertaken, long-term follow-up is mandatory for all surgical interventions.

NONAORTIC ARTERIAL ANEURYSMS

The natural history of nonaortic pediatric arterial aneurysms remains ill defined, as is the categorization of these aneurysms.[22,23]

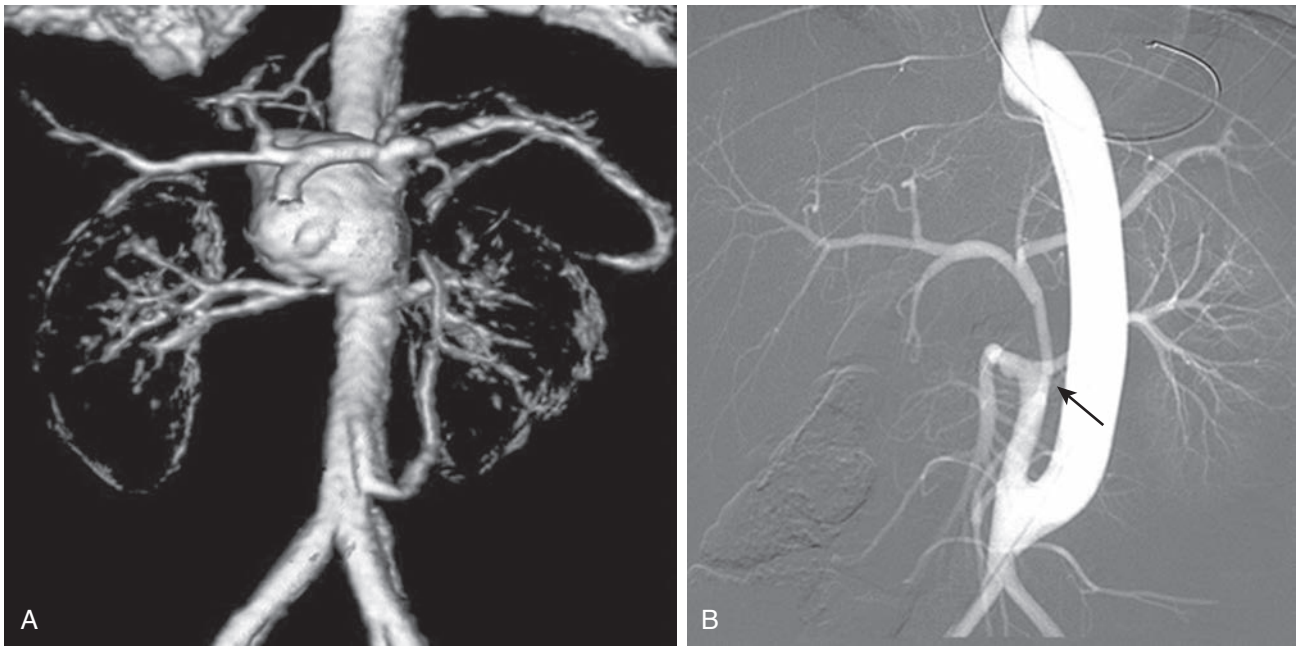

Figure 187.4 (A) Central abdominal aortic aneurysm with involvement of the celiac, superior mesenteric, and renal arteries associated with tuberous sclerosis in a 5-year-old boy (computed tomography angiography). (B) Treatment included aneurysmectomy, 14-mm expanded polytetrafluoroethylene thoracoabdominal bypass, aortic reimplantation of a left renal artery and superior mesenteric artery (SMA), and aortoceliac bypass with a hypogastric artery graft, all from the distal abdominal aorta *(arrow)*, as well as a right nephrectomy (digital subtraction arteriography).[2]

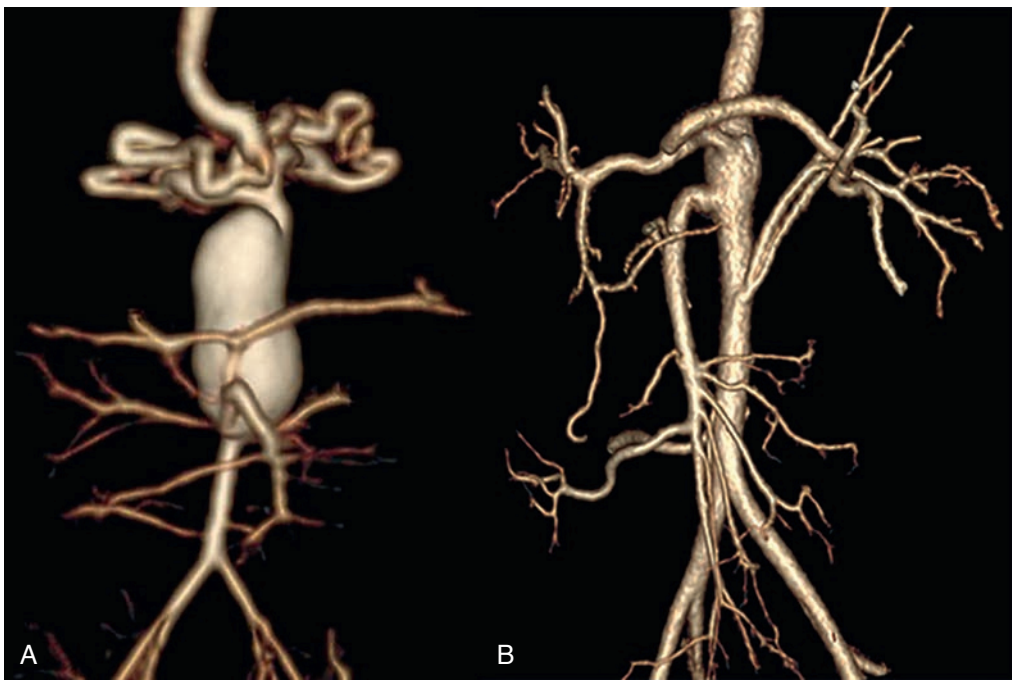

Figure 187.5 (A) Saccular 2-cm supraceliac aortic aneurysm with involvement of the celiac, superior mesenteric, and renal arteries associated with focal and nearly complete occlusion (coarctation) of the diaphragmatic aorta in a 6-month-old (computed tomography angiography). (B) Appearance following resection of the coarcted aortic segment with primary aorto-aortic reanastomosis, open aneurysmorrhaphy, and aortic reimplantation of one of the affected arteries with no evidence of progressive aortic dilation 7 years postoperatively.[2]

The risk of expansion, rupture, thrombosis, and distal thromboembolism of these nonaortic aneurysms warrant intervention in most instances. These peripheral arterial aneurysms are extremely uncommon but share etiologic risk factors similar to aortic aneurysms, including infection, inflammation, inherited vasculopathies, and trauma. In contrast to aortic aneurysms, neurofibromatosis 1 and fibromuscular dysplasia are often associated with nonaortic aneurysms in childhood. It is most appropriate to discuss peripheral arterial aneurysms by the vascular bed affected.

Extracranial cerebrovascular artery aneurysms have been previously defined by De Jong et al., who previously proposed that aneurysms in the region of the carotid bulb should be defined by a diameter greater than 150% of the normal common carotid artery or 200% of the normal internal carotid artery, and for the internal carotid artery dilations greater than 120% of a normal cross-section of the ipsilateral artery were considered aneurysmal.[24]

True aneurysms of the extracranial carotid artery are likely a manifestation of a genetic disorder, inflammatory disease, or traumatic pseudoaneurysms resulting typically from blunt injury, tonsillectomy, or iatrogenic vascular accessing injury (Fig. 187.6). The most commonly reported symptom is a pulsatile neck mass. Horner syndrome and cranial nerve dysfunction rates have been reported to be as high as 4.6% to 11%.[25] Given that the risk of central neurologic complication and rupture rates are reported to be as high as 42%, early surgical treatment is usually pursued.[26]

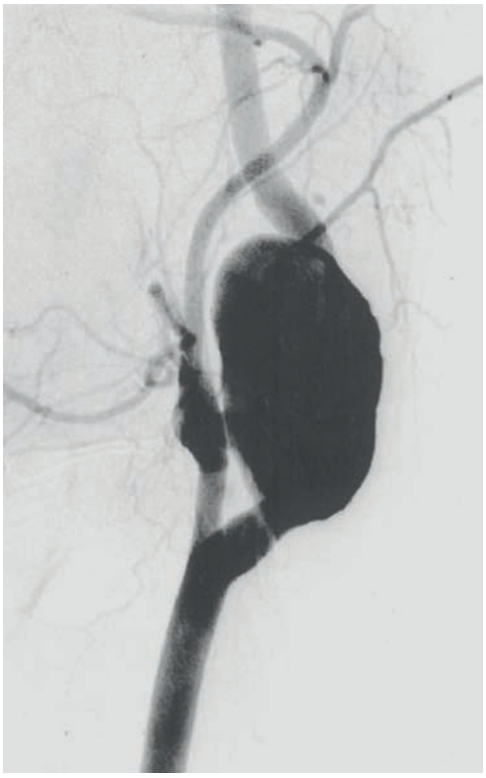

Figure 187.6 Carotid Artery Aneurysm. Preoperative angiogram demonstrating a traumatic 3-cm saccular internal carotid artery aneurysm with 11-mm fusiform ectasia of the external carotid artery.[22]

Aneurysmectomy with an interposition bypass is the most commonly described procedure in treating carotid artery aneurysms, using both autogenous and prosthetic conduits.[27,28] The authors favor the use of hypogastric artery given the risk of late aneurysmal deterioration of vein graft when placed in low resistance arterial beds with high diastolic flow.[29] Procedural morbidity has been associated with cranial nerve injury (4% to 22% incidence) and central neurologic complications, such as stroke (4% to 11% incidence).[25] Ligation may be considered in select patients but only with confirmation of an intact circle of Willis.[30] Endoluminal therapy with placement of covered stents may be appropriate in certain cases.[31,32]

Splanchnic artery aneurysms most commonly have a mycotic, inflammatory, traumatic, or connective tissue disease origin.[33-35] Abdominal pain is common, and luminal gastrointestinal bleeding has also been described.[36] Blunt and deceleration injuries to the liver and spleen can result in small pseudoaneurysms that may thrombose without clinical sequelae or be treated with endovascular embolization if symptomatic or associated with hematobilia. Nontraumatic aneurysms carry a greater risk of rupture and thromboses. Although surgical intervention to exclude an aneurysm and reestablish arterial continuity is ideal (Fig. 187.7), in cases of infection or most genetic diseases, vessel friability may preclude reconstruction, mandating ligation (Fig. 187.8) with reliance on collateral flow to lessen intestinal ischemic complications.[12,33]

Renal artery aneurysms are generally attributed to a connective tissue disorder or a congenital vasculopathy such as arterial dysplasia related to neurofibromatosis and fibromuscular dysplasia. A contemporary radiologic review of renal angiography performed for pediatric fibromuscular dysplasia and neurofibromatosis characterized the phenotype to include 12 cases (28%) of renal aneurysms with a background incidence of occlusive disease affecting 91% of patients (39/43).[37] The clinical relevance of these aneurysms remains ill defined, including the natural history and rupture risk. Pediatric renal artery aneurysms are mainly asymptomatic, although secondary renovascular hypertension and distal thromboembolization have been reported with flank pain and hematuria less common. Aneurysms are often saccular in appearance and occur most commonly at bifurcations. Surgical options for treating these aneurysms are complex and include angioplastic closure, bypass, or reimplantation of the affected artery following resection of the aneurysm (Fig. 187.9). The authors favor hypogastric artery for conduit in cases of aortorenal bypass for reasons aforementioned. Ethanol ablation and coil embolization may also be considered for distal, subsegmental, and cortical aneurysms.[38,39] Primary partial or complete nephrectomy may be required for irreparable disease, including multiple aneurysms not amenable to any form of reconstruction.[22] Closed aneurysmorrhaphy of small (2 to 3 mm diameter) renal artery aneurysms with fine monofilament suture may be appropriate for those aneurysms encountered during treatment of other larger, more clinically relevant aneurysms, or during renal artery revascularization for occlusive disease.

Upper extremity aneurysms most commonly result from trauma, including iatrogenic catheterization-related injury and

In: Rutherford RB, ed. *Splanchnic Artery Aneurysms, in Vascular Surgery*, 6th ed. Philadelphia, PA: Elsevier Saunders; 1973:20115.)

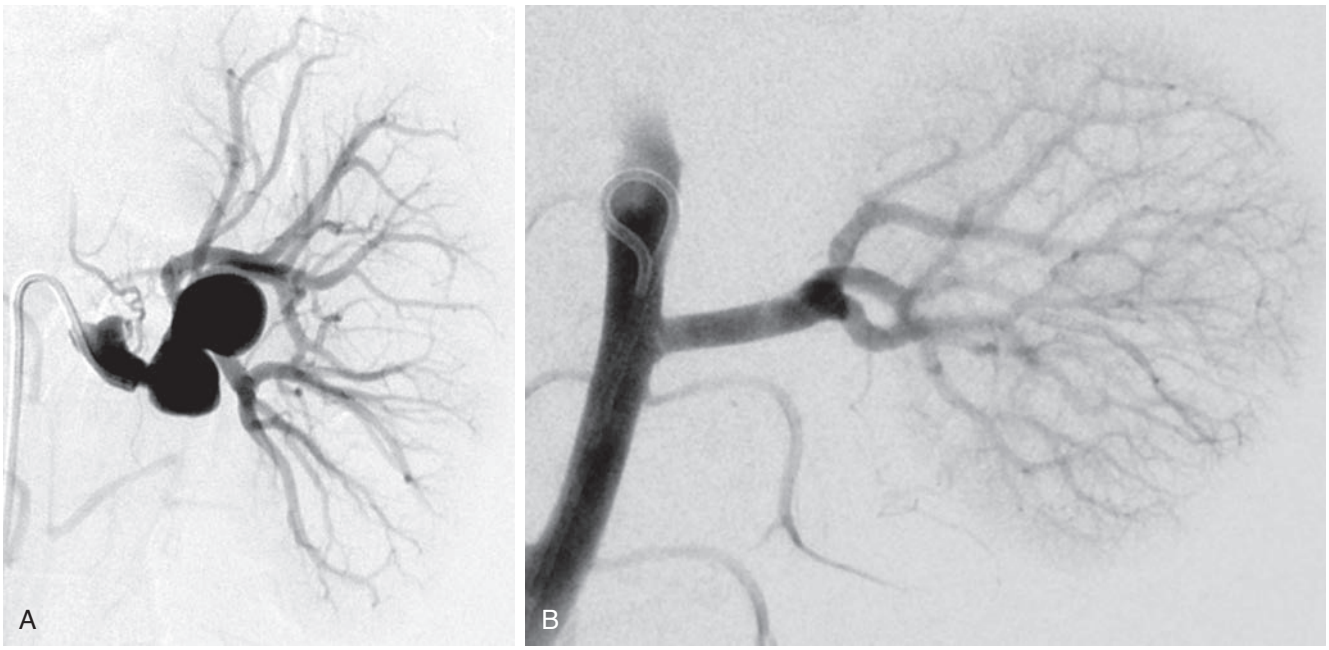

Figure 187.9 Renal Artery Aneurysm. (A) Preoperative angiogram of a 14-year-old with neurofibromatosis (NF1) demonstrating a severely ectatic and diffusely dysplastic left main renal artery with severe left renal artery ostial and distal stenosis associated with two bilobed distal left renal artery aneurysms. (B) Postoperative angiogram following aneurysm resection with ex vivo reconstruction requiring syndactolization of three segmental renal artery branches and aortorenal bypass with hypogastric artery.

the inflammatory arteritides, such as Kawasaki disease (Fig. 187.10). These aneurysms often present as a pulsatile mass, although pain and paresthesia have been reported.[22,40,41] Although rupture of noninfectious aneurysms is rare, the risk of distal hand and digit thromboembolism merits early surgical intervention.[40-43] Aneurysm resection distal to the axillary artery with revascularization by direct reanastomosis, bypass with reversed saphenous vein, or ligation pending the presence of adequate collateral vessels have all been well described with negligible morbidity and mortality.[40]

Lower extremity aneurysms most frequently involve the iliac arteries (Fig. 187.11), sharing similar etiologic risk factors with aortic aneurysm. Although mainly asymptomatic, these aneurysms have been reported to cause abdominal pain and lower quadrant abdominal mass.[44] Although internal iliac artery aneurysms may be safely ligated in the setting of robust pelvic collateralization, common and external iliac arteries require treatment with resection and reanastomosis, interposition grafting, aorto-iliac bypass, or plication. A prosthetic conduit is appropriate in this setting, recommended to be sized as large as possible to facilitate future growth without risking luminal thrombus and distal thromboembolism.[22,45] Cadaveric homografts may have a role in the management of infected iliac artery aneurysms.[46] Femoral pseudoaneurysms and true aneurysms (Fig. 187.12) are subject to acute thromboses and warrant early operative intervention. Arterial reconstructions following

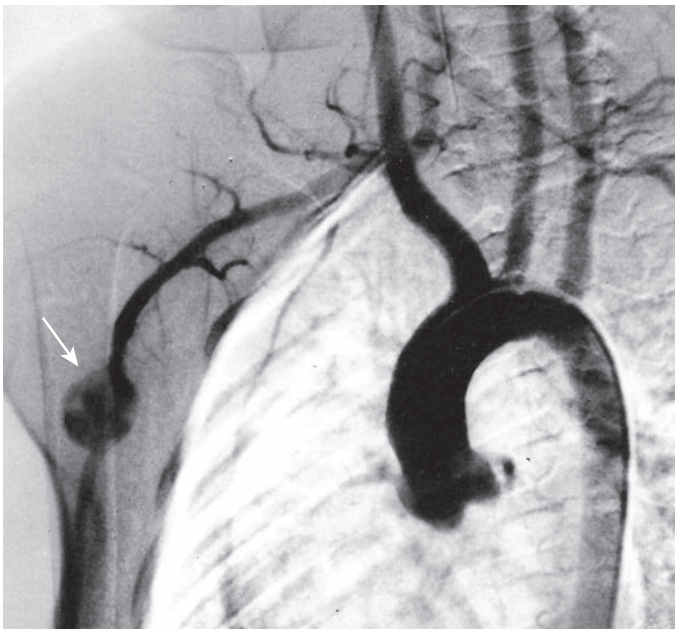

Figure 187.10 Brachial Extremity Aneurysm. Preoperative arteriogram of a 4-year-old with a right brachial artery aneurysm measuring 18 mm resulting from Kawasaki disease. (Stanley JC, Eliason JL. aneurysmectomy in these cases usually use autologous vein conduits. In a contemporary series of nonaortic pediatric arterial aneurysms, no long-term difference in outcomes across vascular territories following operative repair was noted. Although no reinterventions were required following the treatment of extracranial cerebrovascular or extremity aneurysms in the University of Michigan experience, 15% of children treated for visceral aneurysms underwent later reoperations.[22]

SUMMARY

Pediatric aortic and arterial aneurysms represent a variety of complex diseases affecting multiple vascular territories. Individualized surgical treatment that considers patient age and anatomic factors may be undertaken with negligible perioperative morbidity and mortality. It is the authors' contention that a multidisciplinary team of vascular surgeons, pediatricians, radiologists, and anesthesiologists provide the best setting for the most optimal care of children with these aneurysms. Given the predicted long life expectancy of many children affected with these aneurysms, the treatment must be thoughtfully planned and executed, and long-term follow-up is mandatory.

INTRODUCTION

Four major types of primary pediatric tumors have been categorized: infantile hemangioma (IH), congenital hemangioma (CH), kaposiform hemangioendothelioma (KHE), and pyogenic granuloma. Although the majority of pediatric vascular tumors are benign, KHE is considered an intermediate tumor. Most of these tumors are seen in infants and children, except pyogenic granulomas, which can be seen at any age. Vascular tumors occur in many body locations and may cause pain and bleeding or destroy adjacent tissues. Systemic manifestations may include thrombocytopenia and anemia as a result of consumption coagulopathy, or congestive heart failure in the few patients with large high-flow lesions, particularly in the liver. Death is rare.[1,2]

Vascular tumors require differentiation from vascular malformations. Primary vascular and intermediate tumors can be present at birth and usually have proliferative endothelium. Vascular malformations occur from abnormal tissue growth, are present at birth (although not always evident), have quiescent endothelium, and generally grow as the child grows. Primary tumors and vascular malformations may look alike, with blue, red, or purple hues; and the lesions may be flat or raised.[3,4]

Secondary tumors that may surround major vessels are many and include soft tissue, cartilaginous or bony sarcomas, and benign or malignant neurogenic tumors, such as neuroblastoma or ganglioneuroma, among others.

Current management is multidisciplinary. History and physical examination, supplemented by imaging studies if needed, are important for identification and classification of primary tumors. Treatment may vary by tumor type, and biopsy is rarely necessary. Application of topical therapies, the use of antiangiogenic drugs, sclerotherapy, or laser therapy, and the role for surgical excision continue to evolve. For example, IH and CH are often observed, whereas the treatment of pyogenic granuloma is primarily surgical. Vascular anomaly or malformation centers have been created at many referral centers to centralize and coordinate care.[2,5] Similarly, resection of secondary tumors may involve pediatric, orthopedic, and oncologic surgeons and neurosurgeons alone or in combination, with vascular surgery involvement relegated to select patients with large or infiltrative tumors near the aorta or vena cava and their major branches, or the major head, neck or extremity vessels. In contrast to adult patients, major vascular reconstruction is uncommon in the pediatric population.

CLINICAL FEATURES

Infantile Hemangioma

The pathogenesis of IH is development from progenitor cells which normally would evolve into blood vessels.[6] The precursor cell seems to be a multipotent hemangioma-derived stem cell, which produces an erythrocyte-type glucose transporter

Abstract

Primary pediatric vascular tumors are mostly benign and occur in four major types: infantile hemangioma, congenital hemangioma, kaposiform hemangioendothelioma and pyogenic granuloma. Clinical presentation varies according to tumor type, but these can occur in many body locations, may cause pain and bleeding or tissue invasion with physiologic or aesthetic consequences. Systemic manifestations are rare but can be severe. Current management of such tumors is multidisciplinary and has evolved significantly over the last two decades. The purpose of this chapter is to discuss clinical features, diagnosis and management of pediatric vascular tumors.

(GLUT1).[7,8] These stem cells are similar to placental endothelium but genetically derived from the child.[9,10] Hypoxia is widely accepted as the primary stimulus for growth of IH.[11] Endothelial proliferation likely occurs from complex interactions between activated T cells, alterations in vascular endothelial growth factor receptor (VEGFR) expression, and the binding of endothelial growth factor A to VEGFR-2 receptors. Reduction in local antiangiogenic proteins may be another stimulus to tumor growth. Sometime between early infancy and 4 years of age, these tumors involute, the mechanism of which is unclear. Endothelial proliferation slows and apoptosis increases during this time, with potential triggers related to a decrease in proangiogenic maternal estrogens or an increase in angiogenesis inhibitors in the epidermis. The tumor is replaced by fat cells, which also derive from the aforementioned stem cells.[12-14]

IH is the most common neoplasm of infancy and affects white infants more often than dark-skinned children. Premature infants with low birth weight, particularly girls, have a higher risk of developing these tumors.[15] For every 500-g decrease below a 2500-g baby, the risk of IH increases 40%. Lesions tend to be solitary (80%) and involve the head and neck, trunk, or extremity in decreasing order of frequency. The tumors appear at median age of 2 weeks but may be evident as small pale, telangiectatic, or ecchymotic spots in nearly one-half of infants at birth.[15-17]

IH has a proliferative growth phase during the first 9 months of life, with most rapid growth in the first 8 weeks of life. Eighty percent of volumetric growth is achieved by age 5 months.[18,19] Tumor appearance during this stage varies based on whether it involves the superficial or deep dermis. If the tumor is in the superficial dermis, it appears bright red, but when deeper, the lesion either has a bluish or normal color. Many IHs are mixed with both superficial and deep components (Fig. 188.1A to C). Proliferation often slows by 5 to 6 months of age; however, in those with a primarily deep component, proliferation can be prolonged, sometimes up to 18 months of age. Subsequent growth coincides with growth of the child.[19] The involution phase begins by 1 year of age, at which point the tumor shrinks, the color fades, the center of the lesion pales, and the tumor softens. Involution is complete by 4 years of age in most children.[15] Some patients with a large deep component are left with fibrofatty tissue and redundant skin. Scarring is most often associated with ulcerative lesions. Telangiectasias and discoloration are other sequelae after lesion regression is complete.[18,20]

IHs may be multiple and involve the skin or liver. The cutaneous lesions are often less than 5 mm in diameter and domelike (see Fig. 188.1D). If more than five hemangiomas are present, the child has a 16% chance of harboring visceral lesions, with the most common extracutaneous location being the liver. The brain, gut, and lung are rarely involved. Most hepatic IH are small, discovered incidentally, and are classified as multifocal or diffuse. Multifocal hepatic hemangiomas are usually asymptomatic, although high-output cardiac failure by arteriovenous or portovenous shunting occurs rarely. Similar to cutaneous IH, involution begins by 1 year of age and often earlier in most children.[21,22]

Diffuse IHs can be seen in the liver and often does not need active treatment other than close observation. At times, large, diffuse IHs may replace much of the liver parenchyma and cause massive hepatomegaly. Compression of the inferior vena cava or upward pressure on the diaphragm with reduction of the pleural space causes respiratory symptoms or abdominal pain and pressure in select patients. High-output cardiac failure is rarely seen. Almost all infants with profound liver involvement develop hypothyroidism because this hemangioma expresses a deiodinase that inactivates thyroid hormone, necessitating thyroid-stimulating hormone monitoring.[23] The need for large doses of thyroid hormone may be great to reduce the risk of irreversible mental retardation seen with inadequate therapy. As the hemangioma regresses, the need for replacement therapy ebbs. Differential diagnosis includes hepatic arteriovenous malformation (AVM) and malignant neoplasm. Hemangiomas and AVMs exhibit fast-flow characteristics, with 90% of fast-flow lesions being hemangiomas and the remaining ones AVMs. Hepatoblastoma and metastatic neuroblastoma do not have the shunting characteristics of hemangioma.[22]

IHs may be associated with specific syndromes in which there are anomalies of the cardiovascular, gastrointestinal, and urogenital systems; brain or spinal cord; eye; or bone.

A child with a large, segmental midline lumbosacral region IH carries a 33% chance of having a spinal anomaly such as a tethered cord, lipoma, or intraspinal hemangioma (Fig. 188.2A). Magnetic resonance imaging (MRI) between 3 and 6 months of age is important to exclude spinal abnormality in these cases.[24] Lower body IH may be associated with urogenital anomalies or ulceration, myelopathy, bone deformities, anorectal malformations, arterial, and/or renal anomalies. This association is termed LUMBAR, and most children with these anomalies are girls. The IH is usually large, segmental, and superficial, has minimal postnatal growth, and often ulcerates. The hemangioma may be seen in the sacral or lumbar regions, the perineum and genitalia, or lower extremity.[25]

Segmental plaquelike IHs of the face may be associated with one or more anomalies in the brain or cerebrovascular system, heart, eye, sternum, or supraumbilical region, categorized as PHACES syndrome (see Fig. 188.2B). The acronym represents posterior fossa brain malformation, hemangioma, arterial anomalies, coarctation of the aorta and cardiac defects, eye abnormalities, and sternal clefting or supraumbilical raphe. Ninety percent of affected children are female. The most common anomaly is a cerebrovascular malformation in 72% of patients, and approximately 8% of infants sustain a stroke. PHACES is found in less than 3% of all patients with IH, and extracutaneous features in this group are seen in less than one-third of the children.[26] Similar to the LUMBAR association, most affected children are girls. Recognition of PHACE syndrome is critical because these patients have higher risk of complications and sequelae than those with isolated IH.

Rare lesions that can be confused with primary vascular tumors of infancy include arteriovenous malformation, infantile myofibromatosis, infantile fibrosarcoma, Enzinger intramuscular hemangioma, pilomatrixoma, neuroblastoma, and lymphoma.

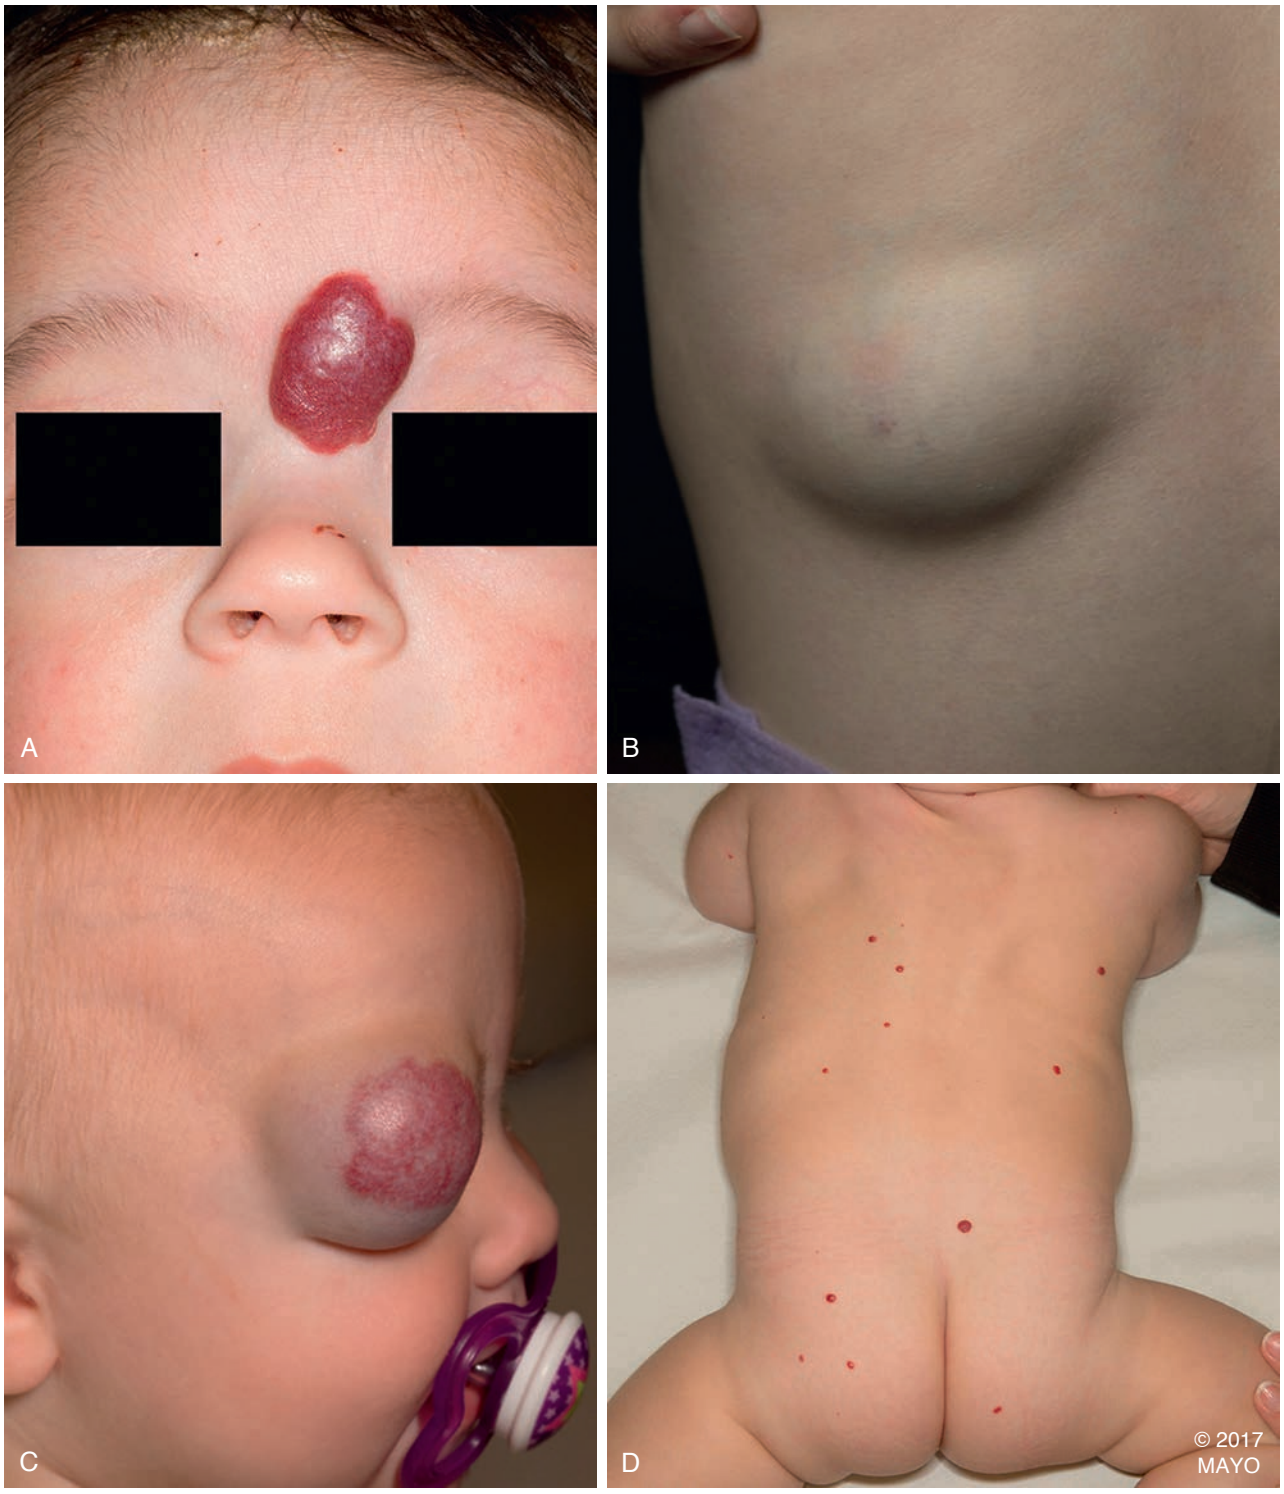

Figure 188.1 Various Types of Infantile Hemangioma. (A) Superficial lesion of the face. (B) Deep lesion of the trunk. Notice the difference in outward appearance and color. (C) A mixed lesion with both superficial and deep components. (D) Multifocal superficial lesions on the trunk and buttocks.

Congenital Hemangioma

CH is fully formed at birth and does not illustrate the postnatal growth of IH. This tumor is most often solitary, although multiple lesions have rarely been described and may range from 1 or 2 cm to more than 20 cm in diameter. CH has a red-violaceous color with coarse telangiectasias, central pallor, and a peripheral pale halo. Unlike IH, CH is more common in the extremities and has an equal sex distribution.[27-29]

CH has historically been defined as rapidly involuting or non-involuting. One small series suggests a third category, defined as partially involuting because some CHs show involution, however

Figure 188.2 Segmental lumbosacral (A) and facial (B) infantile hemangiomas. Such findings should raise suspicion of LUMBAR or PHACE associations.

not completely.[30] Rapidly involuting CH changes quickly after birth, with one-half the lesions completely regressed by 7 months of age and the others by 14 months. Rapidly involuting lesions are noted in the limbs or head and neck in 40% to 50% of cases and the trunk in 6% (Fig. 188.3).[27,28] Involution results in atrophic skin and little underlying subcutaneous adipose tissue, in contrast to regression of IH. Large CH may exhibit high-flow cardiac output. Thrombocytopenia has been reported with a large, rapidly involuting CH, but that association is not Kasabach-Merritt phenomenon (KMP; see later).[31] A solitary hepatic hemangioma in an infant represents a rapidly involuting CH. The lesions are discovered incidentally on prenatal or antenatal ultrasonography, and there is no association with cutaneous hemangiomas. They do not stain positive for GLUT1, a marker for IH.[32] Noninvoluting CHs persist long term, as the name implies, and involve the head or neck 43% of cases, the extremities in 38%, or the torso in 19%.[29]

Kaposiform Hemangioendothelioma

This rare vascular neoplasm has prevalence in infancy of 1 per 100,000, is reddish purple with an ill-defined border, and may be mistaken for ecchymosis on first glance (Fig. 188.4). Sixty percent of KHEs manifest in the neonatal period, and more than 90% are evident by infancy.[33] The tumor is usually greater than 5 cm in diameter, larger than the typical IH, and there may be hair noted in the involved skin, which tends to be a transient phenomenon. KHE has an equal sex distribution, is solitary, and affects the head or neck in 40% of children and the trunk or extremity in 30% each.[34] The lesion is locally invasive but does not metastasize. Multifocal cases are rare but should prompt biopsy when suspected. The natural history of this tumor is expansion in infancy and early childhood and then partial regression. Fibrosis occurs and may cause chronic pain and contractures. Many affected children exhibit KMP.[35] The syndrome is more common in children with large tumors and in those with visceral and muscle involvement.[36] KHE is pathologically similar to tufted angioma, the latter considered by some authors to be a milder form of this tumor.[37] Profound thrombocytopenia (<25,000/mm^3) and consumptive coagulopathy in this condition may prove life threatening in 12% to 24% of children.[35,36] An adult variant occurs and is male predominant, smaller in size but with similar distribution as children, and without risk of KMP.[38]

Pyogenic Granuloma

Pyogenic granuloma, also known as lobular capillary hemangioma, is a solitary red papule that averages 6.5 mm in diameter, rapidly grows, has a stalk, and is complicated by bleeding and ulceration (Fig. 188.5).[39,40] Sex distribution is 2:1 male to female, with mean age at onset of approximately 7 years. The lesion rarely occurs during the first year of life, and the prevalence is inversely correlated with age. Approximately 40% occur at age 5 years or less, another 30% between 5 and 10 years of age, and less than one-fourth after age 10. Nearly 90% of lesions

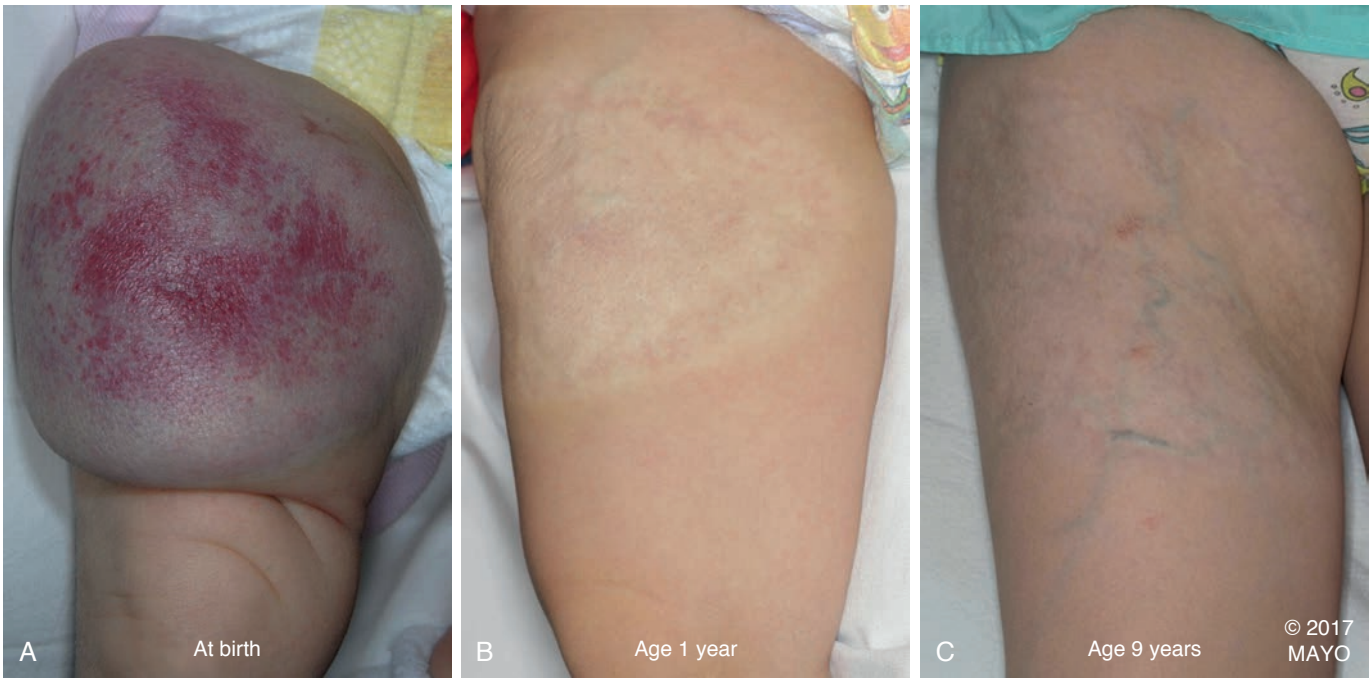

Figure 188.3 Images show progressive regression of a rapidly involuting congenital hemangioma of an extremity.

Figure 188.4 Kaposiform hemangioendothelioma of the extremity.

Figure 188.5 Typical appearance of pyogenic granuloma as a solitary red papule, which often has a stalk.

are cutaneous, with mucous membrane involvement in almost 12%. Distribution is head or neck in 62% of cases, trunk in 19%, upper extremity in 13%, and lower extremity in 5%. Head and neck lesions involve the cheek, oral cavity, scalp, forehead, eyelid, or lips, in decreasing order of frequency.[40] Pyogenic granuloma may be induced by trauma, insect bite, viral infection, or dermatologic disorder in one-fourth of patients.

DIAGNOSIS

Correct diagnosis of a vascular tumor of childhood is made by history and physical examination in 90% of patients. Assessment by handheld Doppler has utility in some cases, particularly if considering fast-flow lesions. When the diagnosis is unclear, radiographic imaging is often diagnostic but biopsy rarely proves necessary. Ultrasound and MRI are the primary imaging modalities when needed.[41]

Diagnosis of IH is made by history and physical examination in nearly all patients. Ultrasound shows a well-circumscribed hypervascular mass. Low-resistance arterial waveforms are present, and venous drainage is seen. MRI can be used if ultrasound imaging is equivocal, but MRI is rarely necessary. IH is seen as a parenchymal mass with dilated vessels and signal voids during the proliferative phase, unlike an arteriovenous malformation. The lesion is isointense on T1 sequences and hyperintense on T2 images and enhances homogeneously after the administration of contrast. An involuting IH is lobular and has adipose tissue and a reduced number of vessels, with signal void or enhancement.[41] MRI or MR angiography is used to image the brain and neck for children with PHACE syndrome. Echocardiography and

an eye examination are important adjuncts in this situation. Although ultrasound may be useful when LUMBAR associations are suspected, MRI often is needed to image the lumbosacral spine, abdomen, and pelvis. Choice of study is based on age of the infant or child and type of lesion.

Less than 1% of IHs require histopathologic evaluation for diagnosis. Biopsy is indicated if malignant disease is suspected or if the diagnosis remains unclear after the lesion is imaged. Microscopic evaluation of a proliferating lesion shows tightly packed capillaries with plump endothelial cells and minimal intervascular stroma. In contrast, an involuting lesion shows reduction in the number of capillaries that have enlarged channels, increased stroma, and fibrofatty tissue.[32,42,43] A hallmark of IH is that it shows GLUT-1 positivity throughout all stages of proliferation and involution.

CH remains a clinical diagnosis. When needed, the findings on ultrasound and MRI are similar to those of IH. Lesions demonstrate fast flow, shunting, and enhancement. Histopathologically, CH is differentiated from IH because CH does not immunostain for GLUT1.[32]

KHE can also be diagnosed by history and physical examination, but biopsy is often used to confirm diagnosis. MRI is used to confirm diagnosis and determine extent of disease. Lesions are infiltrative and hyperintense on T2 images and enhance with contrast. Subcutaneous stranding and ill-defined borders are common, and prominent vessels with hemosiderin cause signal voids.[41]

Histopathology shows an infiltrating lesion with lobules of spindled lymphatic endothelial cells, some of which may be dilated or have a glomeruloid appearance. Vessels contain thrombi and hemosiderin, and mitoses are uncommon. Tumors will immunostain positive for lymphatic markers D240 and PROX1.[32]

Pyogenic granuloma is suggested by its appearance, location, and association with trauma or other factors. Microscopic analysis shows an exophytic mass attached to a narrow stalk on low-power examination and a normal numbers of mast cells, in contrast to a proliferating IH. The superficial part of the tumor shows immature capillaries with interspersed fibroblastic tissue, similar to granulation tissue, and edema in the matrix. The deeper segment has proliferating capillaries arranged in a lobular pattern extending into the deep dermis, and a dense, fibrous stroma.[32]

MANAGEMENT

Infantile Hemangioma

Observation is the mainstay of management because most tumors are small and localized and do not involve esthetically or functionally important areas. Parents can be reassured by showing them examples of proliferative, involuting, and regressed lesions that were managed in other infants. Close observation is needed during the proliferative phase to be certain the tumor does not ulcerate or pose risk of destruction of adjacent important structures.[1,15]

Approximately 16% of lesions develop skin ulceration during the proliferative phase, at an average of 4 months of age.[44] Ulceration is more common on the lips, neck, anogenital, and other flexural regions; larger and segmental IHs are also at risk of ulceration (Fig. 188.6). Standard wound care is topical antibiotic and Vaseline, followed by gauze. These lesions may be very painful, so topical lidocaine may be needed. Topical pharmacotherapy may be appropriate treatment for small IHs that do not require systemic therapy. Topical corticosteroid, such as clobetasol, may prove effective for small, superficial lesions, although hypopigmentation and skin atrophy can occur. Application of timolol, a beta blocker, also has been proven effective for small, superficial lesions. Systemic absorption of the drug is possible if a large amount of medication is applied, particularly for large, deep lesions.[45]

Systemic therapy is indicated for large hemangiomas that cannot be treated with local injections and is considered when topical therapy has been ineffective. Several drugs have been used, including beta blockers, steroids, and antimetabolic agents.[1,15]

Propranolol is standard of care for IHs that cannot be treated by observation alone or with topical agents.[46] This medication is used when there is risk for complications to adjacent tissue, such as anatomic distortion, ulceration, or visual obstruction. Systemic steroids are reserved for those who do not respond to, or have a contraindication to, beta blockers. Propranolol is given 2 or 3 times daily with a usual total dosage of 2 mg/kg per day, although some lesions respond to a lower dose. Rarely is a higher dose needed. Propranolol is administered through the proliferative phase until at least 1 year of age. Most physicians taper the dose thereafter. Lesions that are deep or in critical areas, such as the nose or eye, may require treatment beyond 1 year. Treatment efficacy is best when the medication is started during the proliferative phase for children that require this therapy. Rebound tumor growth occurs if the medication is abruptly discontinued during the proliferative phase. Tolerance seems best when the drug dose is started at 1 mg/kg per day and slowly increased to 2 mg/kg per day. Approximately 90% of tumors stop growing or regress with systemic beta blocker therapy.[47] Medication side effects are uncommon but include bronchospasm, bradycardia, hypotension, hypoglycemia, seizures, and hyperkalemia. Risk of an adverse event is higher in preterm infants and children younger than 3 months of age. The cardiovascular, respiratory, electrolyte, and glucose effects of beta blockers need to be monitored, especially in premature infants or young children and those with airway disease.[48] Introduction of this medication in an inpatient setting is rarely required. Relative contraindications to propranolol include infants or children with reactive airway or congenital heart disease, or glucose abnormalities. Treatment should be on an individual basis. When there is concern about intracerebral abnormalities, such as in PHACE syndrome, guidance by a pediatric neurologist is helpful.[47,49]

If systemic beta-blocker or steroid therapy proves ineffective, third line systemic drugs such as interferon or vincristine are considerations but are rarely, if ever, used. These medications have a high risk of side effects; interferon is not recommended in children younger than 1 year of age because of the risk of neurologic problems such as spastic diplegia.[1,5,15]

Embolization is considered for large high-flow IHs that cause congestive heart failure, such as multifocal or diffuse hepatic hemangiomas that have macrovascular shunts, particularly when

Figure 188.6 Images of ulcerative infantile hemangioma on the neck (A) and upper back (B).

there is little or only partial response to systemic beta-blocker therapy. The goal of embolization is to provide prompt control of heart failure as the therapeutic benefits of systemic agents accrue. This treatment has little or no role in hepatic hemangioma without heart failure. Drug therapy is used post embolization until the child is approximately 1 year of age, when involution generally begins.

Pulsed dye laser therapy is primarily used to treat residual telangiectasia post involution but can also be used to treat areas of ulceration in lesions slow to respond to other treatments. Carbon dioxide laser has been used to treat subglottic hemangioma during the proliferative phase as drug treatment is initiated.[50,51-53]

Excision of proliferating lesions is rarely indicated, given the success of pharmacotherapy.[1,15] The tumor is highly vascular, so there is a risk blood loss. Anesthetic complications, scarring, and cosmesis in infants must be considered. A well-localized or pedunculated, ulcerated, or bleeding lesion may be excised if the resulting scar is esthetically placed and no worse than would be predicted if excision is done after involution is in process or complete. The ideal time for operative intervention is between 3 and 4 years of age. At this age the tumor is smaller and less vascular and it will no longer involute. In general, the deformity improves with time, which makes long-term memory of the procedure and self-esteem issues less likely.[1,15,20]

Circular hemangiomas with residual fibrofatty tissue or excess skin are best managed with circular excision and purse-string closure.[54] The resultant scar can be revised 6 to 12 months later and closed linearly. This technique reduces the length of the linear scar relative to the initial diameter of the hemangioma. Initial linear excision of a circular hemangioma generates a scar nearly 3 times the diameter of the tumor.

Congenital Hemangiomas

Most CHs are managed initially by observation. A rapidly involuting congenital hemangioma (RICH) is regressed by 1 year of age. Reconstruction with dermal, fat, or acellular dermis grafts is considered for atrophic scarring, best done before 4 years of age. Rarely, large lesions that cause high-output cardiac failure are treated by embolization or excision. Noninvoluting congenital hemangioma (NICH) is a stable lesion and does not respond to pharmacologic treatment. These lesions usually require resection.[1]

Kaposiform Hemangioendothelioma

Treatment depends on size of the KHE and presence of KMP. Patients without KMP are treated to minimize fibrosis, chronic pain, stiffness, and contractures. Surgical resection is applicable to small, localized lesions. However, these tumors are often large and infiltrative and involve multiple tissues, thereby preventing complete excision. Complete blood counts and coagulation factors need to be monitored to identify development of KMP. In the neonatal period, these blood tests are drawn at baseline and then approximately weekly thereafter in the stable infant, with gradual lengthening between blood draws. In those with KMP, blood tests are done more frequently, as indicated by the patient progress. If the KHE becomes larger, firmer, or more painful at any point during therapy, blood tests should be checked

emergently because this may be the harbinger of consumptive coagulopathy. The primary role for medical therapy is to treat KMP. Systemic therapy for KHE is used to prevent life-threatening complications in children with unresectable tumors or KMP. Corticosteroids are often started initially to stabilize patients with KMP, at doses of approximately 2 mg/kg per day followed by a taper. Other systemic therapy may include vincristine or interferon. Response to vincristine is seen in 90% of cases, interferon treatment in 50%, and corticosteroids in 10%.[55] Intravenous vincristine is dosed at 0.05 mg/kg weekly and continued for approximately 6 months until thrombocytopenic or coagulopathic problems resolve. The use of sirolimus has shown good efficacy in cases of KMP, and many experts favor this medication over vincristine because of its efficacy and the efficiency in treatment. The role of sirolimus is currently under study in a clinical trial.[56,57] Platelet transfusion should be avoided unless there is active bleeding or a surgical procedure is necessary. Transfused platelets may be trapped in the lesion and cause pain and swelling.[34] Improvement in KMP is an accepted biomarker of treatment response.

Pyogenic Granuloma

Pyogenic granuloma has been treated by curettage, electrocauterization, shave excision, laser therapy, or full-thickness excision. Of these, the most common treatment is shave excision followed by cautery. Incomplete treatment is fraught with regrowth of the lesion.[40,58] Topical beta blockers have been used to treat facial lesions in children.[59]

SECONDARY TUMORS

Full review of the types, diagnosis, imaging studies, and management strategies for infants or children with secondary tumors that may have vascular involvement is beyond the scope of this chapter. The general precepts of management, including multidisciplinary assessment, are similar to those in Chapter 194. In short, tumor type, location, and extent influence therapy and surgical approach. Even though segmental resection and replacement of major arteries and veins is uncommon, proximal and distal vascular control is important, should vessel injury and bleeding occur in the course of dissection. Autogenous patches or conduits are preferred, except in some cases of aortic or caval replacement. Interrupted sutures are necessary when an interposition or bypass graft is placed, to accommodate growth of the child. If visceral, renal, or supraaortic trunk grafts are necessary, hypogastric artery is generally preferred over saphenous vein because of long-term aneurysmal degeneration in the latter. This caveat is similar to how pediatric aortic branch vessel reconstructions are done for occlusive or aneurysmal disease. Figs. 188.7 and 188.8 highlight illustrative cases in which vascular surgeon involvement was needed.

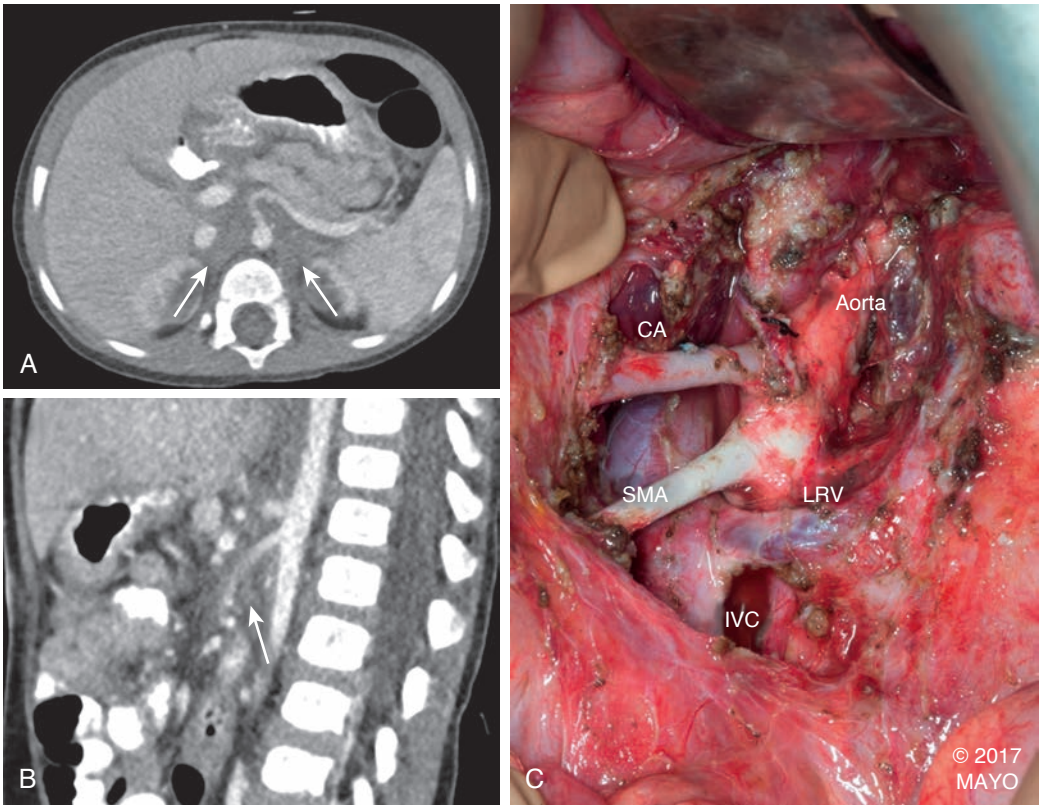

Figure 188.7 Infant with a neuroblastoma surrounding the paravisceral aorta, celiac, superior mesenteric, and left renal arteries and left renal vein, as shown by the *arrows* on axial and coronal CT images (A and B). The tumor could be separated from the aorta, branch arteries, and renal vein (C). *CA,* Celiac artery; *CT,* computed tomography; *IVC,* inferior vena cava; *LRV,* left renal vein; *SMA,* superior mesenteric artery.

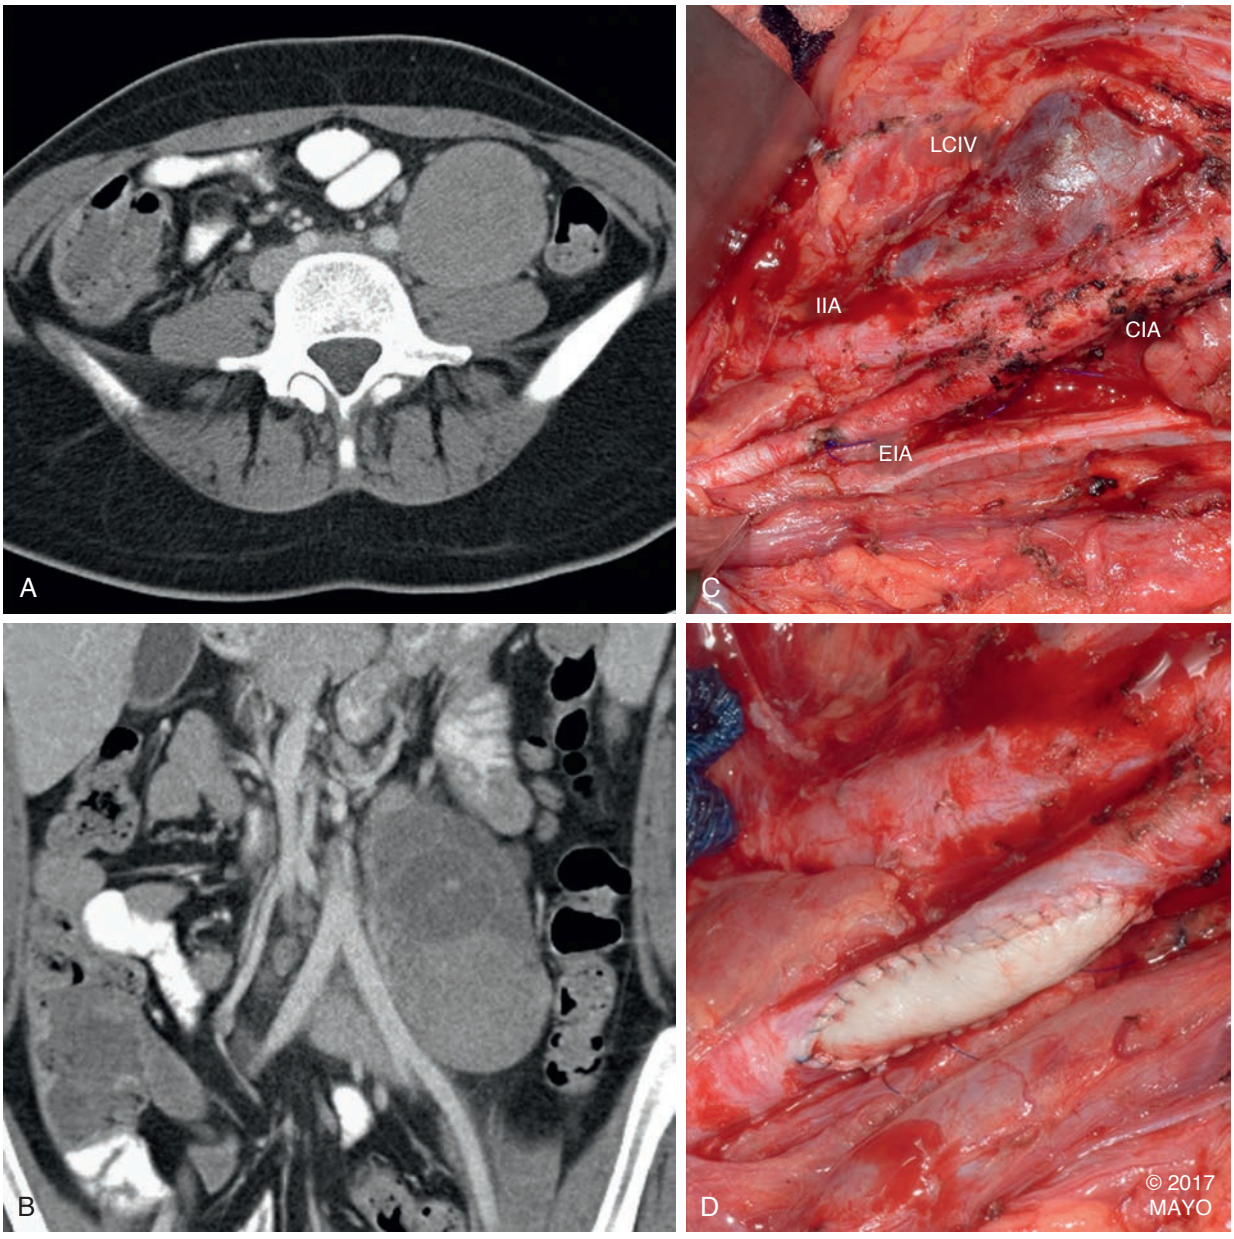

Figure 188.8 Large, lobulated left pelvic neuroblastoma abutting iliac vessels as shown on axial (A) and coronal (B) CT images. The tumor was resected but was adherent to the external iliac artery, which required a bovine patch for reconstruction (C and D). *CIA,* Common iliac artery; *CT,* computed tomography; *EIA,* external iliac artery; *IIA,* internal iliac artery; *LCIV,* left common iliac vein.

INTRODUCTION

Pediatric trauma is the leading cause of death in children older than one year in the United States.[1] Although vascular injuries are infrequent, occurring in in 0.6% to 1% of trauma patients,[2,3] they constitute an important cause of mortality after trauma. Efforts to curb death and morbidity after automobile accidents, such as wearing seat belts and using car seats, have reduced mortality rates in this patient population, but has not significantly changed the *rate* of vascular injuries.[3,4] Overall, the most common cause of pediatric vascular injury is iatrogenic injury after peripheral interventions. Outside of the United States and Europe, warfare which does not discriminate civilians from combatants has also resulted in significant vascular injuries among noncombatants many of whom are, unfortunately, young children.[5,6]

The spectrum of treatment choices for vascular injuries includes expectant therapy, vessel ligation, direct vessel repair, or interposition graft repair. In adult patients, both endovascular and open vascular options are available. It is difficult to standardize the management of pediatric patients with vascular injuries due to a diverse set of factors. First, these vascular injuries are rare, occurring in less than 0.6% of pediatric patients who present with trauma.[2] Additionally, many different specialties participate in repair of these injuries ranging from pediatric surgeons, adult trauma and/or vascular surgeons, orthopedic surgeons, neurosurgeons to plastic surgeons.[3] Each specialty brings their unique perspective and background in how to deal with these injuries which makes arriving at a consensus difficult. Furthermore, pediatric vascular injuries are far more technically challenging to treat and this adds significant complexity to the choice of treatment for these injuries. The unique issues with these patients include size (diameter) of the injured vessel, spasticity of young vessels, and the choice of treatment must accommodate ongoing axial growth in this pediatric population. It is possible to apply the same principles and techniques of adult trauma to the older child but the younger child may require different approaches. In pediatric patients with vascular injuries, historically, definitive arterial reconstruction has not always been the preferred management approach. Ligation or expectant therapy (systemic heparin without repair) was the most common choice of treatment. Adverse outcomes, such as loss of axial growth leading to debilitating gait disturbances, limb overgrowth due to traumatic arteriovenous fistula (AVF), and amputation have prompted calls for a more aggressive approach in management of pediatric extremity vascular injuries.[2]

This chapter is structured to describe the multiple components associated with pediatric vascular injuries including epidemiology, diagnosis, treatment, and outcomes of these injuries.

EPIDEMIOLOGY

The reported incidence of any vascular injury among patients younger than 16 years is 0.6% in the US National Trauma Data bank.[2] This, however, does not account for iatrogenic injuries that are sustained during instrumentation for vascular or cardiac procedures. Although the exact prevalence of iatrogenic injuries is unknown, since these occur during hospitalization for admissions other than trauma, few case series have evaluated their experience with these type of injuries.[7-9] In tertiary pediatric hospitals, iatrogenic vascular injuries range from 33%[8] to 100%[7] of an institution's experience with pediatric vascular trauma. These penetrating vascular injuries can occur from misadventures during intravenous (IV) insertion, arterial puncture for blood gas analysis, transfemoral diagnostic or intervention procedures, umbilical artery catheterization or during surgery (e.g., during cardiopulmonary bypass operations or during orthopedic procedures). It is *estimated* that half of pediatric vascular injuries across all ages are iatrogenic penetrating injuries. The prevalence of iatrogenic injuries decreases with advancing age.[10] Neonates have the highest frequency of iatrogenic vascular injuries which then declines in the 2- to 6-year-old range (50% iatrogenic), followed by those children over 6 (33% iatrogenic).[11] Lin and colleagues identified four factors in their series of patients with iatrogenic injuries that were associated with increased risk of iatrogenic femoral complications.[10] These factors included age younger than 3, type of therapeutic intervention, ≥3 earlier catheterizations and the use of a 6F or larger guiding catheter.[10] Even with heparinization and use of appropriately sized catheters, the thrombosis rate ranges from 1% to 25%.[10,12] Both artery and vein accessed can be thrombosed after intervention. In a report of neonatal injuries after instrumentation, for example, two of seven patients presented with phlegmasia cerulea dolens who were interestingly successfully treated by leech therapy.[13]

Other causes of vascular trauma become more prevalent as a child's age increases and as noted above more than 2/3 of vascular injuries in children over the age of 6 are due to non-iatrogenic causes.[14] Mechanism of pediatric vascular injuries differs in and out of war zones. In review of National Trauma Data Bank, Barmpares et al. noted that the most common cause of trauma in children was motor vehicle accidents (24.3%).[2] Other causes of trauma included firearm injuries (19.6%), stab wounds (16.6%), and falls (11.8%).[2] Blunt injuries constituted the majority (57.7%) of injuries in this study of the US national trauma registry[2] which was similar to a Swedish registry data.[4] In most large contemporary single institution studies, penetrating causes were the most frequent causes of vascular injuries in children over 6 years of age.[3,9,15,16] It is observed that pediatric patients with blunt injury had an overall higher injury severity score than those presenting with penetrating injuries.[9] Needless to say in areas of the world in which children are exposed to warfare, these unfortunate children are more prone to sustain penetrating vascular injuries due to high-energy gunshot wounds and IEDs with complex wounds and combined bony and tissues injuries.[5]

Anatomic location of injuries is somewhat predicated on the mechanism of injury. Overall, however, the most common site of noniatrogenic vascular injuries in pediatric population is upper extremity vessels.[2,3,5,9,11,15,16] Penetrating upper extremity injuries are significantly more common than the truncal vessels, which include abdominal, thoracic, and cervical vessels. Among patients with blunt mechanism of injury, upper extremity vessel injuries constitutes a third of vascular injuries often combined with an orthopedic trauma.[2] In patients with noniatrogenic injuries, penetrating injuries are significantly more common in the vessels of the upper extremity than other vessels.[2,3,5,9,11,15,16] Truncal injuries however carry the highest mortality rates, in excess of 50%.[17,18] Most of these patients sustain concomitant significant organ injuries[17] and these patients have significantly higher injury severity scores (ISS) than patients with other injuries (e.g., 45.4 ± 19.8 vs. all injured patients 12.3 ± 11.7 in one study[9]). Truncal injuries significantly increase the odds of mortality independent of all other confounders.[9]

It should be noted that venous injuries are less common than arterial injuries and more difficult to diagnose in pediatric population. Combined arterial and venous injuries also significantly increase the odds of mortality. In most contemporary studies of pediatric vascular injuries, the most common site of observed venous injury was IVC[2,9,19] followed by other truncal vessels such a cervical veins,[17] portal veins,[20] and iliac veins.[18] The most commonly injured extremity vein is the femoral vein.[19] In one study of injuries to the truncal vessels, Hamner et al., noted a mortality rate of 67% among patients with IVC injury[20] making these injuries significantly morbid.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Anatomical landmarks used to access arteries and veins in adults for insertion of large-bore IV catheters or arterial access are not as helpful in children, and this is one of the major contributing factors to iatrogenic injuries in children. In children, for example, there are reports of 12%[21] to 33%[22] minor overlap of femoral vein and artery which can lead to inadvertent arterial injury during venous access obtained without ultrasound guidance. Use of ultrasound during peripheral intervention has shown to significantly decrease complications after interventional procedures in adults,[23] but the effects of routine use of ultrasound on preventing these injuries among pediatric population merit further exploration.

Another significant contributor to the iatrogenic injuries is the size of vessels used for pediatric interventions. Using ultrasound, Warkentine et al., showed a significant correlation between size of the femoral artery and child's weight and body surface area.[21] In a large study of pediatric patients undergoing cardiac catheterization, the authors developed a risk scoring system for the prediction of serious adverse events (SAE) among these pediatric patients.[24] In this model, age <30 days and weight <2.5 kg, and procedures that required endovascular intervention (i.e., required larger sheaths) were highly predictive of SAEs that included vascular injuries.[24] These findings correlate well with the observation by Lin et al. noting a high correlation of vascular injuries with the use of larger (>6F) sheath.[10] The

effects of sheath size and complications afterward in pediatric population may be due to significant spasm encountered in these arteries after catheterization. In an older study, Mortensen has demonstrated complete arterial occlusion due to arterial spasm around a catheter in children.[25] It was observed by Franken and colleagues that size of catheter in relationship to the size of artery can significantly affect arterial spasm.[26] Franken and colleagues observed that when either catheter diameter was greater than 50% of arterial diameter or when catheter diameter was less than 1.9 mm smaller than arterial diameter significant spasm was observed.[26] The smaller size of pediatric vessels and highly spastic nature of these vessels can lead to spontaneous thrombosis and severe persistent vasospasm that may last for hours.[26] Other physiologic factors that contribute to arterial thrombosis in this patient population are related to the low intravascular volume and other medical conditions that exist in these children. Children requiring cardiac catheterization often suffer from low cardiac output that can also exacerbate thrombosis by relatively low flow to the distal tissue beds.

Iatrogenic and traumatic vascular injuries may lead to disruption, obstruction, or spasm of injured vessels. Obstruction of the vessel will lead to occlusion of the vessel and downstream ischemic symptoms that require urgent attention and restoration of flow. When vasospasm is suspected, conservative therapy after removal of the offending agents (e.g., a catheter) may be adequate to alleviate vasospasm and restore arterial flow. One of the most common pediatric vascular injuries is blunt brachial artery injury after supracondylar fracture. Arterial spasm after orthopedic injury may lead to ischemic arm after this injury. These injuries are often self-limiting and improve after orthopedic repair, and unless the arm is significantly ischemic, observation and conservative therapy may be equally effective as surgery (see later).[27] Adjuncts such as use of intra-arterial vasodilators such as papaverine may reverse spasm and restore blood flow if spasm does not improve. Warming the patients with injured lower extremity artery may also reverse arterial spasm.

Unique to vascular injuries is traumatic AVF due to iatrogenic or other traumatic causes. Since these fistulae are often asymptomatic initially, they may go undetected for years. These injuries can then lead to high-flow cardiac failure by gradual enlargement of the fistula communication and subsequent increase in demand for cardiac output. Flow disturbances due to these fistulae can lead to both high-pressure venous[28] and ischemic arterial ulcers[29] in the affected limb. Additionally, in certain cases, high flow to the affected extremity may lead to limb overgrowth. Once diagnosed, the majority of these AVFs can be ligated or coiled.

DIAGNOSTIC EVALUATION

Hard signs of vascular injury often seen in patients with penetrating vascular injuries, which include external bleeding and/or expanding hematoma, are reliable indicators of vascular injuries. When these signs are absent, the diagnosis of pediatric vascular injuries requires a high index of clinical suspicion and careful vascular examination. As noted above the majority of non-iatrogenic traumatic pediatric vascular injuries in countries at peace are due to blunt mechanisms.[2,4] Without evident hard signs of vascular injuries in many patients with blunt arterial injuries, the diagnosis of pediatric vascular injuries can be difficult and requires careful vascular exam. As in adults, examination of the affected and contralateral extremity includes skin color, capillary refill, and pulse examination even in the absence of actual vascular injuries, because, as noted previously, pediatric vessels are highly reactive and can go in spasm due to trauma leading to reduced or absent pulses. In one series of non-iatrogenic traumatic injuries, Myers and colleagues noted 26% of intraoperative spasm as the cause of low pulse exam in pediatric patients.[15] Additionally, combined orthopedic and arterial injuries, a very common occurrence in pediatric population, can lead to significant arterial spasm which can often be corrected after such injuries have stabilized.[16] It is therefore important in the multiply injured child, lacking hard signs of vascular injury, to address life-threating injuries first, resuscitate and warm the child, and then re-evaluate pulses to avoid unnecessary diagnostic tests and possible operative intervention.

In the absence of hard signs of vascular injury, serial exams using continuous wave hand-held Doppler can be an effective tool. Doppler can be used to listen to the pulse if it is absent but more importantly it can be used to measure ankle brachial index (ABI) in the injured extremity. Doppler can also be used for measurement of the injured extremity index (IEI), which similar to ABI, allows for the Doppler occlusion of an injured limb compared to a noninjured extremity. Katz and colleagues showed that ABI in children younger than 2 is not as reliable as in older children.[30] These authors observed that ABI is less than 1.0 until child is above 25 months of age or has attained a body surface area of greater than 0.5 m^2.[30] For this reason, Cannon et al. recommend using IEI in children instead of ABI and recommend strong consideration of poor perfusion as due to vascular injuries or systemic causes when IEI is less than 0.9 in children older than 2 and less than 0.88 in children 2 and under.[11] No direct comparisons of these two measurements are made in any study, but given the limitations of ABI in children younger than 2, IEI seems be a more accurate objective test of ischemia due to injury. Pulse oximetry has also been shown to be effective in following patients with arterial injury, for example, in those who have blunt brachial injury due to supracondylar fracture.[31] Regardless of the technique used, if resuscitation, warming, and correction of bony injuries does not correct the malperfusion of an injured limb, diagnostic tests should be used to identify the location and severity of the arterial injury.

Duplex ultrasound can identify the location and severity of these injuries in children suspected of vascular injuries. The specificity and sensitivity of arterial Duplex have been shown in many studies. It is suggested that Duplex can be the first investigation study in evaluating arteries and able to detect arterial injuries.[32] Duplex can also be highly useful in detection of cervical carotid injuries, but it cannot assess other more proximal or cephalad truncal injuries. Computed tomography (CT) angiogram (CTA) has been shown to be a very reliable study for detection of blunt truncal injuries, such as when a child has signs of direct trauma to neck, chest, or abdomen such as the seat belt sign.[33] CTA is often employed in patients

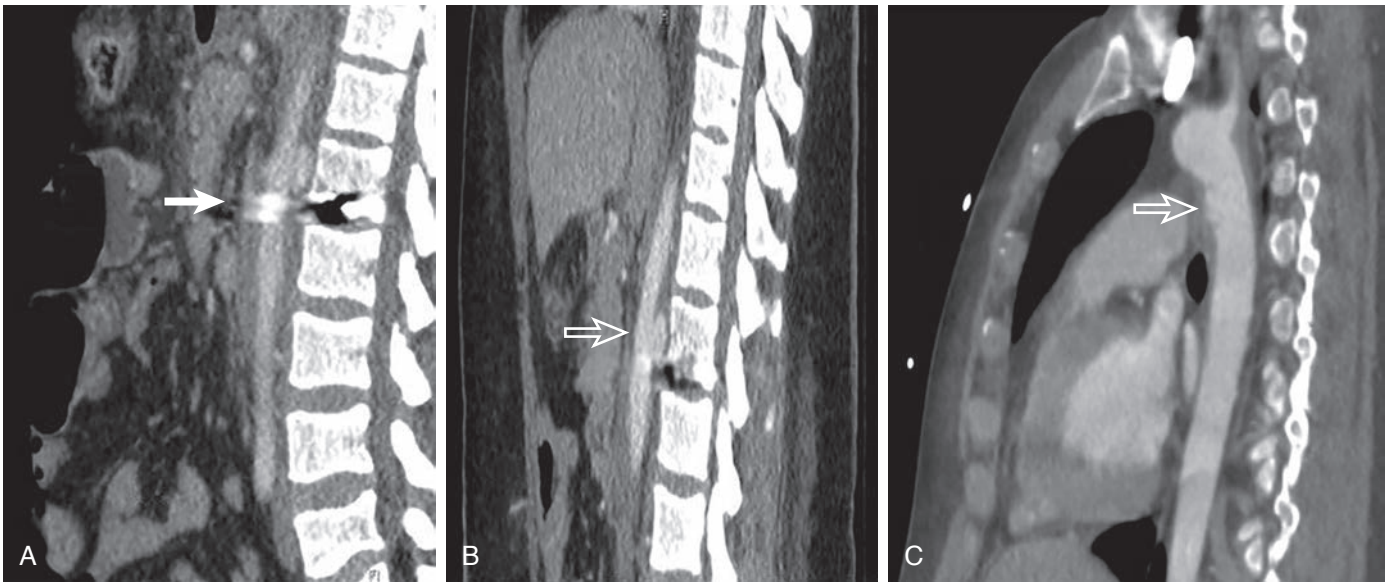

Figure 189.1 Utilization of CTA in detecting arterial truncal injuries; A and B are CTA of a 17 year-old-male shot through abdomen (*solid arrow* points bullet trajectory whereas *hollow arrow* points to aortic pseudoaneurysm due to heat/blast injury). (This was not appreciated during abdominal exploration.) (C) A thoracic aorta injury in a 16 year-old-male involved in a motor vehicle accident.

with multiple injuries and can often detect occult truncal injuries that were missed during physical exam or not appreciated due to the location of the injury (Fig. 189.1). CTA is not as useful in the detection of extremity arterial injuries in children. In such cases angiography may be indicated, while appreciating the significant risks of angiography in young children. Angiography is very useful in identifying the location of arterial injury and in distinguishing arterial injury from vasospasm. If diagnostic tests are not conclusive, in the setting of limb hypoperfusion, exploration of the suspected artery is indicated regardless of patient's age and size.

MANAGEMENT OF PEDIATRIC VASCULAR INJURIES

As noted previously many tenets of adult vascular trauma are applicable to pediatric patients. Similar to adult vascular trauma, the principles of care related to vascular injury include exposure of injured vessel, control of hemorrhage, and restoration of blood flow to the end organ. In that regard, several adjuncts in adult vascular trauma can be translated to the pediatric patients with vascular injuries. These include the following:

1. *Use of Temporary Vascular Shunts*—This adjunct has been quite useful in adult trauma by reducing the ischemia time and possible consequences of ischemia (e.g., nerve injury, muscle loss, compartment syndrome) while other injuries are treated. As with adult patients, a shunt should be inserted, after distal embolectomy and infusion of heparinized saline in the distal artery. Argyle shunts used for carotid surgery or a pediatric feeding tube can be used as a shunt in these smaller vessels.
2. *Role of Heparin*—Heparin is used extensively in adult vascular trauma provided there is no other contraindication to its use—such as excessive bleeding from poly-trauma or documented allergy to heparin. Heparin mediates platelet aggregation and decreases the propagation of formed thrombosis and may reduce formation of thrombosis in a narrowed spastic artery. The same principle applies to pediatric patients who should receive systemic heparin if there is no contraindication to its use. Temporary use of systemic heparin may also be used in cases of pediatric vascular injury where vasospasm has been a complicating factor, reducing distal outflow.
3. *Nonoperative management of arterial injuries*—In adults, minimal arterial disruption observed in patients with arterial injury is often managed nonoperatively. This may be the case of both blunt and minor penetrating vascular injuries identified during the work-up for vascular injury with CTA, angiogram, or Duplex. Similar to adults, if the distal circulation is intact, and the injury is minor (i.e., minimal vessel wall and intimal disruption or no active bleeding), the injured child can be observed. The basis of this practice is the observation by Stain and colleagues that these intimal injuries healed without any intervention during the follow up in adult patients.[34] Extrapolating from adult literature, it is reasonable to observe minor arterial injuries provided that there is intact distal circulation and the child can be observed carefully and monitored by follow-up imaging studies.

Lower Extremity Arterial Injuries

Historically, early exploration of pediatric vascular injuries was avoided unless there was an evidence of ongoing exsanguinating bleeding. However, poor long-term outcomes from

this conservative therapy strategy have led to more aggressive approaches with some recommending exploration even in the setting of vasospasm.[10] Although this approach may not be appropriate in all cases,[27] the consequences of delayed exploration and revascularization compel many surgeons to intervene and explore early to avoid these consequences. Operative management of the injured vessel in children is challenging as the vessels are spastic and small, and any repair must take into consideration the need for future axial and radial growth of blood vessels as well as the long-term patency of vascular repairs.[35] Management of the injured vessel should be coordinated with the other providers and should not jeopardize the injured children's survival. Management of pediatric vascular injuries should follow some of the basic tenets of adult vascular injuries. These include early diagnosis, definitive vascular repair or reconstruction, systemic heparinization, use of intravascular temporary shunts, use of embolectomy catheters, liberal use of fasciotomies and use of endovascular techniques to temporize bleeding (i.e., proximal balloon occlusion) or reestablish flow to the injured extremity if injured vessel size can accommodate endovascular options.

Management of Iatrogenic Vascular Injuries

Iatrogenic injuries may lead to complete or partial occlusion of an injured vessel. When this injury leads to complete occlusion, limb hypoperfusion can quickly set in with devastating circumstances. As noted previously, the conservative management of these injuries may lead to devastating long-term consequences perhaps due to the short "ischemic threshold" time beyond which limb quality deteriorates rapidly as shown in animal models.[36] In cases of arterial occlusion, arterial exploration, embolectomy, and patch angioplasty will lead to acceptable outcomes even in children younger than 2 years of age.[10]

If iatrogenic injury has not caused complete arterial occlusion, definitive repair can be delayed as long as the limb is well perfused. Small flaps and dissection often can be followed by serial exam and systemic heparinization to avoid arterial thrombosis. These patients must be monitored carefully and operated upon if the limb perfusion deteriorates. Interval repair of such injuries may also lead to acceptable outcomes,[10,12] but immediate restoration of perfusion should the gold standard.

Extracorporeal membrane oxygenation (ECMO) cannulation is a common cause of iatrogenic pediatric vascular injuries in tertiary pediatric centers.[37,38] These injuries that occur in about 20% to 52% of ECMO patients[38,39] can affect either femoral or carotid cannulation site.[37-39] Carotid injuries have shown to lead to cognitive disabilities which can be avoided by carotid repair after ECMO, and this has led centers to perform routine carotid reconstruction after ECMO, with good patency and neurologic outcomes.[37]

Management of Noniatrogenic Injuries

Management of noniatrogenic injuries is dependent on the location and mechanism of the injury. As noted previously the majority of vascular injuries after the age of 6 is related to noniatrogenic causes.[14] The epidemiology of these injuries was previously discussed.

Penetrating trauma to vascular injury requires immediate attention to temper blood loss and repair injured vessels in an attempt to save life and limb. High-energy penetrating blast injuries in urban warfare or war zone areas may require extensive soft tissue debridement, use of vascular shunts, and liberal use of fasciotomy while other injuries are addressed using a multispecialty approach to these injures as reported by Peck and colleagues.[40] The successful experience by these surgeons operating in Iraq and Afghanistan and reporting of 12 unfortunate children who sustained combat related injuries,[40] lends significant support to the philosophy of early diagnosis and operative management of vascular injuries in children.

The tenets of arterial repair, applicable to adult arterial injury, apply to children with the special consideration that children's vessels are smaller, spastic and any repair or interposition graft must accommodate the axial growth of the injured vessel and limb. Similar to adult injuries, if the injury is confined to a short segment of the arterial wall, primary repair of the injured artery with interrupted nonabsorbable polypropylene sutures is the procedure of choice. Patch angioplasty may be required in cases where simple repair is not possible due to lateral wall injuries. This type of repair avoids luminal growth issues at the anastomosis site and has been used with good success in low-velocity penetrating injuries and blunt injuries.[3,41] Patch angioplasty can be safely performed with a segment of noninjured greater saphenous vein (GSV).

Special considerations should be given to cases where interposition graft is required in children. The issues to consider are details pertinent to techniques of anastomosis creation, choice of suture material, and the type of conduit to accommodate the axial growth in children and avoid luminal narrowing at the anastomosis site. Since there is a need for these arteries to grow both axial and radial, the running-type suture technique commonly used in adults may not be ideal in pediatric population (Fig. 189.2). This type of suturing technique, in theory, may cause purse-string narrowing of the anastomosis and may hinder the radial expansion of the artery at the site of anastomosis. This has prompted some authors to recommend interrupted sutures instead of running sutures in pediatric patients.[42]

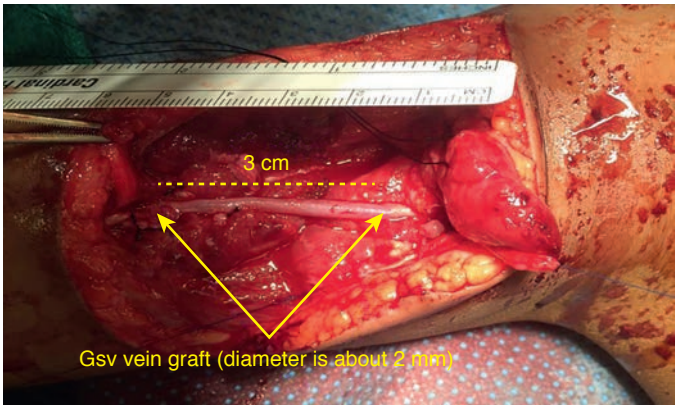

Figure 189.2 Penetrating injury to proximal brachial artery in a 7 YOM. Repaired with an interposition graft using grater saphenous and interrupted 8-0 prolene. (Courtesy of Dr. John Eidt.)

Although there are no comparative studies in pediatric patients comparing the types of anastomosis among pediatric patients, in animal studies, the use of running-type anastomoses has been shown to cause arterial narrowing in growing pigs at the site of anastomosis.[43] These authors also noted that nonabsorbable sutures were less thrombogenic than absorbable sutures.[43] These observations suggest that interrupted nonabsorbable sutures on a beveled anastomosis further enlarges the anastomotic connection between conduit and artery, may be the best method of arterial reconstruction in pediatric patients. The GSV has shown to be a durable conduit among children who underwent vascular reconstruction.[44] Therefore similar to adult trauma patients, the contralateral GSV should be the conduit of choice if an interposition graft is needed. This conduit should be preferentially used when there is high blast injury to the artery, which requires debridement of artery and the surrounding tissues to provide a clean and tension-free repair. In children, these types of injuries are often encountered in combat zones and invariably are associated with other injuries. In the setting of other injuries, a shunt can be used while complex neurologic and bony fractures are addressed.[40] It should be noted that dog bites in pediatric population could also present with both blunt and penetrating vascular injuries.[45] These devastating injuries, similar to high blast injuries, require significant tissue debridement and arterial injuries often with interposition graft.[46]

Early and liberal use of lower extremity four-compartment fasciotomy in patients with lower extremity ischemia has shown to decrease limb-related adverse outcomes.[47] This is universally practiced in wartime extremity injuries and is well described in the civilian pediatric literature.[3] This should be practiced in pediatric patients with lower extremity ischemia to improve the quality of limb salvage.

Special Case of Noniatrogenic Arterial Injuries—Blunt Brachial Artery Injury

Combined arterial and orthopedic injuries require a team approach. The majority of arterial injuries are improved once the orthopedic fracture is reduced. Blunt brachial artery injury is a common site of pediatric arterial injury where an orthopedic injury compromises the brachial artery. It occurs in the setting of a fall onto an outstretched hand and can be associated with neurovascular injury. Blunt brachial artery is the most common type of injury in a recent publication from Sweden[4] and is reported in 10% of children with supracondylar fracture[48] with potentially devastating consequences of upper extremity amputation and Volkman ischemic contracture. Stretch injuries to the artery, which can disrupt the vessel intima or impingement of the vessel by surrounding tissue, are the usual causes of this (Fig. 189.3). The presentation can range from normal to pulseless pink hand (PPH) to severe ischemia. After the orthopedic injury is corrected, pulses may return, obviating any necessity of intervention on the brachial artery. In patients with no pulse and evidence of ischemia after orthopedic reduction, the brachial artery must be explored and repaired in situ after thromboembolectomy or interposition graft with proximal GSV. Controversy exists about the best course of therapy among patients with PPH. Traditionally, PPH was managed expectantly with anticoagulation and serial exam of the hand that appeared well perfused (pink) and arterial exploration considered *only* if the patient developed neurologic signs of ischemia.[49] Other authors recommend arterial exploration for *every* case of PPH.[50] Although no prospective randomized trial exists, we suggest that there may be equipoise between observation and exploration for patients who present with isolated blunt brachial artery injury

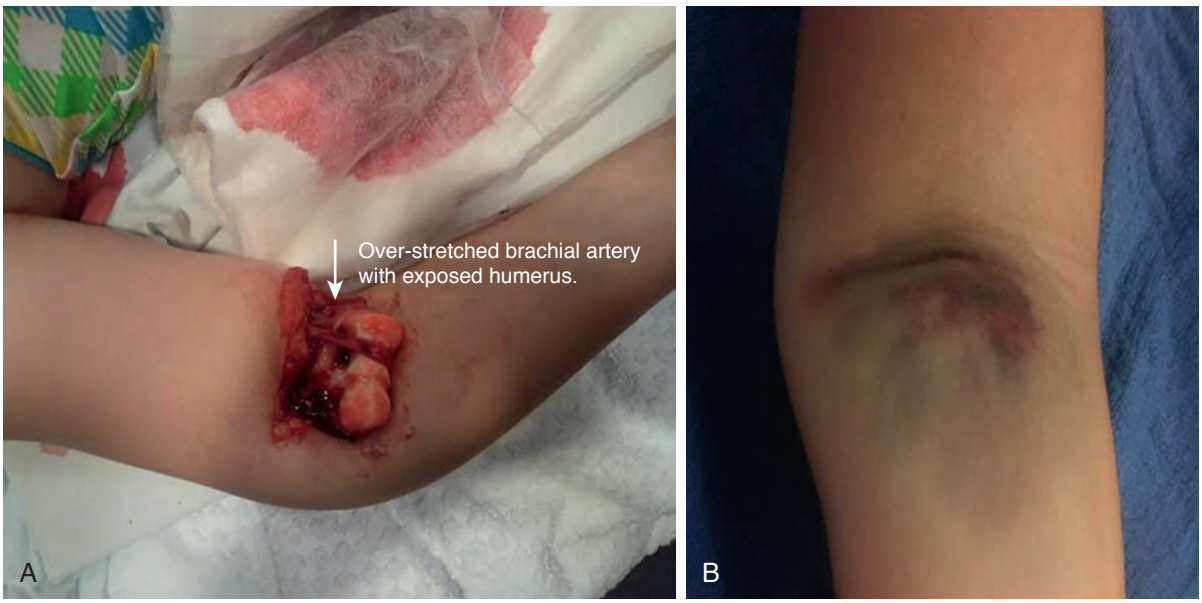

Figure 189.3 A common orthopedic injury is supracondylar fracture. Both of these patients presented with pulseless pink hand. Both improved after orthopedic repair. But patient in B required vascular exploration, embolectomy, and patch repair. (Courtesy of Dr. Timothy Ward, Dept. of Orthopedics, UPMC, Pittsburgh, PA.)

using a large administrative database.[27] This study was somewhat limited, however, being a retrospective analysis of an administrative database, and much clinical information beyond the index admission was not available.[27] Regardless of our findings in this publication, it is strong belief of this author that until level I prospective studies confirm that nonoperative management of pink pulseless hand does not affect long term limb function, a stable patient with PPH should be explored to evaluate the artery and repair the vessel as needed. Lack of pulses after orthopedic repair should therefore prompt exploration of the brachial artery and restitution of pulses with arterial repair or interposition graft.

Truncal Vascular Injuries

Similar to the adult, the injuries to the truncal vessels in children are life threatening and require immediate attention. The overall mortality rates of vascular injuries in US children is about 13% using NTDB.[2] These rates are significantly higher among patients with truncal arterial injuries.[2] Barmparas et al. observed a 16% to 41% mortality rate for truncal vessels: neck 16%, chest 41%, abdomen 25%.[2] In a large trauma center, Corneille et al. observed that *all* cases of mortality out of 116 children with significant vascular trauma were due to truncal arterial injuries.[9] The most important predictor of outcome in pediatric patients with truncal injuries is hemodynamics at the time of presentation with other factors affecting survival including caval injuries, anatomic location of the injury, and the mechanism of injury.[17] Unlike adult patients, blunt injury to the aorta is uncommon in pediatric population and, as this is typically accompanied with a variety of other injuries, is universally incompatible with survival.[17] In injured pediatric patients, due to the small diameter of injured arteries, endovascular options, commonly employed in adults with great success, are very limited.

These injuries can often be diagnosed with high resolution CTA without any need for angiography.[17] Most cases of pediatric thoracic aortic injuries and great vessel trauma are managed with open surgery. Thoracic aortic injuries are treated with clamp-and-sew technique without any significant adverse neurologic outcomes.[17,18,51] Although among patients with severe truncal artery injuries who present in shock outcomes are extremely poor, using this clamp and sew technique Allison et al. reported survival rates of 81% to 92% among patients who were hemodynamically stable at presentation with *no* paraplegia.[17] Similar to adults with blunt thoracic aorta, delayed repair with early initiation of beta-blocker therapy has shown a survival benefits to patients.[52] Smaller diameter thoracic stents can be used in some adolescent children with blunt thoracic artery injuries,[53] but long term results are lacking and should be used only cautiously (Fig. 189.4).

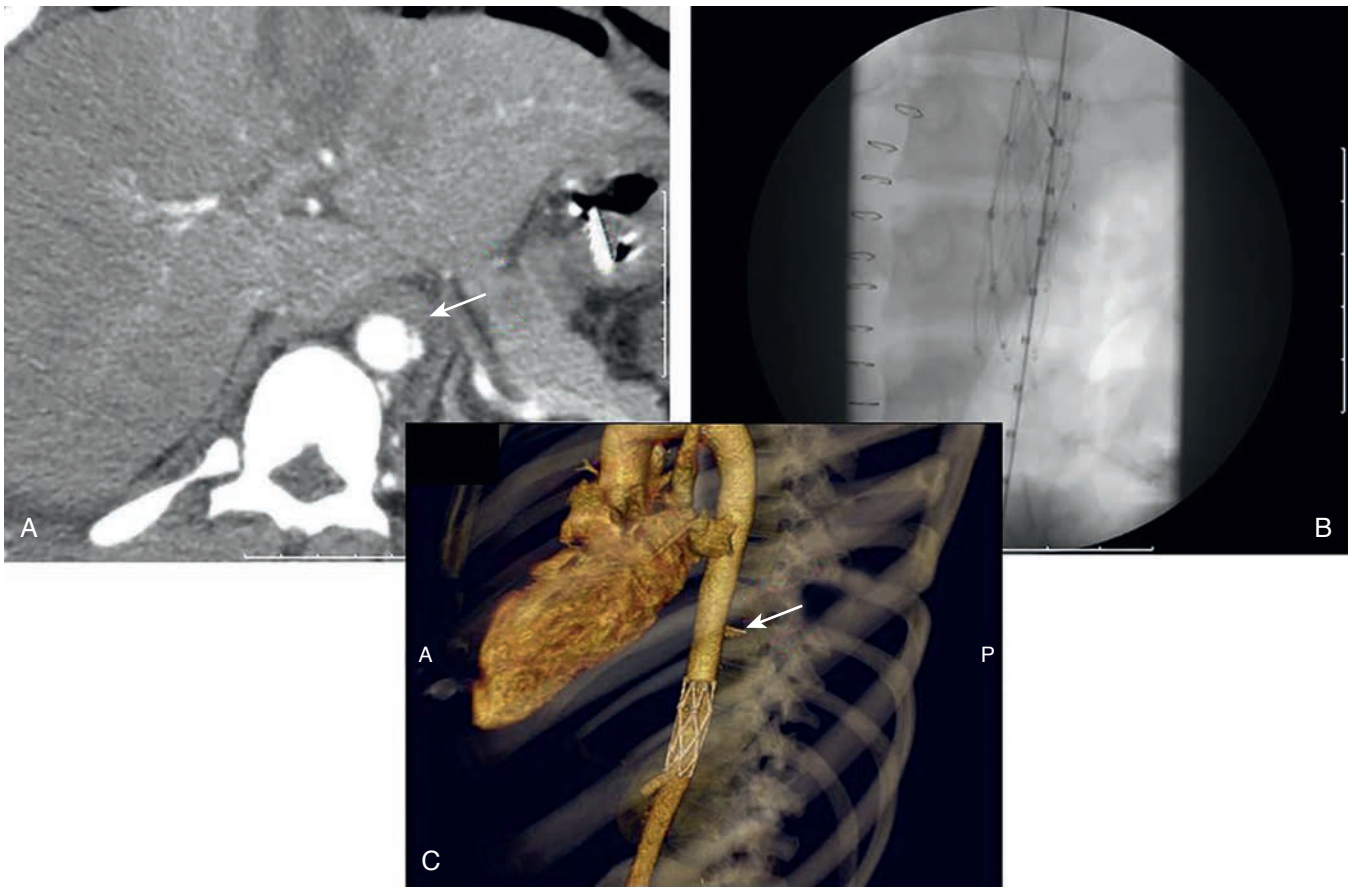

Figure 189.4 Endovascular repair of GSW to distal. (A) Thoracic aorta in a 14 YOM *(arrow)*. (B) This was successfully repaired. A few months later, follow up CT shows that the stent has migrated and covered celiac access (C, *arrow points* to the initial location of stent). (Courtesy of Dr. John Eidt.)

Management of abdominal vascular injuries is dictated by hemodynamic stability and the severity of associated injuries and thus ranges from suture repair of injured vessels to interposition replacement with a synthetic graft for aortic and caval injuries and use of GSV or hypogastric arteries for other intra-abdominal vascular injuries.

Mechanism of injury and anatomical location dictates the appropriate repair of cervical injuries. For lesions due to a penetrating mechanism and located in the anatomically accessible lesions (zone II), simple repair or interposition graft of injured vessel is possible. More proximal injuries (zone I) with penetrating injuries may require median sternotomy. More distal injuries (zone III) may be treated by ligation of the internal carotid artery or endovascular techniques (coiling or use of covered stent) if anatomically feasible to save the child's life. Blunt injuries to the carotid artery are more difficult to diagnose without a high definition CTA, but they rarely benefit from surgical intervention. These patients do worse than patients with penetrating injuries,[3] and treatment is often careful observation, antiplatelet therapy and serial imaging.[54] Injury to the innominate artery requires median sternotomy. This approach also allows exposure of the proximal right subclavian artery. The proximal left subclavian artery can be approached via left anterior lateral thoracotomy. Endovascular control of these proximal vessels with a balloon is gradually replacing the need for proximal control by these open techniques.

ROLE OF ENDOVASCULAR TECHNIQUES IN PEDIATRIC PATIENTS

As noted in the sections of iatrogenic injuries, endovascular interventions in children can be fraught with complications. The smaller vessels in children are also not suitable for large stent graft coverage. So, despite significant use of endovascular interventions for all forms of traumatic vascular injuries in adults, endovascular intervention plays a limited role in pediatric population and then, mainly in adolescents. The adolescent thoracic aorta, for example, can accommodate smaller diameter thoracic stent grafts,[53] but the majority of traumatic aortic injuries in children require open repair. Endovascular techniques can be used to control bleeding by placing a proximal balloon and therefore simplifying exposure; can also be used for embolization of inaccessible bleeding vessels (e.g., see above injuries to zone III cervical injuries); and in some cases there are reported cases of use of covered stents to manage traumatic carotid injuries in pediatric patients (Fig. 189.5).[55] Further smaller profile devices may increase the utilization of endovascular therapies in younger children in the near future.

POSTOPERATIVE MANAGEMENT AND OUTCOMES

Routine postoperative management of injured children requires collaboration with pediatric specialists who can better manage the details of care. With specific reference to traumatic vascular injuries, these patients require routine hourly vascular examination with any changes prompting immediate attention. Similar to adult trauma patients, and barring any medical contraindication, antiplatelet therapy is advisable. Although there are no clear scientific reasons for this, antiplatelet therapy may be beneficial to the injured vessel or the new anastomosis which is often devoid of endothelium and thus prone to platelet adhesion to the injured vessels. The duration of this therapy is not scientifically proven, but it appears that a short course (30 days) is adequate. Routine use of anticoagulation is not indicated and may cause bleeding, particularly in patients with polytrauma.

Other than routine pulse exam and clinical assessment, postoperative surveillance should be tailored to the vascular repair. The issues of appropriate postoperative surveillance beyond the index hospitalization and compliance of these trauma patients is multifaceted. The compliance of trauma patients for follow-up is low,[56] and since trauma care is provided with multiple services, the burden of compliance with follow-up is passed between services.[57] Additionally no clear surveillance follow-up protocol is agreed upon. Patients with thoracic aortic repair with thoracic stent should undergo annual CTA to evaluate the stented aorta until adulthood. Other than this type of injury, routine CT or CTA is not indicated. For lower extremity revascularization, simple pulse exam or IEI can detect a failing graft in the immediate postoperative period.[3] Duplex surveillance of the graft at one month postoperatively and then at routine intervals is advisable to expose early technical issues or stenosis or aneurysmal changes of the graft at later time points.

The difficulty with compliance and the low number of patients with pediatric trauma makes a discussion about long-term postoperative outcomes difficult. The discussion about long-term outcomes after pediatric vascular trauma therefore centers on retrospective case series or observational database studies. In-hospital mortality rates of these patients are reported to be 13.2%[2] with 2.4% of patients dying at the time of presentation to the emergency department based on the US National Trauma Data Bank Data.[2] In case series studies reported crude mortality rates which are similar (9.7%[9] to 12%[3] in two large case series). The highest mortality among the pediatric patients was among infants (18.2%) and of these, the highest mortality was among patients with chest vascular injuries.[2] The overall rate of in-hospital amputations was low but the highest amputation rates were observed among patients with brachial and popliteal artery injuries for upper and lower extremity injuries, respectively.[2] Lin et al., reported the long-term results of a series of 34 patients with iatrogenic injuries.[10] In this series, patients were followed for a mean follow up period of 38 months. No limb loss with surgical repair was occurred and gait disturbance was observed among the three patients who presented with chronic limb ischemia and gait disturbance.[10]

CONCLUSIONS AND FUTURE DIRECTIONS

Pediatric vascular trauma is currently managed by different groups of specialists with different training and backgrounds.

Figure 189.5 Iatrogenic injury during repair of orthopedic injury (A) that was repaired by a covered stent (B) in a 12 YOM patient with unstable patient with multi-trauma. Artery was repaired in few days—after patient improved—with an interposition graft and stent removal and evacuation of hematoma.

Klinkner and colleagues noted that vascular surgeons treated only 17% of pediatric vascular injuries.[3] Since these events are rare, there are no clear guidelines about algorithmic care of these patients. Most data reported here are based on evidence from animal studies, case series, and expert opinion. It is therefore imperative that in every institution, algorithmic care of these patients be developed by all the involved specialists and based on the best available data so all the involved specialties follow the same guidelines in taking care of these fragile patients. It is important that data for these cases be recorded in a registry dedicated to pediatric patients. The National Trauma Data Bank now collects demographic on these patients and Barmparas used this registry for a comprehensive review.[2] Ideally, collaborative efforts by vascular and trauma registries to collect data on vascular injuries, outcomes, and long-term follow-up may provide the best source of information for best quality care. Additionally, the US Military Medical Corps has been involved in many cases of pediatric vascular trauma since 2003. The information about their experience should be added to NTDB and any future vascular trauma registry to help translate their successful management techniques to the civilian pediatric population. Such a registry must also record the information about in-hospital neonatal vascular injuries and their outcomes. Given the significant advantages of the use of ultrasound among adult patients in reducing vascular injuries,[23] guidelines about use of this technology to reduce injuries in these pediatric patients should be investigated.

Despite the limitations of the data noted above, modern data emphasize aggressive operative management of vascular injuries in pediatric patients in clear contradistinction to the

historical, more conservative management approach. This approach, similar to adult vascular trauma, comprises a comprehensive team approach that includes bleeding control, vascular shunting to circumvent ischemia while other injuries are addressed, liberal use of fasciotomy for lower extremity injuries, and use of endovascular approaches as the definitive or contributive mode of treatment. Future research in the field of pediatric trauma should focus on creating endovascular approaches to both possibly mitigate the injury or ultimately treat the injury definitively. Such treatment options must accommodate the small size and expected growth of the arteries of these patients.

BACKGROUND

Pediatric end-stage renal disease (ESRD) is a challenge for caregivers, nephrologists, and surgeons. Although 25.1% of pediatric patients initiating treatment for ESRD do so with index transplantation and 18.3% initiate with peritoneal dialysis, a large majority of patients (55.8%) utilize hemodialysis (HD) as their first modality of renal replacement therapy. Currently, the National Kidney Foundation's (NKF) Kidney Disease Outcome Quality Initiative (K-DOQI) guidelines recommend placing permanent HD access in all patients aged 0 to 19 who are greater than 20 kg and are not expected to receive a kidney transplant within 1 year.[1] Thus, patients expected to be on dialysis greater than 1 year that meet the age and size criteria should receive a permanent arteriovenous fistula (AVF). Over 50% of pediatric patients who initiate ESRD treatment with HD meet these criteria; however, approximately 90% of these suitable patients commence HD treatment via central venous catheters (CVCs).

The Fistula First Breakthrough Initiative (FFBI) was established in 2003 to improve the rates of arteriovenous fistula placement for HD. Combined with the FFBI, the K-DOQI practice guidelines set a goal of 40% AVF placement for first time access patients, and this goal was exceeded by 2011 with 60% fistula use. However, the FFBI does not specifically address the low rates of fistulas in the pediatric population. To combat this problem, the International Pediatric Fistula First Initiative (IPFFI) was established in 2005 with the aim of addressing the lack of AVF use in the pediatric population.[2] The IPFFI was a collaborative effort with the Midwest Pediatric Nephrology Consortium, whose aim was to increase awareness among pediatric providers (nephrologists, surgeons, and dialysis staff) that AVF is the preferred access method for long-term HD in pediatric patients. The initiative has penetrated the United States and evidence supporting fistula first placement in pediatric population is emerging. For example, the initiative's implementation with corresponding reduction in bloodstream infections has been demonstrated at

Children's Hospital at Downstate, SUNY Downstate Medical Center.[3]

INCIDENCE

The incidence of ESRD in patients aged 0 to 21 years old[a] was 1462 in the year 2013.[4] In comparison, the incidence in adults was 117,162 patients the same year. The incidence of ESRD in the pediatric population appears to have peaked in 2003 and has since then been steadily decreasing, although compared to the early 1980s and 1990s, the incidence curve has largely plateaued. Since its initiation of data collection in 1992, the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) reports no significant change in the pattern of incidence of ESRD in pediatric population. When looking specifically at certain age groups, race, or gender, these rates are anticipated to remain stable.[5] The cumulative prevalence of ESRD in pediatric patients as of December 31, 2013 was 9921 children.

The United States Renal Data System (USRDS) reports HD as the most common index treatment for patients initialing care for ESRD; in 2013, 55.8% of pediatric patients initiated care with HD, 25.1% had preemptive transplantation, and 18.3% started with peritoneal dialysis.[4] Compared to adults, where index transplantations are rare, there is a wider distribution of index treatment modalities in the pediatric population. The index treatment for adults in 2013 was HD in 88.2%, peritoneal dialysis in 9%, and index transplantation in only 2.6% of patients. As many as 37% of children with ESRD underwent kidney transplantation within the first year of starting ESRD care during the time period of 2009 to 2013; this a slightly lower figure compared to the previous listing of 43.6%.

ETIOLOGY

The leading group of disorders responsible for ESRD in pediatric patients continues to be cystic/hereditary/congenital disorders accounting for 33% of cases in the current reporting period (compared to 28.6% in previous report). Glomerular diseases are the second leading etiology, responsible for 24.6% of cases (27% previously), followed by secondary glomerulonephritis in 12.9% of patients (Fig. 190.1). Looking at individual diagnoses, the most common causes of ESRD include focal glomerular sclerosis (12.7%), renal hypoplasia/dysplasia (9.8%), congenital obstructive uropathies (9.2%), and lupus nephritis (7.5%). In African American patients, there is a significantly higher percentage of children with certain nephropathies related to systemic diseases. For example, African American children make up 95% of all children affected with sickle cell nephropathy. In addition, AIDS nephropathy patients in the current reporting period are 97% African American, which is an increase from 91% in previous reporting years. Finally, among those affected by lupus nephropathy, 53% are African American (increased from 50% previously).

[a]While previous USRDS reports included patients aged 0 to 18 years old, the most recent report includes patients up to age 21 years.

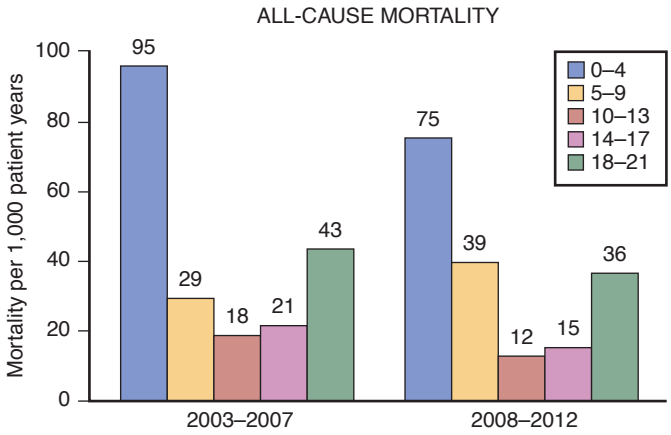

Figure 190.2 One-year adjusted all-cause mortality rates in pediatric patients with End Stage Renal Disease in 2003 to 2007 and 2008 to 2012 shown by age. *HD,* Hemodialysis; *PD,* peritoneal dialysis; *Tx,* transplant. (Source: United States Renal Data System: *2015 USRDS annual data report: epidemiology of kidney disease in the United States,* Bethesda, MD, 2015, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, chapter 8; USRDS ESRD Database. Incident dialysis and transplant patients defined at the onset of dialysis or the day of transplant without the 60-day rule; followed to December 31, 2013. Adjusted for age, sex, race, Hispanic ethnicity, and primary cause of ESRD. Ref: incident ESRD patients aged 0 to 21, 2010 to 2011.)

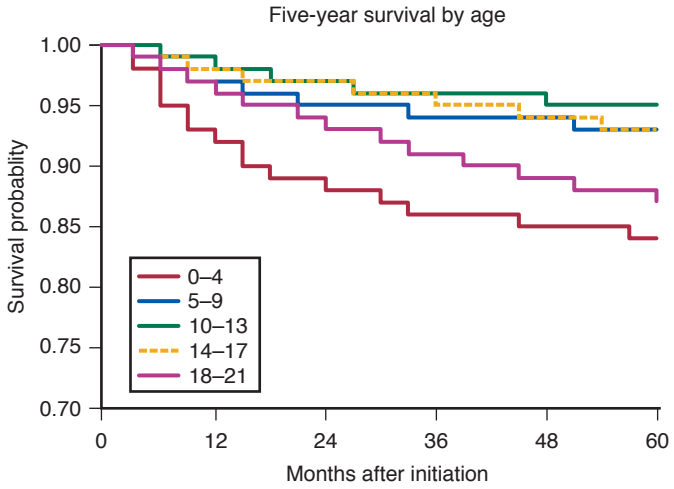
MORBIDITY AND MORTALITY

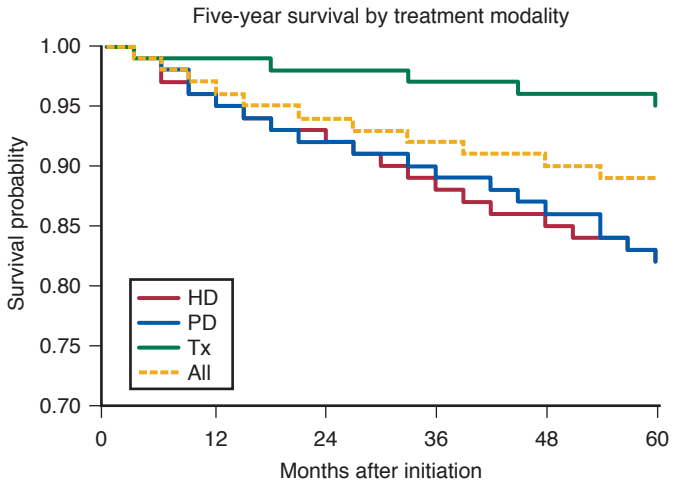
ESRD in children, as it does in the adults, confers an increased morbidity and mortality on those affected compared to the general population. The 2008 to 2012 all-cause mortality was 36 per 1000 patient-years, a 14.3% improvement over the previous time period. Although this rate is relatively low, the most affected are the youngest children. The mortality rates per 1000 patient-years is 75 cases for children aged 0 to 4 years, 39 for 5 to 9 year-olds, 12 for 10 to 13 year-olds, 15 for 14 to 17 year-olds, and 36 for 18 to 21 year-olds (Fig. 190.2).

HD patients also have a higher mortality compared to patients being treated with other modalities. The reported 1-year mortality rate in the 2008 to 2013 period for HD patients was 46 per 1000 patient-years compared to 35 per 1000 patient-years for peritoneal dialysis patients, and mortality is lowest for transplanted patients at 11 per 1000 patient-years.

The combined 5-year survival for pediatric ESRD patients evaluated from 2008 to 2012 was 89%, with the youngest age group having the lowest survival. The 5-year survival percentages were 84%, 93%, 95%, 93%, and 87% for children aged 0 to 4 years, 5 to 9 years, 10 to 13 years, 14 to 17 years, and 18 to 21 years, respectively (Fig. 190.3A). As expected, the 5-year survival is best for those who have undergone transplantation (95%), followed by peritoneal dialysis and HD, both with a 5-year survival of 82% (see Fig. 190.3B). The causes of mortality in pediatric patients are primarily cardiopulmonary issues and infections. Cardiopulmonary complications are responsible for 21% of all pediatric ESRD deaths, followed by infections of which bacterial infections cause 11.1% of deaths.



A



B

Figure 190.3 Adjusted 5-year survival in incident pediatric patients from 2004 to 2008 shown by age (A), and by treatment modality (B). *HD,* Hemodialysis; *PD,* peritoneal dialysis; *Tx,* transplant. (Source: United States Renal Data System: *2015 USRDS annual data report: epidemiology of kidney disease in the United States,* Bethesda, MD, 2015, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, chapter 8; USRDS ESRD Database. Incident dialysis and transplant patients defined at the onset of dialysis or the day of transplant without the 60-day rule; followed to December 31, 2013. Adjusted for age, sex, race, Hispanic ethnicity, and primary cause of ESRD. Ref: incident ESRD patients aged 0 to 21, 2010 to 2011.)

Rates of hospitalization are used as a surrogate for morbidity and a direct indicator of complications. Pediatric ESRD patients average 2005 admissions per 1000 patient-years; the most common causes again are cardiopulmonary issues, resulting in 374 admissions per 1000 patient-years, and infectious complications resulting in 606 admissions per 1000 patient-years.[4] Broken down into hospital admission by modality of treatment, patients who have undergone transplantation have the lowest admission rates at 276 per 1000 patient-years, followed by those on HD at 556 per 1000 patient-years and by those on peritoneal dialysis at 779 hospitalizations per 1000 patient-years.

PATIENT SELECTION

The inherent technical challenges unique to pediatric patients and shorter expected waiting time for transplantation access selection presents a dilemma. Incident access selection depends largely on information provided by caregivers, but it also relies on preconceived notions about HD, parent and caregiver biases, and the age and maturity of the patient.[6] Studies are limited but issues such as small patient size, having a maturing AVF or graft, and communications issues among stakeholders have been identified as limiting factors to successful autogenous fistula placement and use in pediatric patients.[7,8] Chand and colleagues identify several major barriers to successful AVF use including communication problems between providers, a lack of standardized referral practices for chronic kidney disease (CKD) patients, a lack of standardized accepting surgeon, as well as a lack of early communication between those placing and repairing fistulas (surgeons and interventional radiologists) and dialysis staff (nephrologists, nurse practitioners, dialysis nurses) regarding problematic fistulas.[8] Similarly, few studies have looked at psychosocial issues affecting access selection in this population.

Medical decisions can be complex and burdensome; however, when children are allowed to make a decision, long-term implications may not be well understood, although as patients become adolescents, studies have demonstrated decisions are made in conjunction with parents regarding care.[6] In our own practice, patients report fear of needles, inability to wear jewelry or participate in sports, and the ugly appearance of fistulas as barriers to fistula placement. Parents have their own concerns with fistula placement including the uncertainty of knowing what is best for their child despite receiving all the data supporting fistulas over catheters. Brittinger and colleagues evaluated patient discomfort with HD cannulation and 39% of pediatric patients reported no discomfort, 39% had a tolerable amount of discomfort, and only 22% reported significant discomfort; however, 95% of the participants also reported they would prefer not to revert to CVC for access.[9]

Pediatric patients are initiating HD treatment exclusively with a CVC over 80% of the time, a statistic largely unchanged in the last decade. This percentage is higher when considering those with maturing arteriovenous fistulas or grafts, elevating the percentage to 99.2% in patients aged 0 to 4 years, 98.5% in patients 5 to 9 years, 97.3% in patients 10 to 13 years, 92.2% in patients 14 to 17 years, and lowest at 90.4% among patients 18 to 21 years (Fig. 190.4A). The overall trend of catheter presence at index HD has changed very little since 2006 (see Fig. 190.4B). Similar to adults, pediatric fistula placement several months before renal replacement therapy initiation is ideal; thus, nephrologists and surgeons should communicate early about CKD patients such that surgery can be completed in a timely fashion and that fistulas are able to reach functional maturation. Currently, K-DOQI guidelines recommend all patients with CKD stage 4 (GFR <30 mL/min per 1.73 m^2) be referred for education about modality of ESRD treatment and that AVF be placed 6 months before the anticipated start of HD. Although the progression of CKD to ESRD can vary widely, providers should make early referrals whenever possible.

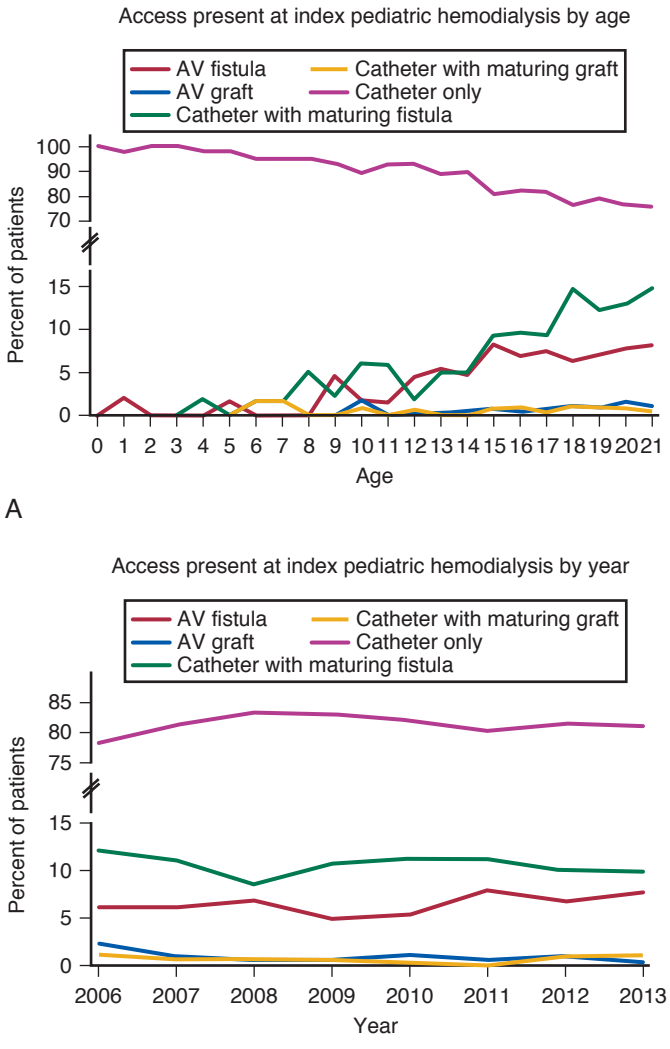


Figure 190.4 Vascular access present at initiation of incident pediatric hemodialysis by age (A) and by year (B). *HD,* Hemodialysis; *PD,* peritoneal dialysis; *Tx,* transplant. (Source: United States Renal Data System: *2015 USRDS annual data report: epidemiology of kidney disease in the United States,* Bethesda, MD, 2015, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Vol 2 ESRD chapter 8; USRDS ESRD Database. ESRD patients initiating hemodialysis in 2006 to 2013.)

TREATMENT WITH HEMODIALYSIS

Establishing access for HD is one of the main considerations in initiating treatment for patients of all ages. Issues, such as central venous stenosis and catheter-associated infections, were among the main concerns leading to the FFBI as well as the International Pediatric Fistula First Initiative. According to the NAPRTCS 2011 dialysis access data report, 78% of patients receiving HD had external percutaneous catheters, 0.3% had external AV shunts, 11.8% had internal fistulas, and 6.7% had internal arteriovenous grafts. Of the external percutaneous catheters, the majority (51.1%) were placed in the subclavian vein exacerbating associated central vein stenosis, 43.7% were placed in the jugular vein, and 4.2% in the femoral vein.[10] Up to 80% of central venous catheters in use are "permanent" catheters instead of "temporary," decreasing the urgency for autogenous AVF placement.[10] Despite the recognized efforts to increase AVF placement, use of external percutaneous catheters for HD at initiation of therapy has increased from 73% in 1992 to more than 90% of all HD access in 2010.[4]

CENTRAL VENOUS CATHETERS GENERAL CONSIDERATIONS

Specific reasons delineating the common use of permanent catheters for HD access are sparse, yet those describing complications of the catheters are abundant. Fadrowski and colleagues reported that 59% of patients followed by their center had central venous catheters.[7] The reasons given for catheter use included "small body size" in 18.8%, having "AVF/AVG maturing" in 7%, and having a "transplant scheduled" in 10.9% of the patients. Of those patients who listed having a pending transplant, 69% had in fact received a transplant within a year, yet 31% of them were still waiting for an organ while receiving HD via CVC. Another retrospective investigation by the same group looked at risks attributable to central venous catheters compared to fistulas in 12- to 18 year-old ESRD patients receiving HD for the year 2000.[11] The authors included 418 patients, 41% with AVF/AVG and 58% with CVC. The group discovered a significant higher relative risk among CVC patients with regard to all-cause hospitalization (RR 1.84 CI 1.38 to 2.44), hospitalizations due to infections (RR 4.74 CI 2.02 to 11.14), and complications of vascular access (RR 2.72 CI 2.00 to 3.69). The durability of central venous catheters remains inferior to fistulas, averaging from 4 to 12 months and in some cases as low as under a month.[12] Central venous catheter durability ranges from 0% to 62% at 1 year, and failure is attributed to infection (17% to 40%), thrombosis (33%), accidental extrusion (5% to 10%), and kinking, which is more common in smaller nonprecurved catheters or noncuffed catheters.[12,13]

A major complication of central venous catheters with long-lasting implications is central venous stenosis. In an attempt

to mitigate long-term damage, the K-DOQI guidelines have delineated the sequence of vein selection that is preferred in the event that a CVC is needed.[1] The recommendation of vein selection lists right internal jugular vein, right external jugular vein, left internal and external jugular veins, subclavian veins, femoral veins, and lastly and rarely used would be translumbar and transhepatic access to the IVC. Publications elucidating the prevalence of central venous stenosis link its occurrence to history of subclavian central venous catheter placement as commonly as 25% to 50%.[14] Finally, although the presence of a catheter seems to impair the long-term patency of AVF in adults,[10,15-17] this is not the case in pediatric patients as demonstrated in our investigations.[18] Thus, ipsilateral catheter is not a contraindication to fistula placement and efforts to replace catheters with fistulas would reduce the incidence of central venous stenosis.

CENTRAL VENOUS CATHETERS TECHNICAL CONSIDERATIONS

Central venous catheters by design are either temporary (non-tunneled) or permanent (tunneled), and these are often placed percutaneously under moderate sedation and local anesthetic. Tunneled catheters in pediatric population, however, often require general anesthesia to ensure patient compliance, which comes with its own set of potential complications and side effects. There is no evidence-based rule for catheter size selection, making establishing central venous access for HD a major challenge; compounding the issue is that commercially available precurved catheters are only supplied in larger sizes. Larger catheters offer higher volumes (and shorter times) during dialysis; however, the size of the child and his or her vessels limit the size of the catheter that can be used. Smaller catheters necessitate longer dialysis sessions due to slower flow rates; thus, the size must be large enough to be useful for dialysis but also small enough to be tolerated by the vessel. The authors created a catheter sizing formula that proved to be safe and is utilized in our practice: [Size (Fr) = Age ± 2]. Taking the age of the child and using it as the catheter's, diameter in French measurement and then reducing the size if the patient is small for their age or increasing the size if the child is larger than peers the same age. Precurved catheters available for the adult populations make percutaneous and subcutaneous tunneling possible; however, these catheters are largely unavailable in the smaller sizes for the youngest of pediatric ESRD patients. In these patients, placing a tunneled CVC usually means artificially creating the curve during placement and making one or more counter incisions (Fig. 190.5) over the access vessel for accurate and precise placement.

Figure 190.5 Twelve-year-old pediatric end stage renal disease patient who had a 10 French hemodialysis central venous catheter placed in the internal jugular vein. A 10-French catheter was selected due to the patient being smaller than peers her age, and a counter incision was necessary for proper placement.

AV ACCESS GENERAL CONSIDERATIONS

Autogenous arteriovenous fistulas are the preferred form of access for pediatric patients undergoing HD. Technical success has been demonstrated in a variety of autogenous AV accesses in both upper and lower extremities.[19-23] Early experience with autogenous fistula placement in children demonstrate lower patency rates as shown by Bagolan and colleagues with the placement of Cimino fistulas children from 1985 to 1994; their reported 4-year patency was 63.5%, and the complication rate was 35%, which thrombosis was the most common complication.[19] More recent publications have reported better outcomes. The authors have described factors affecting long-term patency of autogenous fistulas of 101 fistulas placed in 93 children with a mean age of 14 years (range 3 to 19), and weights ranging 12 to 131 kg.[18] At the time of surgery, 82% of the patients had a CVC catheter in place and were on HD for an average time of 18 months; furthermore, 24% of them had a history of multiple catheters. The group performed 43 radiocephalic, 29 brachiocephalic, 20 basilic vein transpositions, 9 femoral vein transpositions, and had an average follow up of 2.5 years. The reported primary and secondary patency at 2 years was 83% and 92%, respectively, and 65% and 83% at 4 years, respectively. Chand and colleagues showed that the implementation of IPFFI was feasible at their institution.[24] While not uniformly utilized, the use of the operating microscope has also been successful in children, with less primary fistula failures.[25,26]

AV ACCESS TECHNICAL CONSIDERATIONS

As with central line placement, the K-DOQI publishes guidelines for a structured approach for the placement HD access.[1] They report a preference for radiocephalic AVF followed by brachiocephalic AVF and lastly by basilic vein transposition. The techniques for standard radiocephalic, brachiocephalic, and basic vein transposition are widely described and can be applied to pediatric populations with some additional considerations for optimal results.

The initial consultation, similar to adults, starts with a complete history including previous central venous access use, a thorough physical exam with detailed vascular examination, and vein mapping on all patients. The operating surgeon should evaluate the vein mapping personally to determine vein suitability. Due to significant vasospastic response in pediatric patients, vein imaging should also be performed intraoperatively once the patient is placed under anesthesia. Size cutoffs of 2.0 mm for forearm veins, and 2.5 mm for upper-arm veins have had successful rates of maturation.[18] One of the attributes unique to pediatric vessels is their intense vasospastic response with handling; for example, tourniquet occlusion can be used for arterial control during fistula construction in lieu of arterial clamping. Loupe magnification (×2.5 or greater) should be standard in all pediatric fistulas. Sanabia and colleagues demonstrated 10% early failure rate, and 70% 5-year patency with the use of either operating microscope or loupe magnification.[26] Subsequently, Bourquelot and colleagues also published a lower primary fistula failure with use of microsurgery.[25] Standard end-to-side anastomosis using a continuous running monofilament suture is recommended, since interrupted suture placement is not imperative. Finally, vein transpositions (brachial or femoral in the event that superficial arm vasculature is not suitable) can be performed in either single or two-stage procedure. Kim and colleagues have described the use of two-stage basilic vein transposition with increased percentage of maturation (87%), lower failure rates (7%), and 91% 1-year patency rates.[27] Groin fistulas have also been successfully placed in pediatric populations, in the setting of unavailable upper extremities or patient preference as described by Gradman and colleagues with a technique similar to that described in adults.[20] Their reported primary patency was 100% and 96% at 1 and 2 years, respectively; secondary patency was reported to be 100%.

CONCLUSION

Establishing pediatric HD access is complex and has yet to become standardized. National data indicate that a large majority of patients initiate HD with CVCs despite results demonstrating that AVF are superior. Central venous catheters are associated with higher complications, more hospitalizations, and shorter lifespans when compared to AVF. Since the initiation of the IPFFI, there has been little change in fistula use for incident HD in the pediatric population. A handful of barriers to fistula placement have been identified, but these have yet to be addressed. Given that the majority of pediatric ESRD patients will outlive at least one transplant and return to HD, providers should steer away from using catheters as the primary treatment modality and avoid the life-long implications of catheter-related complications. Aside from emergent need for dialysis and those that already have a CVC with an impending transplant, CVC use should be largely curtailed. Finally, educational material, such as that used in the IPFFI, should be widely distributed to both providers and patients. Standardizing timing of referrals, improving communication among providers, and delineating pitfalls can greatly increase the prevalence of autogenous fistulas in this population.

CONCLUSIONS 2486

DEFINITION

Erectile dysfunction (ED) is defined as the recurrent or consistent inability to obtain and/or maintain a penile erection sufficient for satisfactory sexual performance.[1] It is a common problem with significant negative effects on the quality of life of both the patient and his partner and is associated with poor relationship satisfaction, negative general health perceptions, and role limitations owing to physical and emotional problems.[2]

EPIDEMIOLOGY

Figures on the prevalence of ED vary; however, it is estimated that at least 20 million men in the United States experience the condition.[3] The Massachusetts Male Aging Study (MMAS) has reported a combined prevalence of ED in 52% of men over the age of 40, with an increase in the rate of moderate dysfunction from 17% to 34% and complete ED from 5% to 15%, between the ages of 40 and 70 years, respectively.[4] Another

Abstract

Erectile dysfunction is recurrent or consistent inability to obtain and/or maintain a penile erection for satisfactory sexual performance. It is a highly prevalent condition, affecting over 50% of men over the age of 40. Origin of ED may be psychogenic, neurogenic, endocrinologic, vasculogenic or drug induced, and is often multifactorial. There are a variety of diagnostic modalities which can be used to help identify the source of the issue. Treatment options include oral medications, injectables and surgical treatment. ED is a frequent comorbidity in men undergoing vascular surgery.

study, looking at data from the National Health and Nutrition Examination Survey (NHANES), reported a combined prevalence of ED in 18% of men over the age of 20 years, with an increase from 7% of the population between the ages of 20 and 29 years to 78% in those over 75 years of age.[5] The prevalence of ED appears to be similar among different ethnic groups, with a different population-based study demonstrating a 22% rate of ED in white men, 24% in black men, and 20% rate among Hispanic men all over 40 years of age.[6] Differences noted in the prevalence rates across these studies are partially due to nonstandardized definitions of the severity of ED, especially given the frequently subjective nature of this reported complaint.

PHYSIOLOGY OF PENILE ERECTION

The penis is a composite structure, including the paired dorsal corpora cavernosa and the ventral corpus spongiosum, which contains the urethra. The corpora cavernosa are surrounded by the tunica albuginea, a bilayered structure, which supports the cavernous tissue and provides the flexibility, rigidity and strength of the penis. The spongiosum lacks the outer layer of the tunica, allowing for a low-pressure urethra during erection. Blood flow to the penis typically originates from the internal pudendal artery, a branch of the internal iliac artery. Distally, it then becomes the common penile artery, where it subdivides into the dorsal, cavernosal, and bulbourethral arteries. Frequently accessory pudendal arteries arising from the external iliac, obturator, vesical, and femoral arteries contribute significantly to the arterial supply to the penis.[7] The cavernosal arteries effect tumescence of the penis and end at the helicine arteries, which open into the endothelium-lined lacunar spaces. Venous drainage begins within the lacunar spaces, which drain into subtunical venules and emerge as emissary veins. The deep venous system continues with these emissary veins draining into the cavernosal veins and deep dorsal or spongiosal veins until they join either the prostatic venous plexus or the internal pudendal veins. Superficial veins coalesce to form the superficial dorsal vein, which drains into the saphenous veins (Fig. 191.1).

Erection is the result of an integrative physiologic complex—comprising psychological, neuronal, hormonal, vascular, and cavernous smooth muscle systems—that begins in the brain. Relevant innervation to the penis includes somatic nerves, responsible for sensation and contraction of the bulbocavernosus and ischiocavernosus muscles, and the parasympathetic and sympathetic autonomic nerves located at levels S2-S4 and T12-L2, respectively, which are instrumental in tumescence. These segments form the hypogastric and pelvic plexi. The fibers that innervate the penis compose the cavernous nerve, which travels along the posterolateral aspect of the prostate and then accompanies the membranous urethra through the urogenital diaphragm.[8] The cavernous nerves then innervate the helicine arteries and trabecular smooth muscle.[9]

The cavernous smooth muscle plays a key role in erectile function and remains contracted in the flaccid state of the penis under α-adrenergic control. The erectile process begins with sexual stimulation, which increases parasympathetic activity

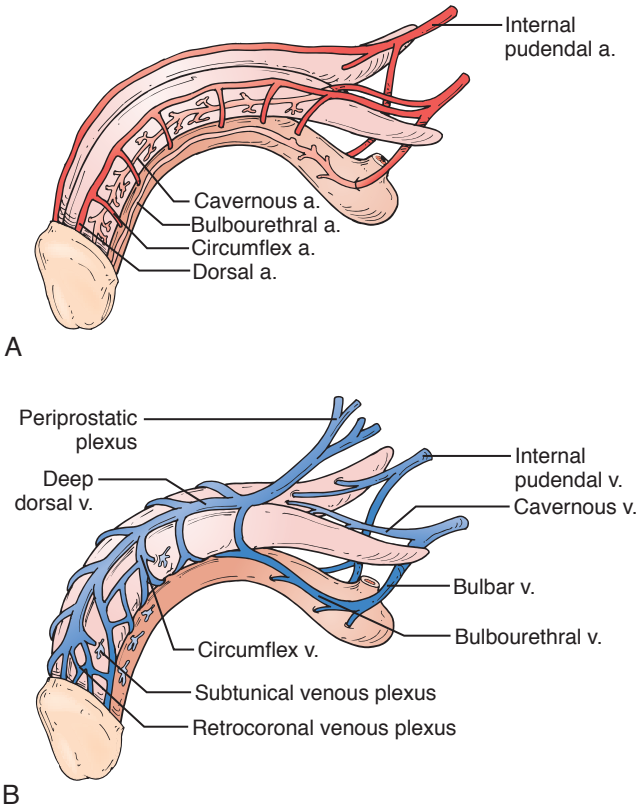

Figure 191.1 Penile Vascular Anatomy. (A) Penile arterial supply; (B) penile venous drainage. (Source: Wein AJ. *Campbell-Walsh Urology*, 10th ed. Philadelphia, PA: WB Saunders/Elsevier; 2011:691-692.)

and stimulates the release of neurotransmitters from cavernous nerve terminals or from the endothelium of the cavernosal arteries, resulting in relaxation of the penile smooth muscle.[10,11] This is mediated by the nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) pathway, ultimately resulting in increased blood flow through the penile arteries (Fig. 191.2).[12,13] This blood flow then expands the sinusoids, compressing subtunical venules and peripheral sinusoids and ultimately reducing venous outflow (veno-occlusive mechanism). This leads to an increase in intracavernous pressure, resulting in an erection.

PATHOPHYSIOLOGY OF ERECTILE DYSFUNCTION

Given the interaction of the multiple different physiologic systems required for adequate erectile function, it is easy to appreciate that derangements in any one system can serve as a cause of ED. ED is classified according to its likely origin: psychogenic, neurogenic, endocrinologic, vasculogenic, and drug-induced. It is often multifactorial in nature.

Psychogenic Erectile Dysfunction

Psychogenic (nonorganic) ED is generally assumed to be ED predominantly or exclusively related to psychological or interpersonal factors.[14] It is estimated to play a role in 10% to 15%

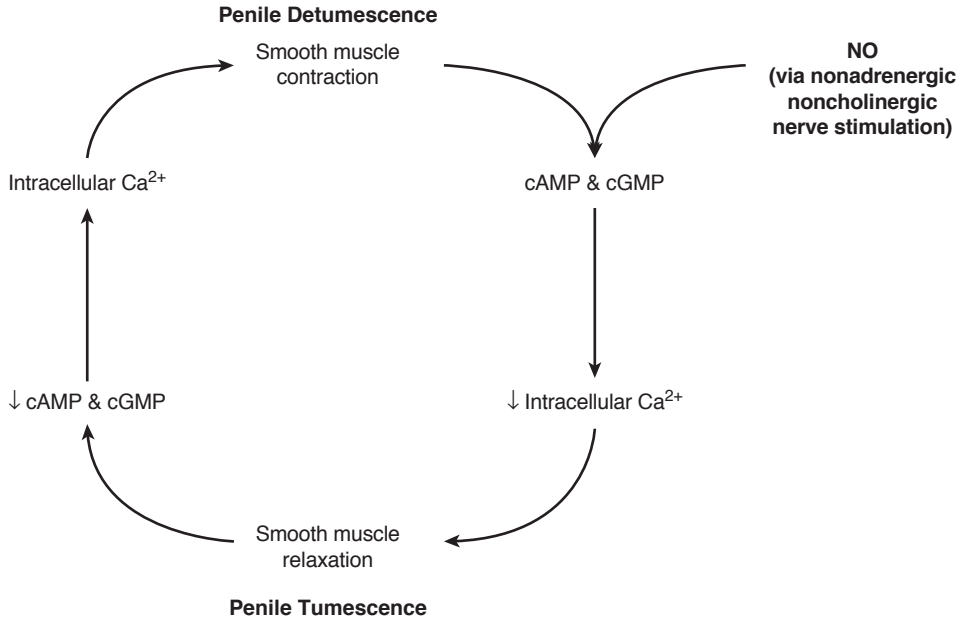

Figure 191.2 **Erectile Physiology.** *Ca^{2+},* Calcium; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *NO,* nitric oxide.

of all men with ED. It has been further classified as either situational psychogenic ED, which is noted to be either partner-related, performance-related, or associated with psychological distress, or generalized psychogenic ED, secondary to a lack of sexual arousability or a disorder of sexual intimacy.[15] Psychogenic ED is an adrenaline-mediated phenomenon and is a diagnosis of exclusion, once physical (organic) factors have been ruled out. The clinical features include sudden-onset ED, with intermittency of function or a situational nature to the erectile problems, as well as reports of good nocturnal erections.[16]

Neurogenic Erectile Dysfunction

Neurogenic ED, an uncommon entity, is secondary to events disrupting central neural networks or the peripheral nerves involved in sexual function. It is further subclassified into supraspinal, spinal, and peripheral neurogenic ED.[17] Supraspinal ED is generally caused by tumor, stroke, Parkinson disease, dementia, or temporal lobe epilepsy.[17] Spinal causes include multiple sclerosis, spinal cord injury, transverse myelitis, myelodysplasia, and lumbar disc disease or surgery.[17-19] Peripheral causes include diseases associated with lower motor neuron lesions, trauma, pelvic pathology, and radical pelvic surgery.[17] Pelvic surgery, particularly radical prostatectomy, has a high risk of causing cavernous nerve injury and has been demonstrated to have a significant effect on erectile function.[20]

Endocrinologic Erectile Dysfunction

Androgens, specifically testosterone, have been linked to sexual desire, organic function, and erectile function. However, low serum testosterone has not been clearly linked to the presence or severity of ED.[21,22] Animal models have shown that testosterone is important in the regulation of the expression of nitric oxide synthase (NOS) and phosphodiesterase type 5 (PDE5) inside the penis.[23] Hyperprolactinemia, leading to the inhibition of luteinizing hormone (LH), is associated with low libido and possibly ED. Profound hypothyroidism (low LH levels) and profound hyperthyroidism (high estradiol levels) may be associated with sexual dysfunction.

Vasculogenic Erectile Dysfunction

ED and cardiovascular disease (CVD) share common risk factors, including hypertension, diabetes mellitus, hypercholesterolemia, obesity, and smoking, leading to the concept that ED is another manifestation of vascular disease.[24] A large survey of over 7500 patients with hypertension and diabetes demonstrated ED in 67% of patients with hypertension alone, 71% of patients with diabetes alone, and 78% of patients with both conditions.[25] A Spanish study of over 2400 patients has demonstrated each of these to be independently associated with ED and age-adjusted odds ratios of having ED of 4.0 in diabetics, 1.58 with hypertension, 1.63 with high cholesterol, 2.63 with peripheral vascular disease, and 2.5 among smokers.[26] ED patients have also been noted to have significantly higher plasma levels of low-density lipoprotein (LDL) when compared with normal counterparts.[27]

The Princeton III consensus guidelines recognize ED as a strong predictor of CVD and specifically coronary artery disease (CAD).[28] Data from a meta-analysis of prospective cohort studies evaluating ED and the risk of CVD demonstrated a combined relative risk for men with ED for overall CVD of 1.48, 1.46 for CAD, 1.35 for stroke, and 1.19 for all-cause mortality.[29] Additionally, ED has been described as an independent marker of cardiovascular events and all-cause mortality after adjusting for age, weight, hypertension, diabetes, hyperlipidemia, and cigarette smoking.[30] ED is also an independent predictor of peripheral artery disease (OR 1.97), with a significant stepwise increase in prevalence of peripheral artery disease with increasing

severity of ED (28% of men with mild ED, 33% with moderate ED, and 40% with severe ED).[31]

A number of theories have been proposed to explain the pathophysiologic association between ED and CVD. Given that atherosclerosis is a systemic disease, with all vascular beds affected to some extent, the artery size hypothesis proposes that symptoms present at different time points according to the diameter of the arterial blood supply.[32] Accordingly, a 50% stenosis of the coronary arteries would amount to a near complete occlusion of the penile arteries despite an equal amount of total atherosclerotic plaque in both vessels. In addition to the flow-limiting stenosis, ED due to arterial insufficiency is related to lower oxygen tension in intracavernous blood.[33] This has been associated with possibly decreased prostaglandin E_1 (PGE_1) and E_2 formation, leading to transforming growth factor (TGF) β_1–induced collagenization of cavernous smooth muscle.[17,34] Increased connective tissue has been correlated with failure of the veno-occlusive mechanism required for good erectile function.[35]

Endothelial dysfunction serves as an additional link between ED and CVD. NO produced by the endothelium is necessary for the increased flow and vasodilation of the penile arteries, which is necessary for erection. In both ED and CVD, a deficiency of NO is brought about by impaired production or increased degradation, thereby decreasing the vasodilation and modulation of smooth muscle cells and inhibiting cellular adhesion.[36,37] Among ED patients without evidence of CVD, endothelial dysfunction has been noted within the penile vasculature but not in the small arteries of the forearm, indicating that endothelial dysfunction may occur earlier in the penile vasculature than in other vascular beds.[38]

ED has also been demonstrated to be a strong predictor of subsequent cardiovascular events. Data from the Prostate Cancer Prevention Trial (PCPT) demonstrated that incident ED was associated with a 25% increased likelihood of subsequent cardiovascular events during the 5-year study follow-up and that men with incident ED during the study period were at a 45% increased risk of cardiovascular events.[39] This association was similar to the risk associated with current smoking or a family history of myocardial infarction. Another study addressing men referred with ED and vasculogenic ED documented on penile ultrasonography demonstrated a 20% rate of abnormal stress echocardiography on cardiac evaluation.[40]

In addition to arterial causes, as indicated earlier, vasculogenic ED is also often the result of inadequate venous occlusion.[41] Corporal veno-occlusive dysfunction (CVOD) may be due to the development of large venous channels draining the cavernous tissue or to degenerative or functional changes in the tunica albuginea, as seen in Peyronie disease.[42,43]

Drug-Induced Erectile Dysfunction

Antihypertensives, psychotropics, and antiandrogens are the primary drug classes associated with ED. Among the antihypertensives, multiple studies have demonstrated significant increases in ED among patients on thiazides as compared with placebo.[44,45] Studies of β-adrenergic antagonists demonstrate mixed results with respect to potentially causing ED, with nonselective drugs such as propanolol showing clear associations with ED and agents with higher selectivity for the β_1 adrenoreceptor, such as acebutolol, showing a reduction in ED compared with placebo.[46] Angiotensin receptor blockers have been consistently shown to have proerectile effects.[47] Antidepressants, specifically selective serotonin reuptake inhibitors (SSRIs), can negatively affect all steps of the sexual response cycle, most notably ejaculatory latency. Differences are noted in the incidence of ED among different medications, with higher rates noted in patients on paroxetine.[48] Antiandrogens cause partial or complete blockade of circulating androgens either by inhibiting their production or antagonism at the level of the androgen receptor; they are frequently used in the treatment of prostate cancer. Use of these medications is generally associated with decreased sexual desire, although medical castration with luteinizing hormone–releasing hormone agonists/antagonists and nonsteroidal anti-androgens such as flutamide or bicalutamide can also contribute to veno-occlusive dysfunction.[49] Other classes of drugs associated with ED include 5-alpha reductase inhibitors (finasteride, dutasteride) and digoxin.[50,51]

ASSESSMENT OF ERECTILE DYSFUNCTION

History and Physical Examination

Since ED is often multifactorial, the initial evaluation must include a complete medical, psychosocial, and sexual history.[52] Care should be taken to assess for signs and symptoms of possible underlying conditions, with a detailed review of current medications, to identify possibly reversible and treatable disorders causing ED. One study of over 270,000 ED patients demonstrated a 68% prevalence of a significant underlying condition at the time of ED presentation.[53]

Given the often sensitive subject matter, clinicians should consider using validated questionnaires in order to ease into the conversation, including the International Index of Erectile Function (IIEF) and the abridged five-item version of the IIEF, and the Sexual Health Inventory in Men (SHIM); these have been demonstrated to accurately diagnose and quantify the severity of the ED complaint.[54,55] Descriptive measures should be used for the rigidity and sustainability of erections during sexual arousal, intermittency or any situational aspect of erections, and the presence of nocturnal erections in order to further define underlying causes of ED. Patients complaining of sudden-onset ED with loss of sustaining capability and strong nocturnal erections are more likely to have nonorganic ED secondary to psychogenic causes. Frequently physical examination will not reveal a specific cause. A general examination, with evaluation of blood pressure, heart rate, abdominal pulsations, peripheral pulses, evaluation of male secondary sex characteristics including the presence of gynecomastia, and a focused genital examination should be performed.[52,56] Attention should be paid to the absence of femoral pulses, indicative of aortoiliac arterial occlusive disease. Genital examination should include examination of the penis, specifically the size and position of the urethral meatus, the

presence of tunical plaques, evaluation of testicular size and consistency, and a digital rectal examination in the appropriately aged man.[56]

Laboratory Evaluation and Adjunctive Testing

According to the International Consultation in Sexual Medicine (ICSM) committee, recommended laboratory tests to confirm the presence of underlying diseases include fasting blood glucose, a lipid profile, and serum testosterone levels, with optional examinations such as thyroid function testing based on the clinical scenario.[52,56] The Princeton III consensus statement recommends that all men over 30 years old with organic ED should be considered at increased CVD risk until recommended checks suggest otherwise; it further recommends a resting electrocardiogram and serum creatinine level in addition to the previously described testing in men without known CVD.[28] It also recommends, in consultation with a cardiologist or primary care physician, the performance of a thorough noninvasive of CVD status and, when indicated, invasive evaluation, including measurement of biomarkers and physiologic stress testing for ischemia or anatomic clarification using coronary computed tomographic angiography.[28]

Nocturnal penile tumescence (NPT) monitoring, used to study the quality of nocturnal erectile function, may be used both in a sleep laboratory setting and with a portable, home use device such as the Rigiscan (Timm Medical Technologies, Inc., Minneapolis, Minnesota).[57] In contemporary practice, its routine usefulness for diagnostic purposes is significantly limited.

Vascular Evaluation

Vascular studies in the patient with ED are designed to determine whether arteriogenic ED or veno-occlusive dysfunction is present.

Penile Brachial Pressure Index

The penile brachial pressure index (PBI) refers to the ratio of penile systolic to brachial systolic pressure and has been used to test for the presence of significant hemodynamic occlusive disease proximal to the penile arteries, thus contributing to ED. Penile systolic blood pressure is measured by applying a small blood pressure cuff to the base of the flaccid penis and measuring the systolic blood pressure with a Doppler probe. The validity of this technique in the evaluation of ED has been called into question, given significant interobserver variability, failure to measure pressure in the erect state, and concerns regarding the false-positive diagnosis of arterial insufficiency. Thus its use in the evaluation of ED is primarily a matter of history.[58,59]

Office Injection Testing

Intracavernosal injection (ICI) testing is performed by injection of a vasodilatory drug (or cocktail of drugs), combined with genital or audiovisual stimulation, in a clinical setting. The erectile response is then evaluated by a clinician to rate both the rigidity and duration of response. Patients are monitored for detumescence while in the office after the test is performed, and those who do not spontaneously detumesce within 1 hour of injection are given intracavernous injections of a diluted phenylephrine solution. Vasodilatory medications used include PGE_1 alone or a combination of medications including PGE_1, papaverine, and phentolamine. Although ICI testing has been used in an attempt to differentiate organic from psychogenic ED, it is now accepted that its only value is to define a functional veno-occlusive mechanism in men who develop a rigid and sustained erection.[60]

Failure to obtain a rigid erection may indicate vascular disease but may also be the result of an excessive sympathetic response associated with anxiety during ICI testing.[61] Currently the ICI test is seldom performed and generally considered to be obsolete.

Duplex Ultrasonography of the Penis

Duplex Doppler ultrasound (DDUS) of the penis is a reliable noninvasive diagnostic method for evaluating ED, allowing an objective quantification of the blood flow to the penis. It also provides a physiologic diagnosis to guide therapy in patients with a poor response to oral ED therapy, differentiates psychogenic versus organic ED, aids in the evaluation of the young man with primary ED or a history of pelvic trauma, and suggests the need for cardiovascular evaluation in the man with vasculogenic ED without overt CVD risk factors.[62]

Given the significant influence of psychological and environmental factors on erectile function, DDUS should be performed in a quiet, comfortable room, isolated from intrusion and distraction. An erection is then pharmacologically induced using ICI with vasoactive medications. If a good erection is not achieved, patients should be redosed to ensure maximal smooth muscle relaxation for accurate interpretation of the results. Rigidity and sustainability of the erection is noted by the examiner. DDUS is performed using a high-resolution linear array ultrasound transducer with a frequency between 7.5 and 12 MHz. With the patient in supine position, the penis is scanned and the locations of the left and right cavernosal arteries are identified. Peak systolic velocity (PSV), end-diastolic velocity (EDV) as well as resistive indices (RI) are measured. The penis is then evaluated using B-mode images to observe for the presence of tunical plaque (Peyronie disease), fibrosis, and the presence of calcification in either the vasculature or the plaque itself.

Various criteria have been suggested for normal PSV values, but it is generally accepted that a PSV below 25 cm/s suggests arteriogenic ED.[63] This level has been noted to have a sensitivity of 100% and specificity of 86% among patients with abnormalities on pudendal angiography.[64] A PSV of 35 cm/s decreases the sensitivity to 76%, but increases specificity to 92%.[65] Significant asymmetry of PSV, with a greater than 10 cm/s difference between right and left sides, suggests a significant atherosclerotic lesion or iatrogenic/surgical cause for a decrease in arterial flows.[65] Veno-occlusive dysfunction is evaluated using EDV in the presence of normal arterial inflow. Generally EDV of greater than 5 cm/s is accepted as the measurement at which CVOD is present (Fig. 191.3).[62,65] Given concerns for the specificity of EDV alone for the diagnosis of CVOD in patients with arterial insufficiency, RI has been used with a cut point

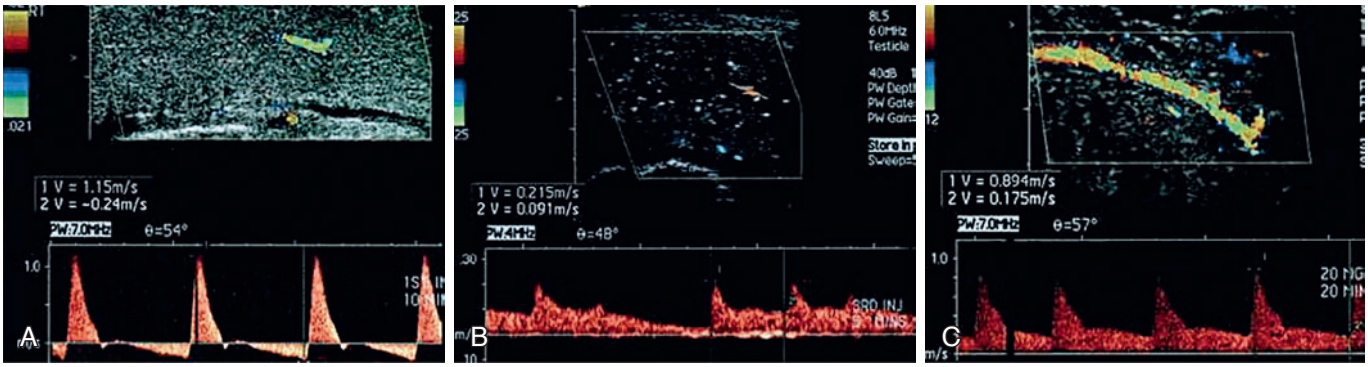

Figure 191.3 Color Doppler Duplex Ultrasound of the Penis. (A) Normal erectile hemodynamics: Doppler waveform analysis demonstrating cavernosal artery peak systolic velocity of 115 cm/s and end-diastolic velocity of −24 cm/s, representing normal erectile hemodynamics. (B) Mixed vasculogenic erectile dysfunction (ED): Doppler waveform analysis demonstrating cavernosal artery peak systolic velocity of 21.5 cm/s and end-diastolic velocity of 9.1 cm/s, indicating the presence of arterial insufficiency and corporal veno-occlusive dysfunction (CVOD). (C) Corporal veno-occlusive dysfunction: Doppler waveform analysis demonstrating cavernosal artery peak systolic velocity of 89.4 cm/s, and end-diastolic velocity of 17.5 cm/s. End-diastolic velocity greater than 6 cm/s indicates corporal veno-occlusive dysfunction. (Source: Wilkins CJ, Sriprasad S, Sidhu PS. Colour Doppler ultrasound of the penis. *Clin Radiol.* 2003;58(7):514-523.)

of less than 0.75 as abnormal.[62,66] It should be noted, however, that RI, calculated as the difference between PSV and EDV divided by the PSV, is ultimately dependent upon PSV. Patients with good arterial inflow and significantly elevated EDV may still have RI values within the normal range; therefore, RI alone should not be used for diagnostic purposes.

Dynamic Infusion Cavernosometry and Cavernosography

Dynamic infusion cavernosometry and cavernosography (DICC) is the most accurate assessment of erectile hemodynamics. Given the widespread availability of DDUS and the specialized equipment and training needed to perform DICC, its clinical use is limited, and it is now generally used mainly in (1) young, healthy men with a history of perineal or pelvic trauma being considered candidates for penile revascularization; (2) young men with ED failing erectogenic pharmacotherapy, presumed to be secondary to CVOD, who are faced with penile implant surgery as their only option; (3) young men with primary ED (who have never had a rigid erection) to rule out CVOD; (4) medicolegal cases where a definitive diagnosis is needed; and (5) patients with Peyronie disease and comorbid ED, where the presence of CVOD will ultimately change surgical management.[67]

Dynamic infusion cavernosometry involves placement of a butterfly needle in each corporal body, one connected to a pressure transducer and the other to a server-controlled pump for heparinized saline infusion.[67,68] After the injection of vasoactive drugs (in doses significantly higher than those used for DDUS), erection ensues and a number of parameters are recorded: (1) equilibrium pressure (in mm Hg) within the corpus cavernosum, which is an assessment of intracavernosal pressure (ICP) development within the corpus cavernosum 10 to 15 minutes after vasoactive agent injection; (2) cavernosal artery inflow gradient (in mm Hg), which is the difference between brachial artery systolic pressure and the cavernosal artery occlusion pressure, measured on both sides; (3) flow to maintain, defined as the flow of saline (mL/min) required to maintain a given ICP; and (4) pressure decay (in mm Hg/30 s), the pressure drop occurring over a 30-second period after raising the ICP to 150 mm Hg. Patients are pharmacologically redosed as needed to maintain flow or if pressure decay values are abnormal.[69] If the cavernosometry demonstrates CVOD, cavernosography may be performed, where a nonionic radio-opaque dye is injected intracavernosally and a radiograph obtained in order to demonstrate the site of venous drainage.

Standardized data for the results for DICC are not available. However, normal values are as follows: cavernosal artery occlusion pressure below 30 mm Hg, flow to maintain of less than 5 mL/min, and a pressure decay of less than 45 mm Hg over 30 seconds.[68] Although abnormal values aid in the diagnosis of CVOD following DICC, additional data are available in terms of the relationships between these parameters. Plotting the flow to maintain against the ICP graphically generates one of two patterns, a curvilinear pattern or a parabolic pattern. Patients with a linear pattern are generally accepted to have genuine evidence of CVOD, whereas those with a parabolic pattern generally have abnormal veno-occlusive parameters secondary to excess sympathetic tone.[67]

Selective Internal Pudendal Angiography/ Penile Angiography

Penile arteriography is an essential component of the evaluation for any patient under consideration for penile revascularization surgery. Such patients have (1) pure arterial insufficiency without CVOD, (2) a focal occlusion of one or both common penile or cavernosal arteries, (3) perforating branches traveling from the dorsal to the cavernosal artery, (4) at least one patent inferior epigastric artery (IEA) of sufficient length to serve as a donor artery, and (5) at least one patent dorsal artery to act as a recipient artery. Another indication is in patients with high-flow priapism, where angioembolization of the cavernosal artery–corpus cavernosal fistula is potentially curative.

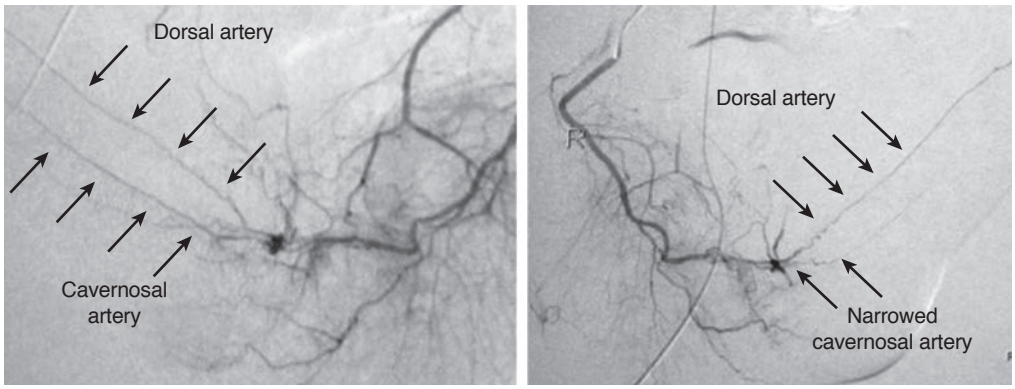

Figure 191.4 **Selective Internal Pudendal Angiography.** *Left image:* Normal internal pudendal angiogram demonstrating patent dorsal and cavernosal arteries of normal caliber. *Right image:* Internal pudendal angiogram demonstrating patent dorsal artery with occlusion of the cavernosal artery. (Images courtesy of Dr. Irwin Goldstein, MD, San Diego Sexual Medicine, Alvarado Hospital, San Diego, CA.)

A technically challenging and invasive procedure, pudendal/penile angiography requires an endovascular specialist with skill at cannulating both the internal pudendal arteries and the inferior epigastric arteries, which are used for revascularization.[62] Arterial inflow to the penis should be maximized with the use of ICI delivered vasoactive agent, which is usually administered prior to contrast injection. The timing of injection should allow for maximal arterial inflow to the penis but should not be administered at such a time point as to cause reduced arterial flow at full rigidity. Selective catheterization of the internal pudendal artery is performed to increase detail (Fig. 191.4).[70]

Despite the anatomic detail provided by arteriography, it represents only a road map and is not a functional test. Thus the results must be interpreted in light of the functional results obtained using DDUS and/or DICC.

TREATMENT OF ERECTILE DYSFUNCTION

Given the safe and effective oral therapies widely available for the treatment of ED, a process-of-care model has been established to guide the practitioner through a structured treatment algorithm (Fig. 191.5).[71] After ruling out adverse medication effects, patients with presumed organic ED are first referred for lifestyle modification, targeting the factors commonly associated with ED and frequently CVD, including smoking cessation, weight loss, and increased aerobic exercise. Numerous trials have demonstrated improvements in erectile function with smoking cessation, giving the clinician additional evidence to motivate a patient to quit smoking.[72] In a randomized controlled trial of obese Italian men, participants were randomized to receive (1) intervention based on detailed advice for a 10% weight loss (including diet and exercise) or (2) control, where no advice was given.[73] At 2-year follow-up, the patients in the intervention group had significant weight loss and reported significant improvements in erectile function defined by the IIEF.

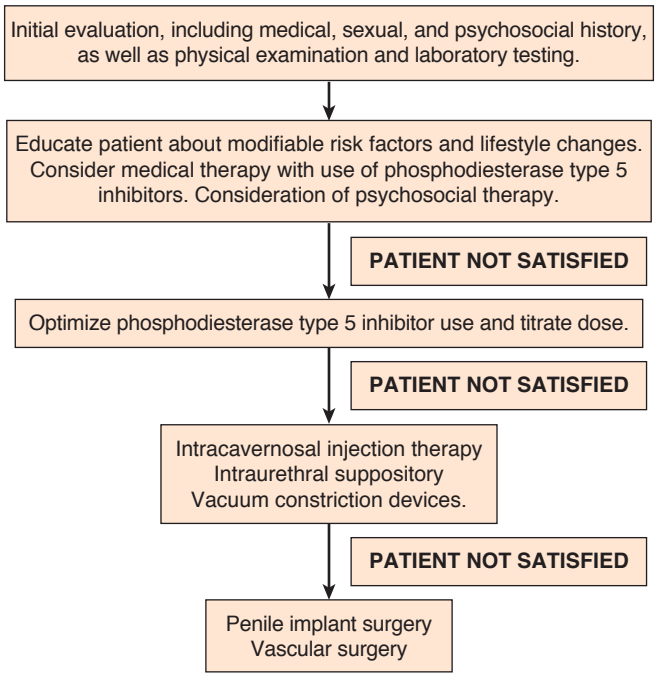

Figure 191.5 Process-of-care model for the treatment of erectile dysfunction (ED). A goal-oriented treatment approach to ED, with a stepwise escalation of therapeutic modalities in patients unsatisfied with treatment results.

Among patients with psychogenic ED, psychosocial interventions have demonstrated some improvement in erectile function when used in combination with sildenafil therapy, compared to sildenafil therapy alone.[74]

PDE5 inhibitors (PDE5i), described further on, complete the available first-line therapeutic modalities for ED. Vacuum constriction devices, although once considered first-line, are now generally considered a second-line treatment for ED, in addition to ICI and intraurethral alprostadil. Surgical therapy in contemporary practice is considered a third-line therapeutic modality and includes penile implant surgery and vascular reconstructive surgery.

Phosphodiesterase Type 5 Inhibitors

In 1998, the PDE5 inhibitor sildenafil citrate (Viagra, Pfizer Inc., New York) became the first oral drug for ED treatment to be approved by the U.S. Food and Drug Administration (FDA). It dramatically changed the treatment of ED compared with historic therapeutic modalities. Utilizing similar mechanisms of action, four PDE5 inhibitors have been approved to date by the FDA: sildenafil, vardenafil hydrochloride (Levitra or Staxyn, Bayer Pharmaceuticals Corp, West Haven, Connecticut, and GlaxoSmithKline, Philadelphia, Pennsylvania), tadalafil (Cialis, Lilly LLC, Indianapolis, Indiana), and avanafil (Stendra, Vivus Inc., Mountain View, California).

Mechanism of Action and Means of Use

As suggested by their name, PDE5 inhibitors work by inhibiting the PDE5 enzyme, which degrades cGMP, the downstream effector of NO. Prolonged activity of cGMP decreases intracellular calcium concentration and maintains smooth muscle relaxation, thus leading to an erection. Means of use for the tablets, including the time to maximum concentration and the half-life of each medication, vary (Table 191.1). The choice of the optimal PDE5 inhibitor for the individual patient is dependent upon the patient's sexual dynamics, particularly the frequency and predictability of sexual activity as well as the presence of comorbid conditions, which may potentially be treated with a daily dose of a PDE5 inhibitor such as tadalafil for concomitant benign prostatic hypertrophy (BPH).[75]

Outcomes

The majority of the drug trials in ED are short term, lasting less than 12 weeks. Across these studies, sildenafil was more effective than placebo, with per-patient sexual intercourse success rates of 69% (range 52% to 85%) versus 36% (range 19% to 68%), respectively.[76] Sexual intercourse success rates with vardenafil and tadalafil have been shown to be similar (68% and 69%, respectively), although no single published trial comparing all agents exists.[76] In pooled estimates, use of sildenafil, vardenafil, and tadalafil had an approximate 2.5-fold increased likelihood of improvement in erectile quality compared to placebo in general ED patients.[76] The ability of these agents to permit sexual intercourse depends upon the underlying etiology of ED, with men with psychogenic ED responding better than men with veno-occlusive dysfunction.[77]

TABLE 191.1 Pharmacokinetics of FDA-Approved Phosphodiesterase Type 5 Inhibitors

Generic Name	Trade Name	T_{max} (min)	$T_{½}$ (h)
Sildenafil	Viagra	60	4
Vardenafil	Levitra, Staxyn	42	4.5
Tadalafil	Cialis	120	17.5
Avanafil	Stendra	45	5.1

FDA, U.S. Food and Drug Administration; T_{max}, time required to attain maximal plasma concentration; $T_{½}$, half-life, time required for elimination of half of the medication from plasma.

Adverse Events and Contraindications

Side effect profiles tend to be similar among PDE5 inhibitors. The most commonly reported effects include headache, flushing, nasal congestion, heartburn, and temporary alteration in color vision, all of which can frequently be easily managed with other over-the-counter medications.[76] Other side effects include myalgia, nausea, diarrhea, vomiting, and dizziness with risk of serious cardiovascular events in 0.2% to 0.5% of patients on sildenafil, vardenafil or tadalafil versus 0.1% to 0.2% of those on placebo.[76] Among these medications, the incidence of adverse effects (range 24% to 34%) is similar, with discontinuation secondary to adverse effects ranging from 0.53.8% to 8%.[76] Ischemic nonarteritic optic neuropathy (NAION) and priapism have been rarely reported among users of PDE5 inhibitors, but no clear causal link has been established.[76]

PDE5 inhibitors are contraindicated in patients who use nitrate medications owing to a risk of severe hypotension.[78] Although not specifically indicated, patients with serious CVD should use PDE5 inhibitors with caution, primarily due to risks associated specifically with physical exertion (sexual activity) as opposed to risks posed by the PDE 5 inhibitors themselves. Vardenafil use is contraindicated among patients taking type 1A or type 3 antiarrhythmics and among those with prolonged QT syndrome.[79]

Intracavernosal Injection Therapy

Intracavernosal injection therapy (ICI) was accidentally discovered and first described for the treatment of ED in 1982; it is recognized as a safe and effective treatment strategy.[80] ICI is generally relegated to second-line therapy for ED and can prove effective in up to 90% of ED patients and in more than 50% of those who fail to respond to a PDE5 inhibitor.

Mechanism of Action and Means of Use

There are three main drugs (although many others exist) used in ICI: PGE_1, phentolamine, and papaverine. These medications are frequently used in combination (Trimix—PGE_1, phentolamine, papaverine; Bimix—phentolamine, papaverine) for increased efficacy and potency. PGE_1 (the FDA-approved version is known as alprostadil and marketed as Caverject, Pfizer, Inc., New York, or Edex, Actient Pharmaceuticals, Lake Forest, Illinois), activates prostaglandin receptors, resulting in an increase in the intracellular concentration of cyclic adenosine monophosphate (cAMP) in the cavernosal smooth muscle.[81] Phentolamine is a nonselective α-adrenoceptor antagonist, which induces relaxation of cavernosal smooth muscle.[82] Papaverine acts as a nonspecific PDE inhibitor and initiates an increase in both intracellular cAMP and cGMP, resulting in penile erection.[80] Use of ICI therapy involves direct injection of these vasoactive medications into the corpora cavernosa by the patient. The patient is trained to self-administer the medication at home. Responses are generally seen within 5 to 10 minutes, with dose-dependent changes in duration and rigidity of the erection.

Outcomes

Used in patients who generally have ED refractory to PDE5 inhibitor therapy, ICI therapy is highly efficacious, with an 89% response rate (patients able to achieve a penetration-hardness erection capable of sexual intercourse) and at least a 24% discontinuation rate across ED patients at 36-month follow-up.[83] Discontinuation rates and reasons vary according to the patient population and can be secondary to recovery of erections following radical prostatectomy, progression of ED such that the patient requires escalating medication doses, and declining interest in sexual activity. Patients with a history of radical prostatectomy, a combination radical prostatectomy, or pelvic radiation therapy, diabetes, and a long preexisting history (>5 years) of untreated ED are more likely to fail ICI therapy.[83] True failure of ICI therapy is generally a clinical indicator of the presence of cavernosal smooth muscle damage (veno-occlusive dysfunction).

Adverse Events and Contraindications

The predominant concern about ICI therapy is priapism. Other minor adverse effects include pain, ecchymosis, and hematoma formation. Priapism rates with ICI vary in the literature from 0.25% to 7.3%, with figures in the lower part of the range in centers with careful patient selection and superior patient education and counseling.[83] Aching or burning penile pain has been reported more often with the use of PGE_1. Reversal of a prolonged erection is accomplished with the intracavernosal administration of an α-adrenergic agonist agent (phenylephrine).

Intraurethral PGE_1 Suppository

Intraurethral PGE_1 in the form of alprostadil (known as Medicated Urethral System for Erection, or MUSE, Meda Pharmaceuticals Inc., Somerset, New Jersey) is an alternative method for delivering medication directly to the corporal bodies. The drug is absorbed through the urethral mucosa and into the corpora cavernosa, where it has a similar mechanism of action to intracavernosal alprostadil. A small plastic device is inserted into the urethral meatus by the patient, and the pellet is deposited into the urethra. The efficacy of MUSE is variable, with small trials suggesting superior efficacy for ICI versus MUSE.[84,85] Penile pain is reported in 33% of patients, with approximately 5% reporting urethral bleeding.[86]

Vacuum Constriction Devices

Vacuum constriction devices, also known as vacuum erection devices (VEDs), have been approved by the FDA since 1982.[87] VEDs consist of a suction cylinder and pump, which induces a vacuum around the corporal bodies, with a resultant increase in corporal blood inflow. This requires the application of a compression band around the base of the penis to restrict venous drainage and maintain rigidity. Compression rings cannot be left in place for longer than 30 minutes in order to avoid ischemic injury to cavernosal tissue. Patient satisfaction is generally low; up to 70% of men discontinue VEDs at a median of 1 month of use because its application is cumbersome and due to the cooler, cyanotic nature of the VED-erected penis.[88]

Penile Implant Surgery

Penile implant or penile prosthesis surgery, represents the first available treatment option for patients presenting with organic ED, with the first inflatable device described in 1973.[89] It remains an excellent option for patients who have attempted and failed to achieve satisfactory results with other modalities, have grown weary of second-line therapy use (ICI, intraurethral alprostadil, VED), or are not deemed candidates for vascular surgical options (see further on). Implants act solely to allow a patient to achieve a rigid erection on demand and have no effect on the patient's sensation, ability to ejaculate, or achieve orgasm.

Technical Considerations

There are two main classes of implants: malleable (or semirigid) and hydraulic (or inflatable). Semirigid prostheses consist of two malleable rods that are placed into the corpora cavernosa; they are manually shaped by the patient at the onset of sexual activity and are reshaped after sexual relations are completed. Inflatable implants are further subdivided and classified according to the configuration of the prosthesis: a two-piece inflatable, which consists of two cylinders attached to a scrotal pump; and a three-piece inflatable, which consists of two cylinders attached to a scrotal pump and a separate reservoir, which is generally placed extraperitoneally in the space of Retzius. Choice of implant is both surgeon- and patient-dependent. Malleable implants are less commonly employed in the modern implant era and tend to be implanted only occasionally with some uncommon exceptions. Our practice is to preferentially place three-piece implants, given their superior rigidity and girth, better concealability and zero rigidity in the deflated state. Two-piece implants are generally placed in patients who have an obliterated extraperitoneal space, have small bowel loops abutting the deep inguinal ring (patients who have undergone radical cystoprostatectomy), have a renal transplant, or have poor grip strength and may have difficulty deflating a three-piece implant.

Outcomes and Adverse Events

Patient and partner satisfaction are generally high following penile implant surgery, with satisfaction rates varying between 75% and 97% depending on the patient population and implant used.[89] This is mostly related to the excellent rigidity and spontaneity of these devices. The most significant complication of penile implant surgery is infection, with data from the most recent generation of penile prostheses varying from 0.7% to 3%.[90,91] Treatment of infection requires complete device removal, which can lead to difficulty with subsequent reimplantation due to scarring and decreased penile length and girth. Protocols for salvage implantation (infected device removal with simultaneous reimplantation) demonstrate an 84% success rate.[92] Other complications include component erosion (most often occurring in the infected implant), reservoir herniation, visceral erosion, device autoinflation, cylinder migration, and device malfunction.

Five-year mechanical failure rates range from 0% to 9% for currently available prostheses.[89]

Penile Revascularization Surgery

Given the myriad of causes for ED, penile revascularization (penile artery bypass surgery) currently serves as one of only two modalities with the potential to cure the ED patient without a future necessity for vasoactive medications or implant surgery (the other is crural ligation surgery). However, penile revascularization, unlike revascularization in patients with coronary disease or peripheral arterial insufficiency, is not successful in patients with CVD, as these patients have a significant underlying element of endothelial dysfunction and corporal smooth muscle dysfunction as the main factors leading to ED.[89] In addition, patients with ED secondary to diffuse atherosclerosis will have significant disease present in the small penile arteries, thereby ruling out the presence of an adequate recipient vessel.[93] Thus patient selection for revascularization surgery is of paramount importance, as it is most likely to be successful in a highly selected group of young men with an isolated arterial stenosis following pelvic trauma. Inclusion criteria for consideration for revascularization generally include young men (age is poorly defined, although most authorities would not revascularize men older than 40 years old), absence of vascular risk factors, absence of evidence for other etiologies of ED, absence of evidence of CVOD with evidence of pure arterial insufficiency (as described earlier), and the presence of focal occlusive disease in the common penile artery or cavernosal artery that is amenable to distal bypass by the previously outlined arteriographic criteria.[89,94]

Technical Considerations

The IEA has been identified as the ideal donor vessel for bypass. Although many bypass procedures have been identified (historically over 20 procedures in total), the most commonly utilized approach is to perform an IEA to dorsal artery bypass.[93] Given the paucity of data pertaining to the use of venous target vessels, the arterial revascularization adapted from Goldstein et al. is reported here (Fig. 191.6).[94,95]

A variety of scrotal incisions may be made to expose the dorsal artery at the base of the penile shaft. An abdominal incision is made to expose the rectus muscle, which is reflected medially, and the IEA is identified. It is then mobilized from its origin near the external iliac artery to a point near the umbilicus, where it is transected. It is then transferred through the posterior wall of the inguinal canal onto the dorsum of the penis. The abdominal incision is then closed. The adventitial layer of the distal aspect of the IEA and proximal aspect of the dorsal artery are stripped with microscissors, and a microsurgical simple interrupted anastomosis is performed with 10-0 nylon sutures. Following completion of the anastomosis and after achieving complete hemostasis, the penis is replaced in its anatomic position and the wound is closed.

Endovascular management of focal arterial occlusion has also been previously studied, with the majority of the reports published in the 1980s using balloon angioplasty without stenting.[96] Results are variable and poorly defined.

Outcomes and Complications

Data on outcomes following penile revascularization are sparse, with most studies limited by varying inclusion and exclusion criteria, lack of validated markers to evaluate success, and generally short-term follow-up.[93] In addition, the published studies have discrepant patient populations, use different anastomotic and bypass techniques, and frequently do not assess long-term patency. As a result, practice guidelines from the American Urological Association consider penile revascularization unproven and controversial.[97] Among these studies, subjective success rates vary depending on type or revascularization procedure, definition of successful outcome, and patient population; they range from 50% to 82% (Table 191.2).[98-103] Looking specifically at arterial revascularization surgery as already described, a recent review of 71 patients with 34-month mean follow-up demonstrated that 55% of men had IIEF scores qualifying them as having normal erectile function without the use of a PDE5 inhibitor.[98]

The most frequently reported complications include failure to improve erectile function, inguinal hernias, penile shortening,

Figure 191.6 Penile Revascularization. TABLE 191.2 Most Recent Published Reports on Outcomes of Penile Revascularization

Report	Number of Patients	Follow-Up (Months)	Success Rate (%)
Vardi et al.,[99]	35	60	49
Kawanishi et al.,[100]	51	60	66
Munarriz et al.,[98]	71	35	55
Kayigil et al.,[102]	110	60	64
Zuckerman et al.,[103]	17	37	82

loss of penile sensation, and—in cases where arterialization of the dorsal vein was used—glans hyperemia.[89,98]

Surgery for Veno-Occlusive Dysfunction

Current guidelines from the American Urological Association, given an absence of clear data demonstrating benefit to patients, do not recommend surgery to limit the venous outflow from the penis.[97] CVOD is now considered the result of damage to the cavernosal smooth muscle; thus the venous leak is a symptom of an underlying pathology that is not generally correctable through venous ligation.[89,93] Despite this, venous ligation surgery has been attempted for decades, with poor long-term results. However, crural ligation surgery among highly selected young patients with isolated crural venous leak (generally secondary to blunt perineal trauma) has demonstrated some medium-term efficacy.[104] One study of 15 patients with a mean age of 29 years and isolated crural venous leak demonstrated on DICC resulted in unassisted sexual intercourse in 71% of men after crural ligation surgery and 93% of men reported improved erectile function as quantified by the IIEF.[104] This confirmed results from a similar population of 11 patients, with a mean age of 28 years, with 82% improvement in erectile function.[105]

FUTURE THERAPEUTIC STRATEGIES

Given the significant amount of ED research that has been performed over the past decade, increased understanding of the physiology of erection and pathophysiology of ED has identified a myriad of potential targets for the treatment of ED. Studies focusing on medications targeting the central nervous system as well as innovative methods for targeting the NO/cGMP pathway, as PDE5 inhibitors do, are currently ongoing.[106] Gene therapy, focusing on signaling pathways for penile erection, has been effective in improving ED in a variety of animal models.[107] Two of the more exciting and promising therapeutic modalities currently evaluated in man are described in the following paragraphs, including endovascular stenting and stem cell therapy.

Endovascular Stenting—ZEN Trial

Initial results from the ZEN (Zotarolimus-Eluting Peripheral Stent System for the Treatment of ED in Males with Suboptimal Response to PDE5I) trial were published in late 2012, looking at the safety and feasibility of a balloon-expandable drug-eluting stent for patients with atherosclerotic ED and focal internal pudendal artery stenoses.[108] Patients with atherosclerotic ED and a suboptimal response to PDE5 inhibition as well as specific clinical, DDUS, and angiographic factors were prospectively enrolled in this trial, with a safety endpoint of a major adverse event 30 days postprocedure and a feasibility endpoint of four-point improvement in IIEF erectile function domain scores in greater than 50% of patients at 3 months. A total of 30 subjects with a mean age of 60 years were studied and 45 stents were placed. The majority of patients had known cardiovascular risk factors. Safety endpoints were met in all subjects, with 59% of patients in an intention-to-treat analysis meeting the feasibility endpoint at 3 months (unchanged at 6 months). Restenosis greater than 50% of the posttreatment luminal diameter was noted in 34% of patients at 6-month follow-up (32 lesions evaluated). Longer-term results are pending.

Stem Cell Therapy

The use of pluripotent stem cells as a curative therapy for ED has been evaluated in a number of animal studies and is currently being investigated in at least one phase I human clinical trial.[109] Stem cells are believed to be able to differentiate into the various cell types instrumental in erectile function; therefore, it was hypothesized that systemic or ICI of stem cells may replenish lost or deteriorating tissues contributing to ED, although this mechanism has not been proven in animals. A number of stem cell types—derived from bone marrow, adipose tissue, skeletal muscle, embryonic cells, endothelial progenitor cells, and umbilical cord blood—have been used in rats, with promising results.[109] One report of seven human patients undergoing treatment and three control patients with a long history of diabetes (mean 29 years) and ED refractory to medical therapy investigated the benefit of ICI of umbilical cord blood stem cells. In the experimental group, six patients reported some increase in rigidity, with two able to achieve penetration and maintenance with use of 100 mg of sildenafil at 6-month follow-up, compared with no improvement in the control group.[110] Further research is obviously needed to prove the feasibility of this treatment modality.

ERECTILE DYSFUNCTION IN MEN UNDERGOING VASCULAR SURGERY

Prevalence of Erectile Dysfunction in the Vascular Surgery Population

Given the significant cardiovascular risk factors and comorbidities present among patients requiring vascular surgical interventions, it is not unexpected that ED is a frequent and common complaint among patients both before and after abdominal aortic aneurysm (AAA) repair and treatment of aortoiliac disease. One study, looking at the prevalence of ED among a population of 137 vascular surgery patients, identified a 90% rate of ED

(defined as IIEF erectile function domain score less than 25), with moderate or severe ED in 70% of cases.[111] Among patients with an untreated AAA, the rate of moderate or severe ED was 82%. Another study looking at self-reports of preoperative sexual dysfunction in 56 AAA patients using SHIM scores described a 27% rate of ED in patients undergoing elective open AAA repair, 63% for those undergoing endovascular repair of AAA (EVAR), and 45% for those undergoing open repair for AAA rupture.[112] It should be noted that these figures are considerably higher than historically reported preoperative ED rates in AAA and aortoiliac occlusive disease patients, ranging from 22% to 39%, as previous studies had variable definitions of ED without the use of validated questionnaires or defined ED as only the most severe ED cases (IIEF erectile function domain score <11).[113,114]

Erectile Function Outcomes Following Definitive Therapy

Outcomes following AAA repair have recently been more extensively studied following a pair of randomized trials. The landmark Aneurysm Detection and Management (ADAM) study, randomized 1136 patients with 4.0- to 5.4-cm AAAs to surveillance versus immediate open repair.[115] Patients were evaluated by a nurse to rate their sexual function as normal versus impotent without the use of questionnaires. "Impotence" rates were significantly higher across patients randomized to immediate repair from 18 months to 4-year follow-up. Across groups, a steady and significant increase in ED was also noted, pointing to disease progression over time. Another rigorously performed study randomized 881 AAA patients to EVAR and open AAA repair and evaluated sexual function outcomes by use of the IIEF erectile function domain score.[116] Of note, patients had significant preoperative ED at baseline, with a mean IIEF score of 11.4 for the EVAR and 10.3 for the open group. At 1 year, there was a mean decline in IIEF of 2.5 and 2.3 for the EVAR and open groups, respectively, and a decline of 3 and 2.9 points, respectively, at 2 years, demonstrating no significant difference between the EVAR and open AAA repair groups. In a vasculopathic population such a decrease is likely age-related and not related to the surgical intervention.

ED rates after open and endovascular aortoiliac procedures have been evaluated in a single retrospective study of 116 patients following open aortoiliac reconstruction or percutaneous transluminal balloon angioplasty and/or stenting of the common and/or external iliac artery.[117] Patients were evaluated with the IIEF postoperatively and were asked to recall their sexual function before surgery. A significant decline in erectile function was recorded in both groups.

ED following vascular repair has been associated with bilateral internal iliac interruption during EVAR, as would be expected.[118] Internal iliac embolization prior to EVAR has also demonstrated significant increases in reported ED rates across a number of studies.[119] Therefore preservation of the internal iliac artery has been recommended when possible. In addition, adjunct internal iliac revascularization prior to EVAR may improve erectile outcomes, with reports of no change in sexual function and even improvement in erectile ability in a single patient following this procedure.[120]

Given these findings, it would be prudent for the vascular surgeon to consider counseling regarding erectile function changes following vascular surgical procedures. A previous report has shown that 91% of patients undergoing open AAA repair or EVAR do not recall receiving preoperative information regarding the risk of a possible negative impact on sexual function.[121]

CONCLUSIONS

ED is a highly prevalent condition and a potential marker for significant vascular disease; it is frequently unaddressed by vascular surgery practitioners despite the significant overlap of risk factors between ED and cardiovascular/peripheral vascular disease. Although treatment is often easily achieved with use of a PDE5 inhibitor, diagnostic evaluation in a subset of patients may help to better direct patient care and can provide prognostic information regarding potential response to therapy. Further study using validated instruments to quantify erectile function is needed in order to fully appreciate the effect of vascular reconstructive surgery on ED rates.

ACKNOWLEDGMENTS

We would like to gratefully acknowledge the assistance of Irwin Goldstein, MD, Director of Sexual Medicine at San Diego Sexual Medicine, Alvarado Hospital, San Diego, California, in providing us with images from selective internal pudendal arteriography and intraoperative photographs from his extensive experience with penile revascularization.

OVERALL RESULTS OF TREATMENT 2499

Complex regional pain syndrome (CRPS), previously called posttraumatic pain syndrome (PTPS), causalgia, or reflex sympathetic dystrophy (RSD), is one of the most poorly understood and frequently misdiagnosed entities encountered in clinical practice. This painful condition can develop after damage to peripheral nerves in a variety of settings. In susceptible patients, the initiating event may be relatively insignificant or even obscure.

EPIDEMIOLOGY/ETIOLOGY

The exact incidence of CRPS is unknown, but it has been estimated to occur in at least 1% to 12% of patients with peripheral nerve injury.[1] Others have reported that there are 50,000 new cases of CRPS in the United States annually.[2] CRPS has a male to female (particularly postmenopausal) ratio of 1:4 to 1:2, and is seen more commonly with increasing

Abstract

With the development of new arterial revascularization techniques, sympathectomy has ceased to be a routine method for improving arterial flow in patients with ischemia; however, with the development of video-assisted thoracoscopy, it has been increasingly used for the treatment of hyperhidrosis.

In this chapter we initially contextualize this surgical technique, describe the anatomical and physiologic aspects of the sympathetic nervous system, and analyze the current indications, techniques, results, and complications of both thoracic and lumbar sympathectomy.

ischemia
complex regional pain syndrome

age.[3] Three causes of CRPS have been identified: traumatic, nontraumatic, and idiopathic.

Traumatic

Traumatic causes include fractures, dislocations, sprains, crush injury, burn, and iatrogenic injury. Most cases of CRPS are posttraumatic.[4] It occurs acutely in about 7% of patients with limb surgery, limb fractures, or other injuries. CRPS has been reported in 0.2% to 11% of patients with Colles fracture[5] and in 12% to 20% of patients with hemiplegia.[6] The incidence of CRPS type II (as defined later) has varied from as low as 1.5% in the Vietnam War to 8% in the Persian Gulf War[7] to as high as 32% in the Civil War.[8] CRPS has also been reported in patients with spinal cord and brain injuries, with an incidence of 5% to 12%.[7-9]

Recently, Hassantash and colleagues reported the results of a meta-analysis of causalgia, including 110 articles and 1528 cases[10] High-velocity missiles caused at least 77% of the injuries. The median nerve, alone or in combination with other nerves (56%), and the sciatic nerve (60%) were most commonly involved. In 92% of cases the nerve injury was incomplete.

Most cases resolve within the first year, with a smaller subset progressing to chronic stage. This is often associated with a change from "warm CRPS," where inflammatory characteristics dominate to "cold CRPS" in which autonomic features dominate.[11]

Nontraumatic

Nontraumatic causes include prolonged bed rest, neoplasm, metabolic bone disease, deep venous thrombosis, myocardial infarction, and stroke. The incidence of CRPS in patients with myocardial ischemia is between 5% and 20%.[1] Chronic painful conditions of the upper extremity subsequent to myocardial infarction have been grouped into a category designated *shoulder-hand syndrome.* These conditions have been reported in 15% of patients, but this percentage has been reduced significantly because of much more rapid post infarct mobilization.[9]

Idiopathic

In idiopathic CRPS, no cause can be identified.

CLASSIFICATION AND TERMINOLOGY

Box 192.1 lists more than 40 terms that describe CRPS. The most common include *causalgia*, both minor and major (*causalgia* is derived from the Greek *causos*, meaning "heat," and *algos*, meaning "pain"—that is, a burning pain)[10]; *minor* and *major traumatic dystrophy*, describing the intensity of the syndrome when it develops after an injury that does not damage a peripheral nerve; *shoulder-hand syndrome*, or RSD involving the entire upper extremity; and *Sudeck's atrophy*, a posttraumatic reflex dystrophy with bone involvement demonstrable on radiographs.

BOX 192.1 Terms Used to Describe Complex Regional Pain Syndrome (Causalgia and Posttraumatic Pain Syndromes)

- Acute atrophy of bones
- Algodystrophy
- Algoneurodystrophy
- Causalgia
- Causalgia-like states
- Chronic segmental arterial spasm
- Chronic traumatic edema
- Disuse phenomenon
- Homans minor causalgia
- Major causalgia
- Mimocausalgia
- Minor causalgia
- Mitchell causalgia
- Painful osteoporosis
- Peripheral trophoneurosis
- Posttraumatic dystrophy
- Posttraumatic fibrosis
- Posttraumatic neurovascular pain syndrome
- Posttraumatic osteoporosis
- Posttraumatic pain syndrome
- Posttraumatic painful osteoporosis
- Posttraumatic spreading neuralgia
- Posttraumatic sympathalgia
- Posttraumatic sympathetic dysfunction
- Posttraumatic sympathetic dystrophy
- Posttraumatic vasomotor disorders
- Reflex neurovascular dystrophy
- Reflex dystrophy
- Reflex dystrophy of the extremities
- Reflex nervous dystrophy
- Reflex sympathetic dystrophy
- Shoulder-hand syndrome
- Steinerocher shoulder-hand syndrome
- Sudeck atrophy
- Sudeck osteodystrophy
- Sudeck syndrome
- Sympathalgia
- Sympathetic neurovascular dystrophy
- Traumatic angiospasm
- Traumatic edema
- Traumatic neuralgia
- Traumatic vasospasm

To resolve the confusion surrounding the various terms used to describe this syndrome, Stanton-Hicks and associates convened a consensus committee of the International Association for the Study of Pain to discuss the nomenclature of causalgia and RSD.[12] As a result, the term *complex regional pain syndrome* was developed to replace the terms *causalgia* and *reflex sympathetic dystrophy.* CRPS includes a spectrum of conditions with somewhat similar clinical manifestations that often are grouped together for the sake of clinical utility.[13,14] Hallmarks of this syndrome include dysfunction and pain of a duration or severity out of proportion to what might be expected from the initiating event. The new classification scheme is based on a descriptive method that should allow future modifications to reflect new scientific findings.[13,14]

Summary of Key Features

Three components characterize CRPS:

1. *Complex:* This term denotes the dynamic and varied nature of the clinical presentation in a single person over time and among persons with seemingly similar disorders. It also reflects the autonomic, cutaneous, motor, inflammatory, and dystrophic changes that distinguish this syndrome from other forms of neuropathic pain.
2. *Regional:* This term describes the wide distribution of clinical symptoms and findings beyond the area of the original lesion,

and is considered a key characteristic of the syndrome. The distal part of a limb is usually affected, but occasionally CRPS occurs in other parts of the body (e.g., the face or torso) and may spread to other body parts.

3. *Pain:* The hallmark of CRPS is pain that is out of proportion to the initiating event. The designation refers to spontaneous burning pain and thermally or mechanically induced allodynia (i.e., pain from stimuli that are not normally painful).

Syndrome Types

Two types of CRPS have been recognized. Type I corresponds to the former term *RSD*, and type II corresponds to the former term *causalgia.* The definitions of CRPS types I and II contain criteria that exclude (1) pain and other findings that are physiologically, anatomically, and temporally appropriate to some form of injury, and (2) myofascial pain syndrome. The terms *sympathetically maintained pain* (SMP) and *sympathetically independent pain* (SIP) are used to describe types of pain that can be associated with a variety of pain disorders, including CRPS types I and II.

Diagnostic Criteria

The diagnostic criteria for CRPS type I, as adapted from Stanton-Hicks and coworkers[12] and Merskey and Bogduk,[15] are as follows:

- History of an inciting noxious event.
- Spontaneous pain, hyperalgesia, or allodynia beyond the territory of a single peripheral nerve and disproportionate to the initiating event.
- Edema, skin blood-flow abnormality, or abnormal sudomotor activity in the region of the pain that has developed since the initiating event.
- Absence of other conditions that would account for the degree of dysfunction and pain.

The diagnostic criteria for CRPS type II are as follows:

- History of a nerve injury.
- Spontaneous allodynia or pain is not necessarily limited to the region of the injured nerve.
- Edema, temperature and skin blood-flow changes, abnormal sudomotor activity, or motor dysfunction in the region of the pain that has developed since the original nerve injury.
- Absence of other conditions that would account for the degree of dysfunction and pain.

CRPS, NOS (not otherwise specified), is a subtype that describes patients who only partially meet the current criteria, but were diagnosed with CRPS under previous criteria.[15-18]

PATHOGENESIS

Theories and Components

Many theories have been proposed to explain CRPS, but none has been universally accepted. Most were developed to explain the causalgia associated with nerve injury (CRPS type II). Past theories included the artificial synapses theory by Doupe,[19] the vicious cycle of reflexes by Livingston,[20] and the gate control theory.[21] Presently, major theories which have been proposed to explain the causes/pathogenesis of CRPS include the following:

Exaggerated Local Inflammatory Response Theory/Neurogenic Inflammation

The painful affected limb is usually hot, red, swollen, and has reduced function, all of which are signs of inflammation. Recent studies have shown that inflammatory mediators (e.g., TNF-α and interleukin-6) are elevated in blister fluid and blood samples obtained from affected limbs.[22] This theory is supported by the fact that corticosteroids are often successful in the treatment of patients with acute CRPS. The reported efficacy of low-dose intravenous immunoglobulins (IVIG) could be due to an antiinflammatory effect.[23]

It has also been suggested that localized neurogenic inflammation may be involved in the production of vasodilation, acute edema, and increased sweating. Neuropeptides released from sensory neurons, cause skin reddening and swelling, which is seen in affected limbs.

Complex Regional Pain Syndrome as a Sympathetically Mediated Syndrome

There is a low centrally mediated sympathetic outflow to cutaneous vasoconstrictors in the affected limb, which may produce red and warm extremities.[24] It has been suggested that the permanent cold temperature in some cases of late CRPS may be due to endothelial rather than sympathetic dysfunction.[24] All four randomized controlled trials that were conducted to assess intravenous regional sympathetic block (IVRSB) have been negative.[24] Many clinicians using this method have demonstrated that it reduced pain in some patients,[24] and one wonders whether this effect was the result of the application of tourniquet. It should also be noted that local anesthetic application to the sympathetic ganglia (e.g., the stellate or lumbar sympathetic block) can relieve pain for the short term in selected patients;[24] however, repeated applications do not prolong that effect.[25] The SMP can be reduced by sympathetic blockade, particularly in the early stage of CRPS, but is rare in long-standing CRPS.[26]

Complex Regional Pain Syndrome as the Result of Limb Ischemia/Reperfusion Injury

CRPS-I is felt to be an abnormal inflammatory response to a deep tissue injury, producing a picture of a compartment syndrome with resultant, oxygen-free radical-induced microvascular dysfunction, further ischemia and inflammation, and nociceptor excitement.[24] Groeneweg et al.,[27] in a recent pilot study showed that tadalafil (a phosphodiesterase inhibitor), reduced pain in some CRPS patients with cold limbs. This was thought to be secondary to its vasodilator property.

Central Sensitization Theory

This theory is thought to be important in most chronic pain.[24] It is believed that *N*-methyl D-aspartate (NMDA) receptors may play an important role in central sensitization. In two

randomized clinical trials, low-dose IV ketamine (an NMDA antagonist) dramatically reduced CRPS pain, which may indicate an important role for such central sensitization.[24]

Complex Regional Pain Syndrome Secondary to Nerve Damage

The similarity of CRPS syndrome to small-fiber-predominant polyneuropathy stimulated the idea that regionally restricted small nerve fiber damage may occur in CRPS, rather than sympathetic dysfunction, and may be responsible for CRPS signs.[24] Studies of CRPS-amputated limbs and skin biopsies showed small fiber loss.[24] Therefore it is postulated that CRPS-I syndrome may, in fact, represent neuropathic pain syndrome.

Complex Regional Pain Syndrome as an Autoimmune Disorder

Goebel[24] and Blaes et al.[28] showed evidence for antineuronal autoantibodies in 30% and 90% of patients with CRPS. Goebel et al. also demonstrated, in a randomized clinical trial, that a single infusion of low-dose IVIG effectively reduces pain in patients with long-standing CRPS.

Cortical Reorganization Theory

Functional MRI studies over the last several years have shown that sensory representations of CRPS-affected limbs are altered, that the degree of this alteration corresponds to the pain intensity, and that reduction in pain is associated with normalization.[24] There are also changes in the motor cortex. CRPS patients often feel alienation from their affected limb; the limb can feel strange and disfigured. Computer-based graded motor imagery (GMI), which consists of exercise to train the brain in better recognizing the affected limb, can decrease swelling and pain in some CRPS patients.[24] The mirror therapy (advocated by McCabe et al.).[24,29] for the treatment of CRPS requires that the patient hides the affected limb behind a mirror that is placed perpendicular to the body midline. When looking into the mirror and performing bilateral synchronized gentle movement, the affected limb (the reflection of the unaffected limb in the mirror) has a normal look and moves normally. This therapy has been shown to minimize both early and late pain in these patients after stroke.

CLINICAL PRESENTATION

CRPS type I can occur in any age group, with a female-male ratio of 2 : 1. Although type I has been reported in children, it is not as disabling as in adults.

Symptoms and Signs

The clinical criteria for the diagnosis of CRPS, as outlined by Stanton-Hicks and colleagues,[12,14] are summarized in Fig. 192.1 and Box 192.2.[12,14]

BOX 192.2 Diagnostic Criteria for Complex Regional Pain Syndrome

Clinical Symptoms and Signs

- Burning pain hyperpathia or allodynia
- Temperature or color changes edema
- Hair or nail growth changes

Laboratory Results

- Thermometry or thermography bone radiography
- Three-phase bone scan quantitative sweat test response to sympathetic block

Interpretation

If total number of positive findings is
- >6: Reflex sympathetic dystrophy probable
- 3–5: Reflex sympathetic dystrophy possible
- <3: Reflex sympathetic dystrophy unlikely

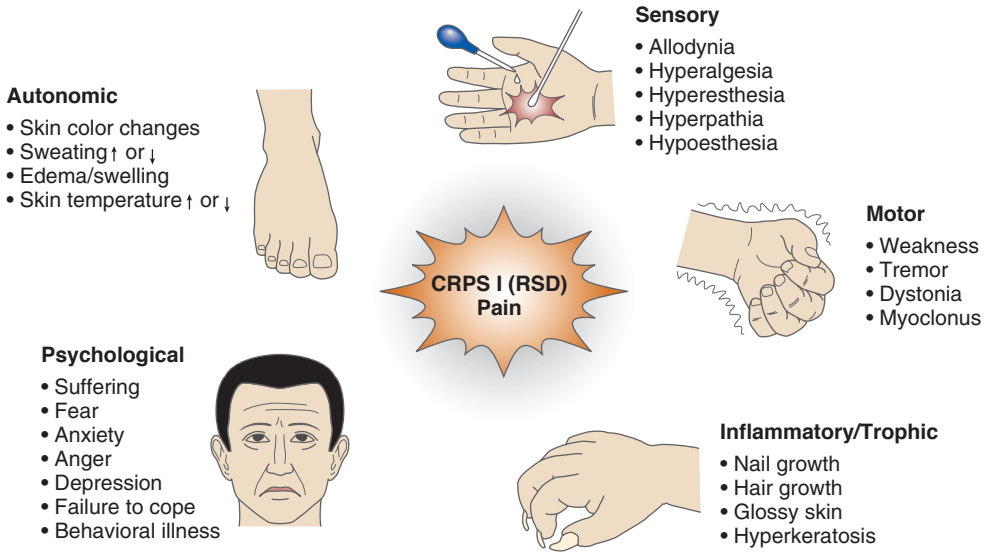

Figure 192.1 Clinical features of complex regional pain syndrome *(CRPS)* type I (reflex sympathetic dystrophy *[RSD]*).

Pain: Pain is a necessary symptom for the diagnosis of CRPS. It is located in the affected extremity and is disproportionate to what would be expected from the initial event. It may be spontaneous or evoked and is usually reported as burning or diffuse pain. The pain may also be described as throbbing or aching, intermittent or continuous, and exacerbated by physical or emotional stress. The pain is not consistent with the distribution of a peripheral nerve, even if the initial injury involved such a nerve. This important feature distinguishes CRPS from pain of other causes and from more specific neuropathic pain disorders. The patient often adopts a protective posture to guard the affected extremity.

Sensory Changes: Sensory changes of CRPS are usually reported at some stage and include allodynia and hyperesthesia in the region of the pain. Allodynia may occur in response to thermal stimulation (cold or warm), deep pressure, light touch, or joint movement.

Sympathetic Dysfunction: Sympathetic dysfunction in CRPS is reported as a sudomotor or vasomotor instability in the affected extremity compared with the unaffected extremity. This dysfunction may vary in severity at different times.

The patient may report that the extremity is warm and red or cold and blue, purple, or mottled. Veldman and associates reported that 92% of patients had altered skin temperature.[30] Sweating, particularly of the palms or soles, may be reported as increased, decreased, or unchanged. Normal sympathetic function may be present at certain times. Swelling can occur at any stage of the syndrome and is typically peripheral; it may be intermittent or permanent and may be exacerbated by the dependent position of the extremity. There can also be pitting or brawny edema.

Trophic Changes: Trophic changes of the skin may occur later in the course of the syndrome. The nails may be atrophic or hypertrophic. Hair growth and texture may be decreased or increased, and the skin may become atrophic. Motor dysfunction includes dystonia, tremor, and loss of strength of the affected muscle groups. Joint swelling and stiffness may also be reported, particularly of the digits.

Budapest Consensus Criteria

The Budapest Consensus Workshop introduced criteria to identify CRPS and rule out other neuropathic conditions. CRPS patients must report symptoms of, and show signs on physical examination, in the following categories: vasomotor, sensory, motor/trophic, and sudomotor/edema (Figs. 192.1 and 192.2; Box 192.3).

Comprehensive Adjunctive Clinical Tests

With the foregoing features in mind, the clinical evaluation can be enhanced by focusing on particular aspects or using adjunctive tests.

Sensory Examination: Sensory impairment can be positive (allodynia, mechanical and thermal hyperalgesia) or negative (hyperesthesia, hypalgesia). These sensory impairments can be localized (glove-like) or generalized. Quantitative sensory testing to confirm the clinical findings of sensory abnormalities can be applied; however, this is not specific for patients with CRPS.[31]

Figure 192.2 A patient with chronic complex regional pain syndrome exhibits dystonic posture of the right ankle along with trophic skin changes. (Figure 2 from Freedman M, Greis AC, Marino L, et al. Complex regional pain syndrome: diagnosis and treatment. *Phys Med Rehabil Clin N Am*. 2014;25(2):291-303, 293.)

BOX 192.3 Budapest Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

1. Continuing pain that is disproportionate to any inciting event
2. Patient must report one symptom in three of the four following categories:
   a. *Vasomotor:* Temperature asymmetry and/or skin color changes and/or skin color asymmetry
   b. *Sensory:* Hyperesthesia and/or allodynia
   c. *Motor/trophic:* Decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or tropic changes (hair, nail, and/or skin)
   d. *Sudomotor/edema:* Edema and/or seating changes and/or sweating asymmetry
3. Patient must exhibit one sign at the time of evaluation in two or more of the following categories:
   a. *Vasomotor:* Temperature asymmetry and/or skin color changes and/or asymmetry
   b. *Sensory:* Hyperalgesia to pin prick and/or allodynia to light touch and/or deep somatic pressure and/or joint movement
   c. *Motor/trophic:* Decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, and/or skin)
   d. *Sudomotor/edema:* Edema and/or sweating changes and/or sweating asymmetry
4. No other diagnosis that better explains the signs and symptoms

Modified from Harden RN, Bruehl S, Perez RS, et al. Validation of proposed diagnostic criteria (the "Budapest Criteria") for complex regional pain syndrome. *Pain*. 2010;150(2):274.

Sudomotor Sympathetic Examination: Resting heat output can be estimated by skin impedance,[32] by quinizarin or cobalt blue testing,[33] or as part of the quantitative sudomotor axon reflex test,[34] which measures resting sweat output by hygrometry and changes evoked by iontophoresis of acetylcholine into the skin.[35] These tests are useful diagnostic tools, but they are difficult to conduct and are generally not recommended for the routine diagnosis of CRPS.[31,36]

Vasomotor Examination: Simultaneous temperature measurements of both the affected and unaffected extremities are taken

at corresponding anatomic sites. The temperature of the digit pads, palms, soles, forearms, and calves can be measured with noncontact thermometry or thermography. Serial measurements should be taken, because peripheral temperatures vary widely under normal circumstances. Skin perfusion can be evaluated visually or by pulse oximetry.

Motor Dysfunction: The presence of dystonia, tremor, and changes in strength can be measured clinically. Objective measurements should be taken (e.g., apposition and opposition pinch strength, grip, weight-bearing on the lower extremity).

Psychological Testing: Psychological testing has not been validated in CRPS. The psychiatrist generally uses familiar instruments as part of the initial assessment and follow-up.[37]

Neurophysiologic Testing: The diagnosis of CRPS type II requires a peripheral nerve lesion, and CRPS may develop following a central nervous system lesion (brain tumor or brain infarct). It is therefore important to confirm or exclude peripheral nerve and central nervous system lesions. Nerve conduction studies may show discrete abnormalities secondary to edema or peripheral vasoconstriction.[31] Distinct abnormalities exceeding 20% of normal values should be observed and may indicate a peripheral nerve lesion, which can be noted in patients with carpal tunnel syndrome or CRPS type II. Somatosensory evoked potentials after ulnar-median or tibial nerve stimulation testing are usually normal in patients with CRPS type I; however, these tests can be abnormal in patients with CRPS type II. Electromyograms are usually not performed in patients with CRPS, because they are painful and may exaggerate the pain of CRPS. Overall, these tests can be useful in the diagnosis of CRPS types I and II and to confirm peripheral nerve or central nerve system lesions; however, the findings are not specific.

Inflammatory Assessment: Neuroinflammatory mediators such as substance P, bradykinin, and calcitonin gene-related peptide are usually increased in patients with CRPS; however, other systemic inflammatory markers, such as C-reactive protein, erythrocyte sedimentation rate, and leukocyte count, are not elevated.[38]

DIAGNOSTIC EVALUATION

Radiographic Findings

The primary radiographic manifestations in patients with CRPS are diffuse osteoporosis with severe patchy demineralization, especially of the periarticular regions, and subperiosteal bone resorption.[31] However, these changes are late and nonspecific.

Three-Phase Bone Scans: Accelerated blood flow in the diseased limb combined with increased, diffuse activity during the blood-pool phase and increased periarticular uptake in the delayed static phase is considered pathognomonic for CRPS (Fig. 192.3). A meta-analysis of 19 articles on the use of three-phase bone scans in patients with CRPS revealed a poor sensitivity of 50%. Therefore many believe that bone scans are not accurate enough for the diagnosis of CRPS.[39]

Magnetic Resonance Imaging: Magnetic resonance imaging (MRI) may reveal characteristic findings during the course of the disease.[31] Skin thickening and changes in bone signal intensity in carpal and metacarpal bones, along with effusions in adjacent joints, may be related to the acute and early stages of CRPS. However, several studies have suggested that the consequences of surgery or trauma may mimic CRPS type I–like MRI findings; therefore, MRI is usually not used as a screening method, but it may be helpful in excluding other disease entities.

Figure 192.3 Three-phase bone scan in complex regional pain syndrome of the left hand, demonstrating osteopenia. (From Schurmann M, Gradl G, Rommel O. Early diagnosis in post-traumatic complex regional pain syndrome. *Orthopedics*. 2007;30:450-456.)

Diagnostic Sympathetic Blockade

The validity of a clinical diagnosis of CRPS can be greatly strengthened by a positive response to sympathetic blockade. If there is no relief from pain for the duration of the complete sympathetic blockade, the diagnosis of CRPS is less likely. A documented increase in skin temperature of 1°C to 3°C confirms the success of sympathetic blockade. Patients should be encouraged to quantify the degree of pain relief experienced (e.g., 100% relief, 50% relief). The degree of pain relief a patient experiences with such a blockade is an excellent predictor of how much relief can be expected from surgical sympathectomy.[40] Caution should be exercised, however, because sympathectomy can provide some degree of nonspecific relief of almost any pain, including ischemic pain.[40,41] CRPS pain is usually dramatically relieved by sympathetic blockade (almost always 75% to 100% relief), whereas relief of pain from other causes is usually only mild to moderate (25% to 50% at most).

Sympathetic blockade can be achieved by the intravenous delivery of an alpha-blocking agent (e.g., phentolamine), intravenous regional blockade with bretylium, Bier blockade, differential spinal blockade, epidural blockade, and local anesthetic blockade of the paravertebral lumbar sympathetic

chain. Many consider paravertebral lumbar blockade using lidocaine or bupivacaine most effective because it blocks both sensory and motor nerves.[40]

Differential Diagnosis

Causalgia-like pain can occur if a nerve is caught in a suture, entrapped by scar, or compressed by surrounding structures. Nerve entrapment must be considered when causalgia appears immediately after an operation. If peripheral nerve entrapment is the cause, there is often a "trigger point" where focal application of pressure causes sharp pain. The pain can be relieved by the infiltration of a small amount of local anesthetic at that point (see Chapter 45).

Patients who present with cutaneous signs and symptoms characteristic of early stages of CRPS are sometimes thought to have Raynaud syndrome; however, with Raynaud syndrome, the patient's symptoms should be episodic, related principally to cold exposure, and relieved by warmth. The pain of peripheral neuritis is often burning and associated with hyperesthesia and vasomotor phenomena. However, the clinical syndrome associated with peripheral neuritis is more anatomically diffuse and gradual in onset, and the patient has no history of trauma or another discrete precipitating event. Other conditions must be kept in mind, including inflammatory or infectious disorders, such as rheumatic arthritis, unilateral vascular occlusive disease, bone or soft tissue injury, thoracic outlet syndrome, compartment syndrome, and psychological disorders.

NONSURGICAL TREATMENT

In the past, when there was no effective treatment, CRPS frequently resulted in chronic invalidism, emotional deterioration, and drug addiction. Thus the proper treatment of CRPS is based on prevention and early recognition. For patients known to be susceptible to CRPS, such as those who have hemiplegia or myocardial infarction, early mobilization of an injured extremity is critical. When early sympathetic dystrophic changes occur, pain relief and active use of the hand, arm, or leg are indicated. Passive motion by physical therapists should be avoided because it may increase the pain and edema. Opiate analgesics, when needed, should be used conservatively. Splinting the hand in a functional position may help.

Few evidence-based treatment modalities for CRPS are available.[41-47] Treatment of CRPS usually requires a multidisciplinary approach, including a neurologist, anesthesiologist, vascular surgeon, orthopedic specialist, psychologist, and physical therapist.

Physical Therapy

Physical therapy should be considered not only essential but also the first line of treatment for patients with CRPS. Intensive physical therapy should be initiated, including full range-of-motion exercises and whirlpool exercises. Aggressive therapy should be avoided, however, because patients with CRPS have an exaggerated response to painful and nonpainful stimuli,[48] and any pain may exaggerate the syndrome. The primary objective of physical therapy is goal-oriented functional restoration, which includes (1) mobilization, swelling control, and isometric strengthening; (2) desensitization of the affected region; (3) stress loading, isotonic strengthening, range of motion, postural normalization, and aerobic conditioning; and (4) vocational rehabilitation.[14] Physical therapy should be combined with pharmacologic therapy.

Recently, Barnhoorn et al. reported on a randomized trial of pain exposure physical therapy (PEPT) compared with conventional treatment in CRPS syndrome type 1 and could not conclude that PEPT is superior to conventional treatment.[49]

Mirror Visual Feedback: Mirror visual feedback has been used in the early stages of CRPS type I. The effect of this therapy is based on findings that visual input from a moving, unaffected limb re-establishes the pain-free relationship between sensory feedback and motor execution of the affected limb. McCabe and coworkers reported good results in patients with early stages of CRPS type I.[29]

Recently, Vural et al. reported that in stroke patients with CRPS type 1, addition of mirror therapy to conventional stroke rehabilitation program provides more improvement in pain perception and motor functions of the upper limb, compared with conventional therapy without mirror therapy.[50]

Transcutaneous Electrical Nerve Stimulation: Transcutaneous electrical nerve stimulation (TENS) has been used to treat CRPS.[47,51] It may be tried before more aggressive treatment is attempted. In the hands of an experienced practitioner, the success or failure of TENS will be apparent by the third to fifth treatment.[51]

Acupuncture and Electroacupuncture: Chan and Chow reported on the use of acupuncture in more than 20 patients with CRPS after hand injuries.[52] A total of 14 patients experienced marked permanent improvement, and four had some improvement.

Pharmacologic Therapy

Pharmacologic therapy, particularly as it applies to early stages of CRPS, can be combined with intermittent sympathetic blockades and physical therapy. Drug therapy may require nonspecific analgesics, but these should be superimposed, only when necessary, on a "background" of medication designed to attenuate the symptoms by direct effect. Of these, phenytoin, amitriptyline, carbamazepine, and baclofen can be effective, and they are usually used in that order owing to increasing side effects. Tricyclic antidepressant amitriptyline hydrochloride (Elavil) is used in doses of 50 to 75 mg nightly.

Opioids: Opioids inhibit central nociceptive neurons through interaction with μ-receptors. There are no long-term studies of oral opioids in the treatment of neuropathic pain, including CRPS; however, the expert opinion of pain clinicians is that opioids should be part of a comprehensive pain regimen protocol. Opioids should be tried early in the course of CRPS, not as a "last resort."

Tricyclic Antidepressants: Tricyclic antidepressants are some of the best-studied drugs in the treatment of neuropathic pain, and they have shown an analgesic effect. They inhibit the reuptake

of monoaminergic transmitters. There is solid evidence that the reuptake and noradrenaline blocker amitriptyline and the selective noradrenaline blocker desipramine produce pain relief in several neuropathies.

GABA-Agonists: GABA-agonists such as gabapentin (Neurontin) have also been used in the treatment of CRPS. The action of gabapentin probably includes the inhibition of calcium channels.

α-Adrenergic Blocking Agents: The use of α-adrenergic blockers is based primarily on the fact that patients with CRPS have altered blood flow as a result of increased local secretion of norepinephrine and vascular endothelial hypersensitivity. Inhibition of the receptors leading to vascular dilation and increased blood flow may be helpful. Pain relief following intravenous phentolamine administration has been suggested as a diagnostic tool, as well as a prognostic guide for favorable response to sympathetic blockade.[44,53] Its 15-minute plasma half-life precludes its use as a therapeutic modality. Other medications include phenoxybenzamine and prazosin.[44,45] Phenoxybenzamine has antiadrenergic effects and is an irreversible α-antagonist and has been shown to be beneficial in treating CRPS. It is considered a third-line agent and works best in cases lasting less than 3 months.[53]

Oral β-Blocking Agents: Propranolol, which antagonizes serotonin, has been partially successful.[43,44]

Oral Calcium Channel Blocking Agents: These agents produce smooth muscle relaxation of the arteriole walls, leading to increased blood flow.

Bisphosphonate Therapy: This therapy is based on the concept that pain results from osteopenia as part of CRPS. These are potent inhibitors of osteoclastic activity, which are used for management of osteoporosis and other metabolic bone diseases. Their primary action is reduction of bone turnover.

With recent publication of results from a randomized clinical trial with neridronate,[54] there is fairly convincing evidence that various bisphosphonates can significantly relieve spontaneous and stimulus-evoked pain, improve functional status, and have an acceptable safety profile in patients with early disease (<6 months duration) and abnormal uptake in three-phase bone scintigraphy. Most studies had a short follow-up period, but in the largest and most recent study, improvement seen after neridronate treatment was sustained or even better over a follow-up period of at least 1 year. However, the doses required for long-term remission are quite high (100 mg neridronate or 90 mg pamidronate, each given IV 4 times over 10 days).[55]

Five randomized controlled trials have reported oral and IV alendronate and IV clodronate, pamidronate, and neridronate to be effective in improving physical function and reducing pain in patients with CRPS type 1, with tolerability and a good profile of safety.

Nonsteroidal Antiinflammatory Drugs: These drugs inhibit the enzyme cyclooxygenase (Cox), which leads to decreased production of the prostaglandins (which mediate inflammation and hyperalgesia) and thromboxanes that increase nociceptor sensitivity to painful stimuli and promote vascular constriction.

In most cases, patients are started on analgesics and NSAIDS and some guidelines recommend using the WHO ladder, except for strong opioids.[55] However, these are usually ineffective in sufficiently reducing pain; therefore, they are often followed by medications used for the treatment of neuropathic pain.

Steroid Therapy. These are potent antiinflammatory agents that decrease tissue edema, which decreases pain and improves joint motion. Prednisone, prednisolone, and methylprednisolone are commonly used.[44] The usual starting dose of prednisone is 60 mg/day. The dose is tapered every 3 days by 5 mg, so the total course of therapy lasts about 5 weeks.

Sympathetic Blockade

Because many patients experience at least a temporary response to nonoperative treatment in the early stages of CRPS, a common error in management is persisting with such treatments too long and shifting repeatedly from one to another. This subjects patients to wasted time and expense and prolonged suffering, and it may also compromise their chances of obtaining complete and lasting relief by surgical sympathectomy. Thus if the measures described earlier are not effective in relieving the patient's symptoms promptly, or if the symptoms are exacerbated over the course of several days, the physician should proceed directly to sympathetic blockade, which is both diagnostic and therapeutic.

An initial sympathetic blockade is appropriate in the early stage (<6 months) to confirm the diagnosis and test the procedure's therapeutic potential. The rapid pain relief gained from a sympathetic blockade can be extremely helpful psychologically. Also, the condition may be reversible at this stage, and complete remission can sometimes be achieved, particularly in patients who experience long-lasting relief from serial sympathetic blockade, thus allowing aggressive physical therapy. When relief is short-lived, however, repeated blockade is counterproductive and expensive. Sympathetic blockade of the affected extremity has been used as an alternative therapy for patients with CRPS, but proof of its effectiveness is scanty.[56]

Sympathetic blocks involve injection of local anesthetics along the lumbar sympathetic chain for lower limb CRPS, or stellate ganglion for upper limb CRPS, which is done under fluoroscopic guidance. A good response is categorized by an increase in temperature in the affected extremity, without a sensory or motor block, reduced pain, improved range of motion, and decreased allodynia.[57] If there is any short-term benefit, block can be repeated. These blocks are usually more beneficial in patients who demonstrate sympathetically mediated symptoms. Response duration and efficacy may vary. Success is expected to be greater in patients with SMP than in patients with sympathetic independent pain.[2]

Several uncontrolled studies have reported on the effect of sympathetic blockade in patients with CRPS. About 85% of patients reported positive results, but fewer patients (60%) reported long-term relief.[40,58] Other authorities have questioned the role of the sympathetic system in the pathogenesis of CRPS and therefore its role in treatment.[59,60] A Cochrane review of local anesthetic sympathetic blockade for CRPS concluded

that the published evidence is too scarce to support the use of sympathetic blockade as the "gold standard" treatment for CRPS.[61] However, it continues to be used at various centers worldwide.[62,63]

Rocha et al. reported the results of a double-blind randomized study of thoracic sympathetic block for the treatment of CRPS type 1. CRPS type 1 patients were treated with standardized pharmacologic and physical therapy and were randomized to either thoracic sympathetic block or control procedure as an add-on treatment. Clinical data, pain intensity and interference, pain dimensions, neuropathic characteristics, mood, upper limb function, and quality of life were assessed before, at 1 month, and 12 months after the procedure. Thirty-six patients were included, 17 of which had the thoracic sympathetic block. The average pain intensity was not significantly different between the two groups at 1 month. However, at 12 months, the average pain item was significantly lower in the thoracic sympathetic block group. In addition, the pain dimensions, evoked pain symptoms score, and depression scores were significantly lower in the thoracic sympathectomy block group at 1 and 12 months. However, the quality of life was only slightly improved by the thoracic sympathectomy block.[64]

Lumbar Sympathetic Blockade Technique

Complete sympathetic blockade may be obtained with a single injection of 15 mL of bupivacaine (Marcaine) at the level of L2. Better results may be obtained using two or even three needles, with one point inserted at L2 and the others at L3 and L4 (Fig. 192.4).

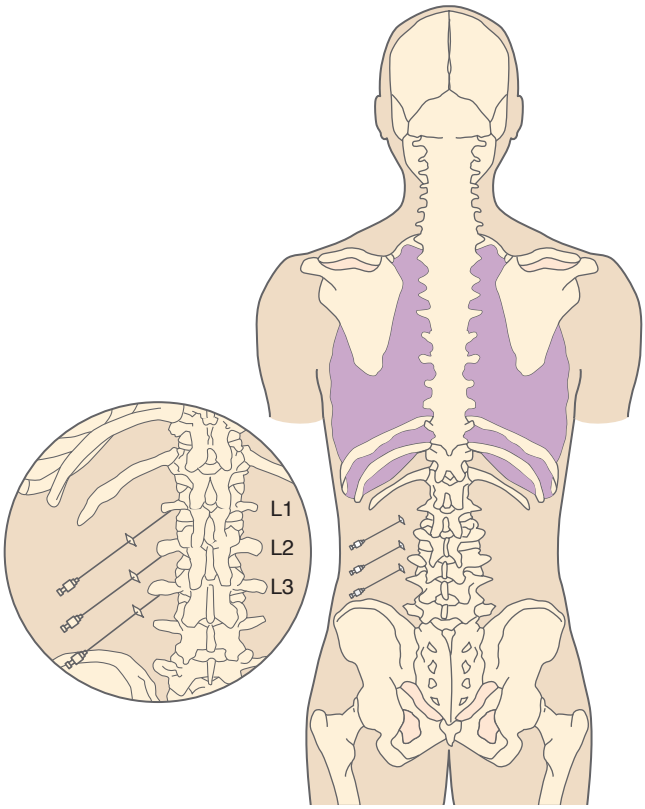

Figure 192.4 Lumbar sympathetic blockade (three-needle technique).

Epidural and Intrathecal Drug Therapy

Continuous epidural anesthesia or an intrathecal narcotic pump allows low-dose narcotics or local anesthetics to be administered, which may result in fewer systemic side effects than intravenous application. Local narcotic use can elevate the pain cycle, whereas the anesthetic agent provides a relatively selective sympathetic blockade. Successful outcomes with placement of an indwelling morphine pump[65] or the administration of continuous epidural anesthesia in conjunction with continuous passive motion[66] have been reported. Owing to the risk and cost of this modality, its use has been limited. Continuous epidural anesthesia also requires hospitalization and carries the risk of urinary retention, hypertension, and skin breakdown. Intrathecal morphine pumps are usually expensive and require refilling of the narcotic reservoir. One double-blinded controlled trial reported that epidural clonidine is beneficial in CRPS patients. Intrathecal baclofen therapy has been suggested for CRPS patients who are refractory to conventional modalities.[67]

Neuromodulation

Neuromodulation modalities include peripheral nerve, spinal cord, and thalamic stimulation. Implantable devices such as spinal cord stimulators are increasingly used in patients with intractable CRPS for symptomatic pain relief. In a prospective randomized controlled study, patients with CRPS who received spinal cord stimulation with physical therapy obtained greater pain relief and improvement in health-related quality of life than those who received physical therapy alone.[68,69]

Deer et al. and the Neuromodulation Appropriateness Consensus Committee (NACC) reported on neurostimulation of the spinal cord and peripheral nervous system in the treatment of chronic pain and ischemic diseases. They concluded that the appropriate neurostimulation is safe and effective in some chronic pain conditions and that clinical evidence and further technical refinements will continue to expand its use. The NACC will continue to facilitate the safety and efficacy of neurostimulation.[70]

Psychotherapy

Recently, the International Association for the Study of Pain consensus report recommended that patients with CRPS seek psychotherapy, including psychometric testing, if their pain persists beyond 2 months.[13] This includes the treatment of anxiety, depression, and personality disorders. Counseling, behavioral modification, relaxation therapy, biofeedback, group therapy, and self-hypnosis should be considered in these patients.

SYMPATHECTOMY

Once CRPS has been temporarily relieved by sympathetic blockade, the question arises whether to try to achieve this degree of relief more permanently by sympathectomy.

Indications

The decision to perform a sympathectomy depends on the clinical stage of the disease, the severity of symptoms, and the degree and duration of relief obtained by sympathetic blockade. This applies to both upper and lower extremity CRPS. For example, if a patient with pain of recent onset experiences pain relief from sympathetic blockade that lasts well beyond the known duration of the anesthetic agent used, it is advisable to continue with nonoperative measures. A patient whose condition has persisted for several months, whose pain is disabling, and who experiences nearly total relief from sympathetic blockade, but only for the typical duration of the anesthetic, may be considered a candidate for immediate surgical sympathectomy. A patient with symptoms of long duration (many months to years) and associated trophic changes, whose symptoms are less "classic" and less severe, and who receives only mild to moderate relief from sympathetic blockade should be advised that the long-term results are likely to be disappointing. These examples correspond to Drucker's three stages (over 6-month duration); this is deliberate because sympathectomy is, for the most part, best applied in stage 2 (3- to 6-month duration)—before progression to stage 3 and after stage 1 (first 3 months)—in patients who are unresponsive to nonoperative therapy.

For CRPS of the upper extremity, surgical cervical or dorsal sympathectomy (lower stellate ganglion and T2 and T3) is indicated, whether through the open or the thoracoscopic approach. For patients with CRPS of the lower extremity, lumbar sympathectomy is usually indicated. If surgical sympathectomy is limited to patients who obtain excellent relief from sympathetic blockade with local anesthetic, nearly 90% of patients experience long-term relief.[40,58,71]

Lumbar Sympathectomy

Anatomic Considerations

Sympathetic outflow to the lower extremities originates in spinal cord segments T10 to L3. Preganglionic fibers from these segments form extensive synaptic connections in paravertebral ganglia from L1 to S3 for innervation of the entire lower extremity and pelvic region. Sympathetic innervation of the foot and lower leg is conveyed primarily through the L2 and L3 ganglia; the proximal leg region is innervated primarily through the L1 to L4 ganglia. Overall, three lumbar ganglia are most commonly found, with fusion of the L1 and L2 ganglia most commonly accounting for the reduced number. Crossover fibers occur in 15% of patients, with most leaving via the fourth and fifth lumbar ganglia. For most clinical indications, L2 and L3 ganglionectomy is sufficient, but also removing L4 is advised to reduce the possibility of collateral reinnervation. Extensive ganglionectomy is usually not warranted and may result in ejaculatory disturbances in preclimacteric men when bilateral high ganglionectomies (i.e., including L1) are performed.

Chemical Sympathectomy

The high response rate achieved with percutaneous sympathetic blockade with local anesthetics led to attempts to achieve extended blockade with phenol or alcohol injections via the same approach. To accomplish this, the tips of three needles are placed against the bodies of the L2, L3, and L4 vertebrae (see Fig. 192.4). Their positions must be confirmed radiographically. In the lateral view, the needle points should barely reach the anterior border of the vertebral bodies. In the anteroposterior view, the points should lie over them. After proper needle positioning has been ascertained, 3 mL of 6.5% to 7% phenol dissolved in water, or 3 mL of absolute alcohol, is injected through each needle.

Experience with phenol lumbar sympathectomy is limited in the United States but is increasing. Long-term results have not been reported. The clinical impressions are that this approach produces a less complete and less durable effect than surgical sympathectomy. Chemical sympathectomy must not be taken lightly, because phenol or alcohol injections can cause significant inflammation and scarring, making subsequent surgical sympathectomy, if needed, difficult or unsafe.

Open Technique

The open technique for lumbar sympathectomy is illustrated in Fig. 192.5.

Laparoscopic Technique

The technique of laparoscopic lumbar sympathectomy has been described by several authorities (Figs. 192.6 and 192.7).[72,73] A 12- to 15-mm incision is made midway between the iliac crest and the costal margin at the anterior axillary line. This is carried down through the external and internal oblique muscles, which are separated along their respective fibers to reach the retroperitoneal space. Using blunt dissection, the areolar fatty tissue is dissected while the peritoneal sac is gently pushed forward, which creates a safe space for insertion of the distention balloon system into the retroperitoneum. The balloon is inflated under direct vision via a 30-degree scope introduced into the balloon trocar. A Hasson trocar is introduced into the space created and secured with two sutures to the fascia to avoid gas leakage. The space created is insufflated with carbon dioxide to a pressure of 10 to 12 mm Hg. Two or three additional 5-mm ports are inserted under direct vision into the retroperitoneal space along a line 2 to 3 cm posterior to the first trocar, at the mid and posterior axillary lines.

Decompression of the peritoneal cavity can also be accomplished using a Veres needle, which equalizes pressures. The surgeon and assistant should stand in front of the patient so they can clearly identify the peritoneal sac, which is pushed backward and medially, and the psoas muscle, which is in front and upward. The gonadal vessels and ureters should be clearly identified. The genitofemoral nerve is visualized descending obliquely along the psoas muscle. Two instruments are used for dissection, traction, clipping, and cutting, and a third instrument is sometimes used for retraction of the psoas muscle and for suction, if needed. The sympathetic chain is identified along the inner margin of the psoas muscle, and small communicating rami and blood vessels are divided with cautery, clips, and endoscissors. The sympathetic chain is then transected between clips at the level of L2 and L4. The retroperitoneal space is deflated, the trocars are removed, the fascia at

the large port site is sutured, and the skin incisions are closed.[72,73]

Results of Sympathectomy/Complex Regional Pain Syndrome

In Thompson's 1979 series, 82 patients with upper and lower extremity causalgia were treated with sympathectomy, and 93% had excellent or good pain relief.[21] Olcott and associates[71] reported 91% good to excellent results in 35 patients (17 upper extremity and 18 lower extremity). Some form of postsympathectomy neuralgia occurred in 4 (23%) of the upper extremity cases and in 12 (67%) of the lower extremity cases. In all instances, the neuralgia resolved spontaneously.

Mockus and coworkers reported 97% pain relief in 31 patients, which was sustained in 94%.[70] In nine patients with upper extremity causalgia, 12 dorsal sympathectomies were performed; in 22 patients with lower extremity causalgia, 23 lumbar sympathectomies were performed. In the nine patients who had dorsal sympathectomies, all nine (100%) had early pain relief, and eight patients (89%) had late pain relief. Of the 22 patients who underwent lumbar

sympathectomies, 21 patients (95%) had early and late pain relief. In a similar, more recent series of 28 patients, my colleagues and I reported 95% long-term success in patients who had experienced an excellent response to sympathetic blockade.[40]

An interesting subgroup of patients was identified in two of the aforementioned reports.[40,72] In the first series, patients with causalgia persisting after disk surgery enjoyed pain relief following sympathectomy equal to that in other patients.

Bandyk and associates reported sympathectomy results in 73 patients with CRPS type I (46 were video-assisted thoracoscopic and 37 were surgical lumbar sympathectomies).[58] At 3 months after sympathectomy, 90% of patients experienced a more than 50% reduction in pain, with pain severity scores decreasing from a mean of 8.7 before surgery to 3.4 after surgery. Overall, patient satisfaction was 77% and was not significantly influenced by patient age, CRPS duration, or extremity involvement (84% lumbar, 72% cervicodorsal).

Hassantash and colleagues reviewed 110 articles containing 1528 cases of causalgia.[10] Response to sympathetic blockades was noted in 88%, and 94% of patients undergoing sympathectomy were cured. However, in a recent Cochrane systematic review of the literature, Cepeda and associates analyzed patients who obtained at least 50% pain relief shortly after sympathetic blockade (30 minutes to 2 hours) and those with pain relief at 48 hours or longer after blockade.[61] They concluded that it was not possible to determine the effect of sympathetic blockade on long-term pain relief because the studies evaluated different outcomes.

Complications

Complications may include injury to the genitofemoral nerve, ureter, lumbar veins, aorta, and inferior vena cava. The most common complication is postsympathectomy neuralgia, which occurs in up to 50% of patients from 5 to 20 days after sympathectomy.[29,72,73] The cause is still speculative. The pain is characterized as an annoying "ache" in the anterolateral thigh region that is worse at night and is unaffected by activity or level of cutaneous stimulation. The discomfort responds to moderate analgesics and spontaneously remits within 8 to 12 weeks after onset.

Retrograde ejaculation can occur in 25% to 50% of male patients undergoing bilateral L1 sympathetic ganglionectomy.[74] This complication rarely occurs after unilateral ganglionectomy, especially when the surgeon takes care to preserve the first lumbar ganglion. Although potency should not be affected, many experienced surgeons insist that such derangements in sexual function do occur in men. Careful preoperative questioning about sexual function is important to evaluate any changes reported after lumbar sympathectomy.

Summary of Treatment Guidelines

The following are the generally accepted guidelines for the treatment of patients with CRPS type I:

Stage 1 (0 to 3 months): Physical therapy with or without TENS is usually useful. A local nerve or sympathetic blockade may be necessary for patients who experience severe pain and are unable to undergo physical therapy. If these measures fail, a course of steroid therapy should be given.

Stage 2 (3 to 6 months): Physical therapy, TENS, and steroid therapy should be combined. Sympathetic blockade and surgical sympathectomy should be considered if these measures fail.

Stage 3 (beyond 6 months): Steroid therapy or sympathetic blockade and surgical sympathectomy should be considered but may be unsuccessful. Neuromodulation (spinal cord stimulation) may be used. Manipulation of joint contractures under general anesthesia, antidepressants, and vocational guidance may be used.

OVERALL RESULTS OF TREATMENT

Most studies indicate that patients with early diagnosis and treatment (within 6 to 12 months) have an overall good outcome.[40,58,62,71] Most authorities also agree that spontaneous resolution can occur if CRPS is diagnosed and managed early.[40,58,62,71]

Failure to promptly recognize and treat CRPS type I results in irreversible changes, including wasting of skin and muscles, fixed joint contractures,[75] and severe demineralization of bone. It is generally believed that initiating treatment in the early stage carries a better prognosis. Patients who are diagnosed later are more refractory to treatment.[40,58,61] In patients with CRPS, restricted movement of the knee joint is very common. Patella baja (an abnormally low position of the patella) and changes in the mechanics of the tibiofemoral joint may occur, leading to chronic degeneration.[76]

Abstract

In this chapter, the authors present the anatomy and physiology of the sympathetic nervous system, as well as the pathophysiology of diseases due to its dysfunction, such as hyperhidrosis, long QT syndrome, Raynaud's syndrome and causalgia. The evolution of the technique of thoracic and lumbar sympathectomy, its difficulties and complications are described. Finally, the surgical indications for sympathectomy as well as its outcomes for each of these diseases is detailed. Sympathectomy is a procedure still widely used in clinical practice, despite the appearance of other therapeutic options for these diseases. It is important that the vascular surgeon is aware of which diseases and which type of patient sympathectomy is still well indicated, as well as the technical details that will lead to the best clinical results.

Raynaud Syndrome

The effects resulting from the blockade of preganglionic and postganglionic neurons were first described in the late 19th century by Langley,[1] and several reports in that era described sympathectomy to treat epilepsy, goiter, and angina pectoris.[1-5] The first to use cervical sympathectomy to treat a patient with hyperhidrosis was Kotzareff in 1920.[6] In 1924, Hunter tried to use sympathectomy to reduce muscle tonus in patients with spastic paralysis; although this intervention did not show any beneficial effect on this condition, he observed increased in circulation in denervated limbs.[7] The first intervention in human lumbar sympathetic chain ganglia was performed by Diez to treat a patient with thromboangiitis obliterans (TAO). In 1924, Diez reported 100% success in treating 150 cases of upper limb TAO.[8] This led to the use of this intervention in treating Raynaud disease and other types of vasospastic disease. There was then a technical evolution in open surgery involving different surgical approaches to resect the sympathetic ganglia: supraclavicular (cervical),[9] axillary transthoracic,[10] dorsal (posterior),[11] dorsal midline,[12] and anterior transthoracic.[13] Leriche (1924) performed the same surgical operation to treat Raynaud disease. Better results than in TAO were observed with sympathectomy for spastic conditions.[14] By the end of the 1930s, the main indications for cervicothoracic sympathectomy had started to be delineated: hyperhidrosis, TAO, and vasospastic conditions. Until the 1960s, due to a lack of revascularization techniques, lumbar sympathectomy was widely used to treat lower limb peripheral artery diseases.

After the development of the thoracoscope, introduced by Jacobaeus in 1910,[15] Hughes in 1942 performed the first thoracoscopic sympathectomy.[16] Kux, in 1953, was the first to publish a large experience with this method.[17] However, despite the good results, for unknown reasons this technique did not achieve international acceptance for almost 30 years. In the 1980s, the endoscopic technique was used to perform sympathetic denervation in the upper limbs by a few groups of surgeons.[18] In the 1990s, advances in optical systems and instruments for thoracoscopic surgery made it possible to use video-assisted thoracoscopy to perform sympathectomy.[19] The low morbidity, good cosmetic results, decreased incidence of Horner syndrome, and short hospital stay prompted patients with hyperhidrosis to ask their physicians to help them by using video-assisted thoracoscopic sympathectomy (VATS).[20] The outcomes of VATS have been positive and VATS surgery is being increasingly performed. During the last 15 years, thousands of operations have been reported, which has led to technical improvements and better results.

ANATOMY

Sympathetic Ganglia

The motor sympathetic route is formed by three neurons (Fig. 193.1). The cell body of the first neuron is located in the sudomotor and vasomotor centers, mainly in the hypothalamus. Its axon projects along the dorsal longitudinal and spinovestibular fascicles to the cell body of the second neuron (preganglionic neuron), which is located in the intermediolateral nucleus of the spinal gray matter, between the first thoracic and second lumbar vertebrae. Its axon (the preganglionic fiber) exits the medulla through the ventral root of the spinal nerves and, through the white communicating branch, projects to the paravertebral ganglion, where it forms a synapse with the cell body of the third neuron, the postganglionic neuron. Its axon (the postganglionic fiber) leaves the sympathetic chain through the gray communicating branch into the spinal nerve and is distributed peripherally. The ganglia are also interconnected longitudinally by axons from preganglionic neurons that run rostrally or caudad to the neighboring ganglia of the chains.

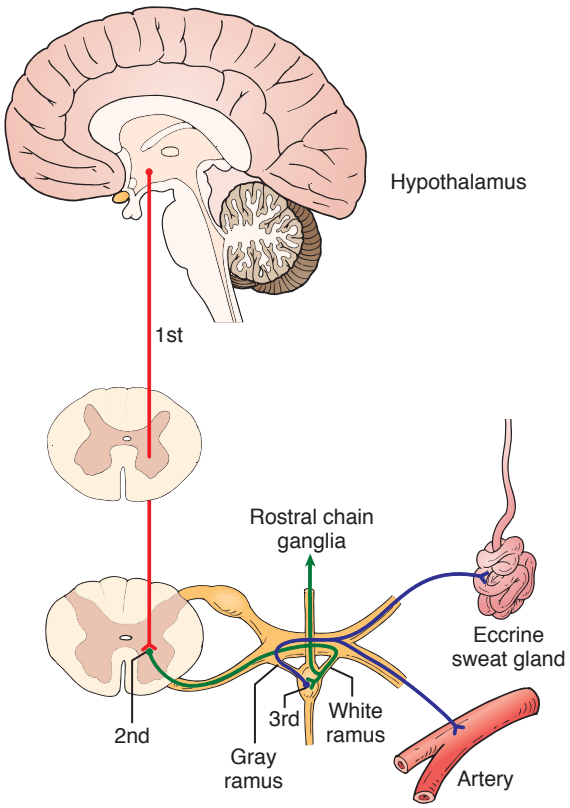

Figure 193.1 The motor sympathetic route. The cell body of the first neuron is located in the sudomotor and vasomotor centers, the second neuron (preganglionic neuron) is located in the intermediolateral nucleus of the spinal gray matter, and the third neuron (postganglionic neuron) is located in the paravertebral ganglia.

As in the somatic nervous system, the axon of the preganglionic neuron exits the segment in which its soma is located. There is one sympathetic paravertebral ganglion (G) for each spinal segment. The sympathetic fiber that originates from the ganglion innervates the area of the spinal nerve corresponding to that segment. Thus the second ganglion (G2) supplies sympathetic innervations for the structures of the second dermatome (D2).

In the neck, there are normally three ganglia in the sympathetic chain. The superior cervical ganglion results from the fusion of the first four sympathetic cervical ganglia; it is located at the level of the transverse process of the second and third cervical vertebrae and supplies the head and neck. The middle cervical ganglion is located at the level of the sixth cervical

vertebra. The inferior cervical ganglion is generally fused with the first thoracic ganglion (G1) to form the cervicothoracic ganglion (stellate ganglion), which is located anterior to the head of the first rib and covered by the pleura.

In the thoracic region, the ganglia of the sympathetic chain are positioned anteriorly to the transverse processes of the thoracic vertebrae and are covered by the parietal pleura. They are fewer in number than the spinal thoracic nerves because of the fusion of the first thoracic ganglion with the inferior cervical ganglion, fusion of the last thoracic ganglion with the first lumbar ganglion, and fusion of the thoracic ganglia with each other.

The greater, lesser, and least splanchnic nerves are formed by preganglionic fibers originating from the 5th to 12th thoracic medullary segments. They cross the corresponding sympathetic ganglia without forming synapses with them and end in the celiac, aorticorenal, and superior and inferior mesenteric ganglia. The major splanchnic nerve plays a particularly important role in visceral pain because of the large numbers of visceral afferent fibers it contains. Hence splanchnicectomy may be employed to treat unmanageable visceral pain, particularly in pancreatic diseases (cancer and pancreatitis).[21] In the past, thoracolumbar sympathectomies were performed to treat hypertension, a technique currently abandoned with the advent of modern antihypertensive drugs.[22]

Sympathetic Innervation of the Upper Limbs

The preganglionic fibers responsible for the innervation of the upper limbs originate from the second to eighth thoracic medullary segments, most of them below the fourth segment. The fibers enter the paravertebral sympathetic chain through the white communicating branches of the corresponding ganglia and have an ascending pathway in which a synapse is formed with cells located in the second thoracic ganglion, the stellate ganglion, and probably the middle cervical ganglion. It is of surgical interest that no preganglionic fibers enter the sympathetic chain above the first thoracic ganglion, which participates in innervation of the limb in only 10% of the cases.

In most patients, the thoracic sympathetic trunk is located in the middle of the intercostal space, on the bottom edge of the top rib or the top edge of the bottom rib.[23-25] Therefore when we section the sympathetic chain on two consecutive ribs, there is a high probability that we are making the sympathetic ganglion between them dysfunctional.[26]

Several anatomic landmarks have been used to determine the exact location of sympathetic interruption, including the thoracic ganglion (G), the vertebral level, and the intercostal space. More recently, a rib-oriented nomenclature has been suggested that refers to the rib level (R) instead of the vertebral level for sympathetic interruption.[26] This decision was based on too many patients having mediastinal fat that can obscure clear identification of the specific ganglia and because there are many anatomic variations in the ganglion anatomy. Information about the technique used for ganglionic interruption should also be included in the nomenclature, stating whether clipping, cauterization, or segment removal is performed. For this chapter, we use the ganglionic level as anatomic reference.

Sympathetic Innervation of the Lower Limbs

Sympathetic preganglionic fibers responsible for the innervation of the lower limbs originate from the 12th thoracic medullary segment to the 2nd lumbar segment and reach the sympathetic chain by white rami comunicantes, all having descendant paths.

Postganglionic fibers originate in cells of the lumbar and sacral ganglia. The fibers destined for the lumbar plexus come from the first three lumbar ganglia and those destined for the sacral plexus come from the fourth lumbar nerve and sacral ganglia. Therefore all postganglionic fibers that follow the sciatic nerve originate on ganglia located under the third lumbar nerve, since the greater number of synapses occur on fourth lumbar nerve.

It is known that there are no rami comunicantes under the second lumbar ganglion; therefore, the removal of the second and third lumbar sympathetic ganglia interrupts all preganglionic fibers to the sciatic nerve and consequently to the cutaneous territory located under the knee except the saphenous nerve territory, which originates from the lumbar plexus. To obtain thigh denervation it is necessary to remove the first lumbar ganglion. The removal of the fourth lumbar ganglion does not amplify the scope of denervation but interrupts the many postganglionic fibers destined for the sciatic nerve.

Sympathetic Innervation of the Ocular Structures

The sympathetic preganglionic fibers controlling the smooth muscles of the eye are rostral, from anterior roots of G1 and G2. The fibers enter the sympathetic chain by the corresponding ganglia but do not form synapses. The synapses are subsequently formed when they ascend to the superior cervical ganglion. The postganglionic fibers head toward the ocular-pupillary apparatus through the carotid plexus. Consequently resection of the stellate ganglion causes Horner syndrome (enophthalmos, myosis, and palpebral ptosis).

Sympathetic Innervation of the Cephalic Segment

Sympathetic innervation of the head and neck originates from the first to fifth thoracic medullary segments. The preganglionic fibers ascend the sympathetic chain and form synapses with the first thoracic ganglion and the inferior cervical ganglion. Most of the postganglionic fibers responsible for innervation of the face originate from G2, which implies that craniofacial sweating diminishes through G2 ablation.

Sympathetic Innervation of the Heart

Sympathetic innervation of the heart is supplied from the higher three heart nerves (superior, medial, and inferior) arising from the three cervical ganglia and from the sixth or seventh thoracic paravertebral ganglia. Most fibers converge at the cardiac plexuses. These nerves are more abundant in the fourth and fifth thoracic segments than at higher levels.

PHYSIOLOGY

The sympathetic chain supplies the smooth muscles of the blood vessels through adrenergic fibers and the sweat glands through cholinergic fibers. The vascular system differs from other systems in its lack of antagonistic innervation between sympathetic and parasympathetic vasoconstrictor fibers; thus vasodilation results from a decrease in sympathetic activity.

The autonomic nervous system has a considerable influence on vessels with a more developed smooth muscle layer of the vessel wall in relation to its caliber. Hence arterioles are most affected by sympathetic activity and the autonomic nervous system has great influence on skin circulation but is of little importance in great vessels and muscular arteries.

Eccrine sweat glands, which are responsible for hyperhidrosis, are innervated by the nonmyelinic C fibers of the sympathetic nerves, and acetylcholine is the chemical mediator. Local or systemic administration of cholinergic agents induces sweating, whereas the use of atropine blocks it. Although sweating in the palmar and plantar regions may result from emotional stimuli and abundant sweating is observed under clinical conditions in which catecholamines are released by the adrenal glands, administration of adrenergic agents by any route does not stimulate the sweat glands.[15] Blocking of preganglionic fibers does not stop sweating caused by stimulation of the postganglionic fibers, nor does the local administration of cholinergic agents. However, if postganglionic fibers are cut, such secretion will no longer occur through local stimulation by any pharmacologic agent. This is an exception to Cannon's law (which states that when one unit in a series of efferent neurons is destroyed, increased irritability to chemical agents is developed in the structure that has been isolated and the effect is greater in the part that is directly denervated). Heating of the skin may cause sweating in this situation through an unknown mechanism.

Different neural centers control the various types of sweat glands in a reflex manner. Thus emotional sweating is controlled by a cortical center, thermal sudoresis by a hypothalamic center, gustatory sudoresis by medullary nuclei, and spinal sweating by cells of the intermediate-lateral region of the spinal cord.

The nerve centers and pathways that control emotion-induced sweating are not fully known, although it seems that they are located in the frontal lobe. Emotion-induced stimuli can increase sweating, especially in the palmar and plantar regions.

Under baseline conditions, few impulses pass to the sweat glands, and nonsensory sweating (perspiration) is always present, partly because of the activity of the glands and partly because of loss of water through the epidermis.

INDICATIONS FOR CERVICOTHORACIC SYMPATHECTOMY

The current indications for cervicothoracic sympathectomy are limited to essential hyperhidrosis, selected cases of critical hand ischemia, complex regional pain syndrome (CRPS),[27] clinically refractory long QT syndrome,[28] and Raynaud syndrome.[29]

INDICATIONS FOR LUMBAR SYMPATHECTOMY

The current indications for lumbar sympathectomy are limited to essential plantar hyperhidrosis and selected cases of chronic critical ischemia of the legs with no conditions or revascularization. The few randomized trials that have been performed have not shown beneficial effects on amputation and mortality rates, improvement of rest pain, or the healing of ischemic ulcers, including diabetic ulcers.[30,31] Other less frequent indications are selected cases of Raynaud syndrome and CRPS.[32]

Idiopathic Hyperhidrosis

Hyperhidrosis, the production of excessive quantities of sweat believed to be the result of stimulation of the sympathetic nervous system at the central level, is typically limited to the palms, soles, or axillae in a symmetric manner.[33] It may also affect the craniofacial segment. Hyperhidrosis may arise during childhood, but it is more intense during adolescence, a transitional period of life with potential psychological stress associated with triggers of hormonal and sexual maturation. It may persist into adulthood but decreases in intensity in some patients.[22] Hyperhidrosis affects approximately 3% of the population; in 13% to 57% of patients it can be associated with a family history of hyperhidrosis.[34] Climate is not an etiologic factor, but hot weather exacerbates sweating.[35]

Palmar hyperhidrosis generally takes on greater clinical significance than plantar or axillary hyperhidrosis because it creates significant problems within the educational, social, professional, and affective spheres, which can worsen any emotional issues that such patients may already have.[36-38]

Plantar hyperhidrosis is frequently associated with palmar or axillary hyperhidrosis and is worsened by the use of closed shoes, which hinder evaporation and favor skin maceration. The constant dampness provides conditions for malodorous fungal or bacterial infections.[39]

Axillary hyperhidrosis tends to appear at puberty, with the increased production of sexual hormones. Symptoms of axillary hyperhidrosis are disabling both professionally and socially for almost all patients who seek surgical treatment.[40] Likewise, craniofacial hyperhidrosis and facial rubor may cause social phobia.[41,42]

Nonsurgical treatment should initially be attempted in all cases of hyperhidrosis. If results are inferior to patient expectations, sympathectomy should be considered. Besides oxybutynin, other alternatives include botulinum toxin injection[43] and glycopyrrolate.[44]

Sympathectomy is indicated for patients who do not experience an improvement in quality of life despite appropriate nonoperative treatment and are willing to accept the risks involved in surgical treatment (mainly compensatory hyperhidrosis).[45]

Ischemia of the Hand

Selected patients with ischemic hand pain or finger ulcers, particularly those with TAO and distal arterial obstruction, may benefit from sympathectomy (see Chapter 138).[46-48] Cervicodorsal sympathectomy has been used selectively in cases of critical hand ischemia to improve cutaneous vasodilation, control ischemic rest pain and vasomotor phenomena, and support healing of the skin in patients unresponsive to conservative management. However, no randomized comparison with other treatments is available, and because the disease can be improved by smoking cessation, it is difficult to judge the benefit of sympathectomy from published studies.[49,50]

Complex Regional Pain Syndrome

CRPS, also known as causalgia, reflex sympathetic dystrophy (RSD), posttraumatic pain syndrome, shoulder-hand syndrome, and Sudeck atrophy, is a term that has been used since 1994. It describes a regional pain condition that often occurs after injury, is disproportionate to the inciting event, and is associated with signs of vasomotor dysfunction and sudomotor activity (see Chapter 192).

When CRPS is left untreated, hyperalgesia, allodynia, signs of vasomotor dysfunction, and edema can be seen initially. After 3 to 6 months, there is increased pain, and sensory dysfunction and motor or trophic changes (or both) develop (dystrophic stage). Finally the pain decreases, but there are still sensory disturbances (atrophic stage).[51,52] Sympathetic blockade with local anesthesia has been used to control pain in selected patients. If it is effective, this technique can be repeated, together with physical therapy to recover functionality of the limb.[53] Peridural or intrathecal infusions of anesthetic drugs can be used in selected patients who do not respond to conservative treatment. Because of proximity to receptor sites, the therapeutic effect of intrathecal drug application lasts longer and the rate of systemic side effects is reduced. However, there are catheter-related technical problems, such as catheter dislocation, obstruction, kinking, and disconnection or rupture, as well as drug-related side effects.[54]

Spinal cord stimulation is efficacious in CRPS type I (level B recommendation) that is resistant to medication or other treatments. High-frequency transcutaneous electrical nerve stimulation and repetitive transcranial magnetic stimulation are noninvasive and suitable as preliminary or add-on therapies and provide satisfactory pain relief to many patients, including those resistant to medication or other therapies.[55]

Chemical sympathectomy with phenol or alcohol seems to have at best a temporary effect limited to cutaneous allodynia. Because studies reported in the literature have only a few patients and poorly defined outcomes, well-designed studies on the effectiveness of the procedure are needed.[56,57]

Sympathectomy can be used in selected patients who do not respond to nonsurgical treatment or in those who have good but transient benefit from pharmacologic sympathetic blockade (see Chapter 192).[58]

Long QT Syndrome

Long QT syndrome is an idiopathic congenital disorder characterized by a lengthened QT interval on the electrocardiogram associated with a high incidence of severe tachyarrhythmia, syncope, and sudden death; it often occurs at a young age. There is no clinical or radiologic evidence of heart disease. Severe episodes typically occur during intense physical exercise or emotional crises, which leads to the supposition that the sympathetic nervous system plays an active part in the genesis of the problem. The mortality rate in untreated patients reaches as high as 78%. Beta blockers are effective in preventing such crises in 75% to 80% of the cases.[59] Sympathectomy is only potentially indicated in patients who, even with appropriate clinical treatment, continue to have syncopal crises (about 20%-25% of these patients).[60,61]

Raynaud Syndrome

Raynaud disease and phenomenon are characterized by episodic spasm of arterioles, usually in the digits, with intermittent pallor or cyanosis, precipitated by exposure to cold, emotional upset, or drugs (see Chapter 141). The treatment of Raynaud syndrome is essentially nonoperative. Sympathectomy has been used in rare patients who, despite adequate clinical treatment, continue to have severe symptoms or trophic lesions that heal with difficulty. However, it is difficult to judge the benefit because randomized trials have not been performed and the natural history is variable.

SURGICAL TECHNIQUES

Open Surgery for Cervicothoracic Sympathectomy

Until the 1990s and before VATS, open surgery was the "gold standard" for cervicodorsal sympathectomy. Several approaches are available for open surgery, each with its own advantages and disadvantages. There are three main approaches, the paravertebral, transthoracic, and supraclavicular routes. Today the open technique is indicated only when VATS cannot be accomplished for technical reasons or an associated open operation is being performed.

The paravertebral route, mainly used by neurosurgeons, offers wide exposure of the sympathetic chain. However, it involves extensive dissection and the sectioning of several muscle bunches and requires a long period of recovery.[62]

The transthoracic axillary approach has the advantages of superior exposure, easier access to the sympathetic chain for wide incisions, lower risk of Horner syndrome, and good cosmetic results. The main complication is postsympathetic neuralgia, which is long-lasting and extends the recovery time.[63]

The supraclavicular approach requires an extrapleural access and thus allows the procedure to be completed bilaterally in a single operation. The resulting scar becomes virtually invisible in a short time, convalescence is fast with little pain, hospital stay is short, and surgical complication rates are low. The

disadvantage is that the stellate ganglion is the point of reference for identifying the sympathetic chain, and its simple manipulation can result in Horner syndrome, although in most cases transitory.[64]

Video-Assisted Thoracoscopic Sympathectomy

At present, VATS is considered the gold standard for cervicothoracic sympathectomy. Several approaches (one port, two ports, three ports, four ports, lateral, dorsal) are available, each with its own advantages and disadvantages.[65,66] An easy and practical technique (two ports) is described in the following paragraphs.

Instrumentation

The basic equipment includes a 15-degree angled thoracoscope, video camera with monitor, DVD recorder, light source, video endoscopic instruments, electrocautery (harmonic or not), and nerve hook and vascular clips.

Anesthesia

The patient usually undergoes double-lumen endotracheal general anesthesia, which makes it possible to stop the patient's ventilation and consequently to collapse the lung on the side that will undergo surgery. When necessary, bronchoscopy is used to verify tube positioning. A double-lumen endotracheal tube is used in patients undergoing resection of the fourth ganglion of the thoracic sympathetic chain. When thermoablation is performed on the second or third ganglion, a single-lumen tube may be used in conjunction with adequate control over lung ventilation. Long-acting anesthetic agents are avoided to allow immediate extubation at the end of the procedure.

Positioning

The patient is placed in dorsal decubitus semiseated position with the trunk raised approximately 45 degrees. Two small pads are placed under the shoulders to create a space between the axillae and the surgical table and to bring the shoulders forward, thereby avoiding distention of the brachial plexus when the arms are positioned in 90 degrees of abduction on the arm rests. Another pad under the knees and a securing strap at the hip level allow the legs to be positioned comfortably and stabilize the patient on the surgical table when it is rotated laterally to bring the sites for surgery forward (right or left).

Technique

In cases of hyperhidrosis, which represent more than 95% of the cases and in which thermoablation of only the third or fourth sympathetic ganglion is performed, two mini-incisions about 1 cm in length are made. The first incision is made on the anterior axillary line at the level of the fourth or fifth intercostal space to introduce a video camera. The second incision at the second or third intercostal space on the medial axillary line is used to introduce the surgical instruments (electric or ultrasonic bistoury, scissors, dissecting forceps, retractable hook, and aspirator) into the pleural cavity (Fig. 193.2). In cases where the stellate ganglion must be resected, a third mini-incision is made anterior to the posterior axillary line to facilitate the dissection.

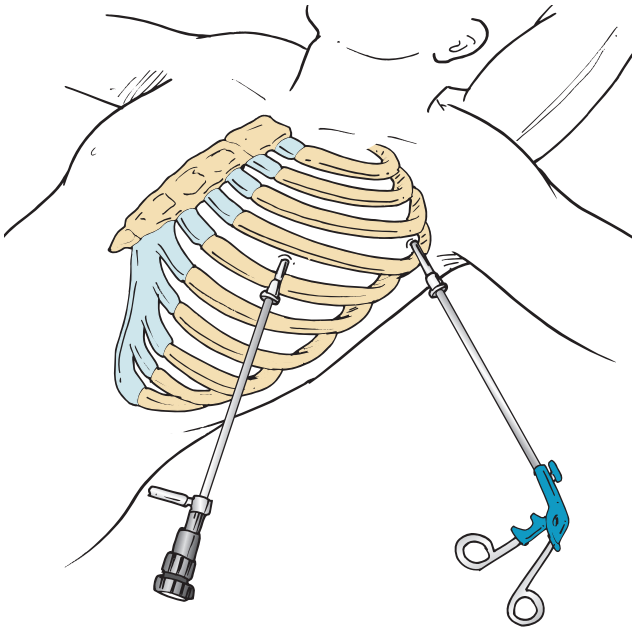

Figure 193.2 Port placement: one in the fourth or fifth intercostal space on the anterior axillary line and one in the medial axillary line in the second or third intercostal space.

Trocars 5.5 mm in diameter are introduced into all the incisions to keep the pathway open and protect the structures of the thoracic wall. Carbon dioxide insufflation into the pleural cavity has been used in some centers to improve surgical access. However, this procedure is not free of risk, and it may cause cardiovascular problems even when it is used at low pressure.[67] To avoid these complications, we have preferred to use open pneumothorax, which has proved to be sufficiently satisfactory.

The sympathetic chain is identified through the parietal pleura as a whitish, longitudinal, multinodular cord that forms a slight prominence in the lateroposterior region of the thoracic vertebrae, above the heads of the costal arches (Fig. 193.3). In elderly patients or individuals with a greater degree of fatty tissue, the sympathetic chain sometimes becomes difficult to distinguish. In such cases the chain is identified by touch with the endosurgical instruments (Fig. 193.4). The parietal pleura is sectioned above the chain and is also dissected by blunt separation. The communicating branches are coagulated and sectioned to the extent desired (Fig. 193.5). The chain is then sectioned above the costal arches and the segment isolated is cauterized (Fig. 193.6). Application of vascular clips to the main sympathetic trunk instead of thermoablation is an alternative.

After hemostasis is achieved, a 14- or 16-Fr aspiration probe is placed through the upper trocar and connected to a negative-pressure aspirator. The anesthetist is then asked to ventilate the collapsed lung until complete expansion has been achieved. This can be verified by direct viewing on the video monitor. The video camera and aspirating probe are then removed and the corresponding incision is sutured. Occlusive bandages are left on the surgical incisions for 24 hours. In the postanesthesia

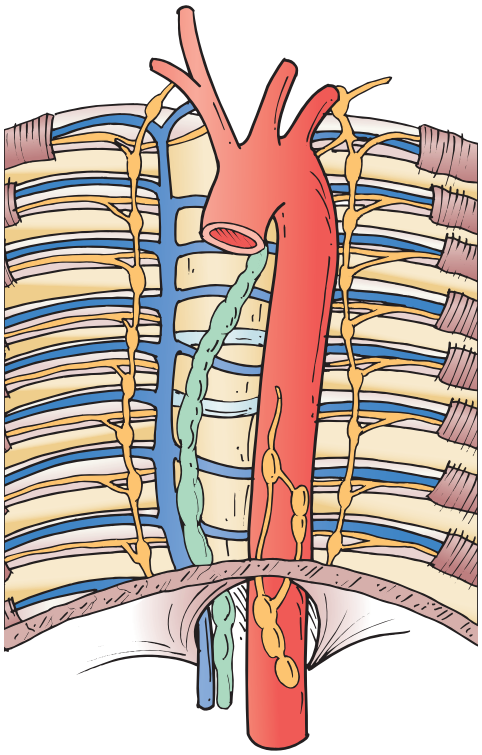

Figure 193.3 Sympathetic chain *(yellow)* coursing above the heads of the costal arches. The stellate ganglion is located anterior to the head of the first rib, the T2 ganglion is between the second and third ribs, the T3 ganglion is between the third and fourth ribs, and the T4 ganglion is between the fourth and fifth ribs.

recovery room, chest radiography is requested to confirm and inspect expansion of the lung and check for possible residual pneumothorax.

Lumbar Sympathectomy

Open surgery performed through anterolateral extraperitoneal access provides a wide surgical field and allows for the execution of bilateral surgery with no need to change the patient's position on the surgical bed. As an alternative to conventional surgery,

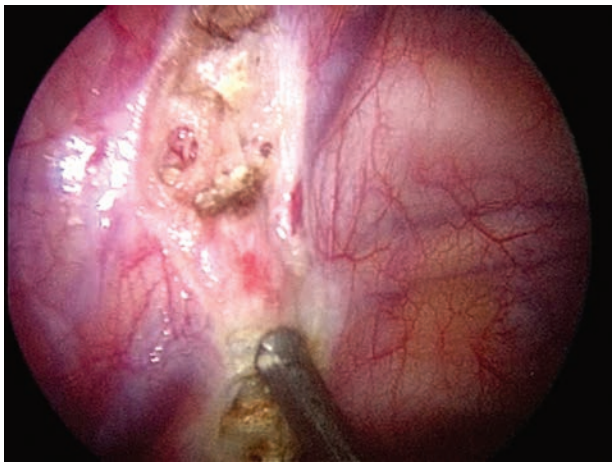

Figure 193.5 Sympathetic chain sectioned above and below the ganglia.

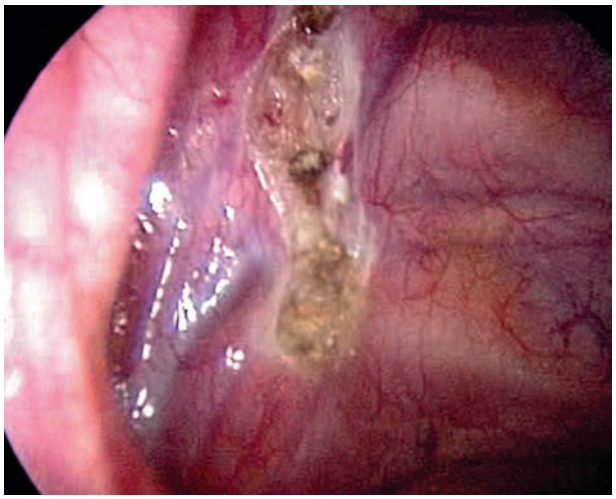

Figure 193.6 Sympathetic chain cauterized.

some services perform the sympathetic denervation through retroperitonioscopy, reporting minimal morbidity, short convalescence time, and similar effectiveness to open surgery.[68,69]

Chemical sympathectomy which consists in blocking the sympathetic nerve with phenol, has increased in application since Reid et al. in 1970 showed the procedure to be safe and effective in a large number of patients.[70] It is a fairly long-lasting method and as an advantage has the possibility to be repeated whenever necessary. Postsympathectomy neuralgia occurred in 9% of the cases in Reid et al.'s experience, a complication that is relatively frequent with surgical sympathectomy.

Technical Difficulties in Video-Assisted Thoracoscopic Sympathectomy

Pleural adhesions are found fairly frequently during thoracoscopy (3%-7%). Firm and extensive pleural adhesions caused by previous pleuropulmonary diseases may make it impossible to perform VATS. In such cases open surgery is the best option. Unfortunately such adhesions cannot be diagnosed preoperatively by routine chest radiography.[71]

The presence of an azygos lobe is an infrequent anatomic variation that involves an accessory pulmonary lobe at the apex of the lung, making it difficult or sometimes impossible to carry out VATS, particularly when the surgeon is not prepared for this contingency.[72] Preoperative chest radiography may identify this anomaly.[73]

Technical Alternatives for Video-Assisted Thoracoscopic Sympathectomy

Alternatives to ganglia resection are interruption of the chain without the removal of ganglia (sympathicotomy)[74] and blockade by endoscopic clipping,[75-77] a technique that can be reversed, within 10 days after intervention, by removal of the clips.[78,79] In both techniques, transmission of sympathetic impulses from the lower sympathetic ganglia through the stellate ganglia to the limbs is interrupted.

Sympathicotomy and thoracoscopic clipping are also acceptable. Early results are comparable to those of sympathectomy, but long-term results are unknown. Sympathicotomy is a good alternative when the anatomy is not appropriate for sympathectomy (large veins over the sympathetic chain). Clipping of the trunk has the potential benefit of unclipping (reverse operation) in case of intolerable compensatory hyperhidrosis. Large-scale prospective studies with long-term follow-up are needed in both techniques.

New alternatives based on emerging technology have been introduced for performing sympathectomy using an embryonic natural orifice: the transumbilical endoscopic surgery with a flexible endoscope. This novel procedure can reduce postoperative pain and afford even better cosmetic benefits by hiding the surgical incision in the umbilicus. It seems to be a safe and an efficacious alternative to the conventional approach.[80-82]

Contraindications to Video-Assisted Thoracoscopic Sympathectomy

The contraindications to VATS are lung infections that evolve with pleural effusion and require puncture or drainage, lung diseases that cause dense pleural adhesions (such as tuberculosis), previous thoracic surgery, thoracic radiotherapy, sinus bradycardia, and clinical conditions in which endotracheal anesthesia is contraindicated.[83] Obesity has also been considered a contraindication to VATS; even though overweight patients have a high degree of satisfaction with the operation, it may be difficult to identify the sympathetic chain when it is covered by a greater layer of adipose tissue. In addition, such patients have a higher risk of severe compensatory hyperhidrosis.[84]

TARGET GANGLIA

The extent of thermoablation, resection, or interruption of the sympathetic chain is an important subject in dealing with thoracic sympathectomy (Table 193.1).[85,86]

With improvements in surgical techniques for the treatment of hyperhidrosis, therapeutic success has been achieved even when sympathectomy is performed at levels distant from the stellate ganglion (G3 and G4 ganglia). This has corresponded to a significant reduction in the complications that were most feared before the advent of VATS: Horner syndrome and compensatory hyperhidrosis.

TABLE 193.1 Denervation Levels for Different Indications

Disease	Denervation Level
Palmar hyperhidrosis	G4 or G3
Axillary hyperhidrosis	G4
Craniofacial hyperhidrosis	G2
Facial rubor	G2
Plantar	L2 and L3
Complex regional pain syndrome	Stellate ganglion, G2, and G3
Vascular disease	Stellate ganglion, G2, and G3
Raynaud syndrome	Stellate ganglion, G2, and G3
Long QT syndrome	Left side, from the stellate ganglion to G4 or G5

Lumbar sympathectomy is a predominantly preganglionic type of surgery, since the fourth ganglion is not manipulated, because the majority of the pre- and postganglionic fibers synapse are in this level. It is generally agreed that resection of the first three lumbar ganglia produces denervation of the whole corresponding lower limb. However, although some have advocated removal of the second and third lumbar ganglia only, this approach limits the sympathetic denervation to the territory located under the knee, although the clinical results are similar to those obtained by longer resection. Further, saving of the first lumbar sympathetic chain, at least one side, prevents interference with the normal mechanisms of male ejaculation. In practice we found that the arrangement of the ganglia in this chain varied considerably. There are cases where the first three ganglia are perfectly identified and others where there are only two ganglia separated by a long chain segment. There have also been a few cases where there was only one identifiable ganglion, giving the impression that all of them had merged into one. Our approach has been to remove the chain from the crus of diaphragm to the level of the fourth lumbar vertebra, saving the first ganglion, which usually is included in diaphragmatic pillar fibers.[87,88]

Palmar Hyperhidrosis

In cases of palmar hyperhidrosis, physicians initially used to resect G2 and G3 ganglia with good results (anhidrosis); however, it was a difficult procedure associated with a high incidence of Horner syndrome and severe compensatory hyperhidrosis.[89] Subsequently, on the basis of the principle that interruption of the transmission of sympathetic impulses from the lower sympathetic ganglia through stellate ganglia resolves hyperhidrosis, thermoablation of G2 accelerated this procedure and gave similar results. However, intervention on the G2 ganglion

resulted in a high rate of compensatory hyperhidrosis (in more than 75% of the cases) because an extensive area is denervated, including the cephalic, cervical, and upper limb segments. This collateral effect has been responsible for dissatisfaction in 4% of patients.[90] To minimize this problem, thermoablation of G2 was initially replaced by thermoablation of G3 and currently G4, which has led to similar results of palmar anhidrosis but considerably decreased compensatory hyperhidrosis,[91] probably due to preservation of sympathetic tonus in the cephalic segment.

Patients who undergo G3 ablation usually have totally dry hands and need to use skin moisturizers, whereas patients who undergo G4 ablation have continued low levels of sweating (not hyperhidrosis but a little greater than normal physiologic levels), which is considered to be a therapeutic success.[92-94]

Axillary Hyperhidrosis

Resection of the second to fourth ganglia of the thoracic sympathetic chain was the first step in treating axillary hyperhidrosis.[95] It was replaced by thermoablation on G3 and G4[96] and then by single G4 thermoablation,[97] which results in excellent therapeutic success (anhidrosis), less severe compensatory hyperhidrosis, and a higher rate of satisfaction.

Craniofacial Hyperhidrosis or Facial Rubor

Sympathetic denervation of the face and head can be obtained by thermoablation of the G2 ganglion.[41] Sympathetic blockade of G3 with the use of clips is an alternative for these patients.[98]

Complex Regional Pain Syndrome, Vascular Disease, and Raynaud Syndrome

Sympathetic denervation of the upper limb must be as complete as possible if sympathectomy is used for these conditions. Hence the stellate ganglion, G2, and G3 should be included.[89] To avoid incomplete denervation of the limb, the communicating branches of T1 and the nerve of Kuntz have to be ablated as well.[99] This approach is always associated with the presence of Horner syndrome.

Long QT Syndrome

Sympathectomy is performed only on the left side, from the stellate ganglion to G4 or G5.[60,100,101]

RESULTS

Hyperhidrosis

The success rate in the abolition of hyperhidrosis (i.e., anhidrosis) is very high and ranges from 96% to 100% for palmar hyperhidrosis,[102,103] from 63% to 100% for axillary hyperhidrosis,[104] and from 87% to 100% for craniofacial hyperhidrosis.[105] In addition, quality-of-life analyses have demonstrated an "overall satisfaction" of around 90% 5 years after sympathectomy.[45,106,107]

Although it is nonspecific for the treatment of plantar hyperhidrosis, which is usually associated with palmar or axillary hyperhidrosis, VATS was shown to immediately reduce plantar sweating in more than 80% of patients; however, there is a reduction to smaller degrees of improvement (60%) during the 1-year period after surgery.[108]

There is no convincing anatomic-physiologic explanation for this improvement. Perhaps correction of palmar hyperhidrosis by the intervention leads to a greater emotional equilibrium, thereby lowering sympathetic nervous stimuli to the feet.

Recurrence of palmar or axillary hyperhidrosis has been reported in 1% to 13% of surgically treated patients and in 2% of the patients with craniofacial hyperhidrosis.[105] The main cause of the recurrence is technical failure. Reoperation is usually successful. Weak adhesions are found in these situations, but they do not cause significant difficulties for the procedure.

Transitory occurrence of sweating of variable intensity in the denervated segment during the first postoperative week (third to fifth postoperative days) is observed in 13% of the cases. It lasts for a maximum of 36 hours and is caused by the release of neurotransmitter at the end of the sympathetic postganglionic fibers as they degenerate.[109]

One adverse effect from sympathectomy is gustatory sudoresis. Its incidence is variable (ranging from 6% to 32%), and it is probably related to eating habits in different regions. In most cases it is of light to moderate intensity and does not interfere with quality of life.[110]

Compensatory hyperhidrosis consists of an increase in the severity of sweating in locations that were previously normal. This is the most frequent and most feared side effect of thoracic sympathectomy. Compensatory hyperhidrosis is present in almost all patients, and when severe (in 1%-4% of the cases), it is considered the main cause of patient dissatisfaction.[111] It occurs mainly on the abdomen, back, and thighs and becomes more uncomfortable on hot days, during physical exercise, and in hot work environments.[112] It may diminish over time, or the patient may learn to live with it.[113]

Compensatory hyperhidrosis has a high correlation with the level and extent of resection.[114] The higher the interruption or resection of the sympathetic chain, the more afferent fibers responsible for inhibition of sweating would be harmed, thereby causing a considerable increase in the quantity and intensity of compensatory hyperhidrosis. By performing thermoablation only in G4 ganglia for palmar or axillary hyperhidrosis, there is a significant decrease in the quantity and intensity of compensatory hyperhidrosis,[62] which leads to an improvement in quality of life. Another risk factor for compensatory hyperhidrosis is a high body mass index (BMI); this is why patients with a BMI greater than 25 should not be operated on. Because of the importance of compensatory hyperhidrosis, it is necessary to attempt medical treatment with anticholinergic drugs first and to operate only on those individuals who do not obtain significant results.[115] Furthermore, it is necessary to alert all patients with hyperhidrosis to this risk before they choose sympathetic denervation or an alternative technique and that treatment with anticholinergics is the best alternative for compensatory hyperhidrosis, although reasonable results are

achieved in only half of these patients.[116,117] The rate of compensatory hyperhidrosis and its severity are tolerated better by children, and their postoperative satisfaction is higher than that of adolescents and adults. Therefore VATS is indicated for children as early as possible.[118]

Another alternative that has been used in attempts to reduce the occurrence and intensity of compensatory hyperhidrosis is utilization of the two-stage unilateral or even the unilateral sympathectomy for the treatment of hyperhidrosis. With these procedures, the incidence and intensity of hyperhidrosis appears to be lower.[119–122]

Patients with poorer quality-of-life evaluations before surgery presented higher levels of improvement after sympathectomy. VATS is therefore considered an efficient therapeutic alternative for patients with initially poor quality-of-life evaluations.[123]

Vascular Diseases

Sympathectomy is seldom used at present to treat vascular insufficiency because of the availability of bypass and interventional procedures. When sympathectomy is used, it is performed for digital and palmar obstructions associated with necrotic lesions of the fingers.[124] In selected patients, sympathectomy has been reported to decrease pain and to assist in clinical treatment.[125,126]

Complex Regional Pain Syndrome

VATS is highly effective in reversing symptoms when it is performed early in the evolution of CRPS, at which time it has a success rate of 80% to 90%.[58] However, sympathectomy is ineffective if it is delayed until after joint contracture or nerve atrophy has occurred.[127] It should be used cautiously in clinical practice, in carefully selected patients, and only after other treatment options have failed.[32,128]

Long QT Syndrome

Favorable results from left thoracic sympathectomy in high-risk patients (preventing complications) have been demonstrated in the literature since the 1970s. VATS is associated with a significant reduction in the incidence of aborted cardiac arrest and syncope in high-risk patients with long QT syndrome compared with pre–left cardiac sympathetic denervation events, but changes in the QT interval after sympathectomy are variable and the clinical results cannot be fully predicted.[129] In a group of high-risk patients undergoing left cardiac sympathetic denervation, 46% remained asymptomatic; syncope occurred in 31%, aborted cardiac arrest in 16%, and sudden death in 7%.[59]

Raynaud Syndrome

The results of sympathetic denervation in cases of Raynaud syndrome are transitory.[130] Vasospastic episodes reappear within a short time, and dissatisfaction with the procedure is observed in almost 50% of patients.[131] This has led some authors to no longer recommend sympathectomy for such patients.[132]

BOX 193.1 Complications Associated With Thoracoscopic Sympathectomy

Common

Compensatory sweating (70%-100%)
Segmental atelectasis (1%-5%)
Pneumothorax (1%-5%)
Subcutaneous emphysema (1%-2%)

Rare (<1% of Cases)

Horner syndrome
Hemothorax
Pleural effusions
Injury to the vagus nerve
Injury to the phrenic nerve
Injury to the subclavian artery and vein

COMPLICATIONS OF VIDEO-ASSISTED THORACOSCOPIC SYMPATHECTOMY

Although VATS is a minimally invasive procedure, it is not free of risk. A detailed awareness of the technical difficulties and complications (Box 193.1) is important to improve the safety and outcomes of the procedure.[133]

Pneumothorax

The most common perioperative complication is pneumothorax. Most patients (75%) have some residual gas in the thorax at the end of the surgery. Small amounts of residual air in the pleural cavity remaining after sympathectomy are absorbed. However, when pulmonary fistulas are present, 1% to 3% of patients may require thoracic drainage.[134] Tension pneumothorax after surgery is rare. It results from direct injury to the lung at the time of trocar insertion or from tearing of an apical adhesion when the lung is depressed.[135]

Apical bullae may occasionally be found; they may rupture during anesthesia when high pulmonary insufflation pressure is used at the completion of the procedure. This complication can be prevented by careful reinsufflation at the end of the operation.[136] Subcutaneous emphysema around the trocar insertion site confined to the thoracic wall may occur in 2% to 7% of patients.[137] Treatment is conservative in the absence of pneumothorax.

Hemorrhage

Significant intraoperative hemorrhage is rare and mostly originates from intercostal vein disruption during dissection of the sympathetic chain. It may also occur at the trocar insertion site. Laceration of the subclavian artery and intercostal artery pseudoaneurysms requiring thoracotomy have been reported.[138]

Chylothorax

Chylothorax is an extremely rare complication resulting from laceration of the main or accessory thoracic duct.[139]

Cardiac Complications

Transitory bradycardia during sympathectomy occurs in 1.2% of the patients,[140] but it is usually self-limited and does not require intervention. Recovery takes place after a few minutes of clinical observation. Extensive thoracic sympathectomy may have a beta-blocker effect, leading to a moderate decrease in heart rate at rest and during maximal exercise.[141,142] Intraoperative cardiac arrest has been reported in only two patients during the surgical procedure, but they were both successfully resuscitated.[143]

Neurologic Complications

Severe postoperative pain is a common event, presenting in more than 95% of cases. It occurs independently of the electrocautery type. Most patients report acute pain, especially when breathing in deeply, for some hours after the operation, but a significant number complain of pain of lower intensity that is more constant in the dorsal region, which may occasionally require nonsteroidal anti-inflammatory agents for 2 weeks along with analgesics as necessary.[144]

Paresis and paresthesia in the upper limbs occurred in 2.9% of the patients as a result of tension of the brachial plexus caused by their position on the surgical table.[145] In most patients, these manifestations regressed within 3 days to 3 weeks.[146]

Horner syndrome is a side effect from complete sympathetic denervation of the upper limb when the stellate, G2, and G3 ganglia are resected.[48] However, in cases of hyperhidrosis in which only G3 or G4 is manipulated, this complication is rare.[147]

CAUSES OF FAILURE

Incomplete Denervation

Late activation of the intermediate ganglia (microscopic aggregates of ganglion cells distributed in the communicating branches or in the anterior roots of the cervical and brachial spinal nerves) may explain failures in the sympathetic denervation of the upper limbs.[13]

Regeneration

There is no evidence of regeneration of the sympathetic ganglion cells. However, if only the axis cylinder is sectioned, regeneration of new fibers from the ganglion cell may occur. This may have a negligible effect in operations where the paravertebral ganglia are removed.[63]

Functional Reorganization (Collateral Nerve Sprouting)

Degenerated fibers produce humoral substances that stimulate closely intact nerves to establish connections with denervated ganglion cells.[148] Hence cutting of only the preganglionic fibers responsible for the innervation of the upper limbs (the fibers that pass by the stellate ganglion on their pathway to the superior cervical ganglion) would give rise to favorable conditions for sprouting in the stellate ganglion.[149] Furthermore, there may be a functional connection between these branches and the ganglion cells in the spinal nerves, which would explain the return of sympathetic activity in the limb.

REVERSAL OF SYMPATHECTOMY

A small subset (currently less than 1%) of patients submitted to VATS for hyperhidrosis develop postoperative intense compensatory hyperhidrosis that is perceived as more debilitating than their initial complaints; therefore they seek medical assistance to reverse the sympathetic blockade. Studies in this area are still scarce, and the initial outcomes are poor, probably because of technical flaws.[150]

Promising technical advances with robotics technology have been achieved through implantation of a nerve graft using 10-0 nylon sutures on the epineurium.[151]

INTRODUCTION

Over the past 15 years, surgical treatment of primary or secondary malignancies involving the arteries and veins has become more aggressive.[1-6] This is due in part to careful patient selection, improvement in surgical techniques and critical care, and the lack of curative adjuvant therapies. The primary challenge to management is the inability to diagnose these tumors at an early stage, in which case surgical resection would be more broadly applicable. This chapter reviews the selection of patients, surgical principles and management, the approach to, and technical aspects of, resection and replacement of major central and peripheral arteries and veins.

TUMOR TYPES

Tumors of the arteries and veins are classified by their origin. In general primary tumors arise from the media, often the smooth muscle. They rarely arise from the intima except for aortic sarcoma. Aortic tumors have been classified in two ways. Salm described three morphologic types of primary aortic tumors: polypoid or intraluminal, intimal, and adventitial.[7] Wright classifies both the polypoid and intimal types as intimal tumors and those of the adventitia as mural tumors.[8] Polypoid tumors are attached to the intima, grow intraluminally, and have a propensity to embolize. Intimal tumors are infiltrative and grow along the endothelial surface, which may result in large vessel branch occlusion. Adventitial or mural tumors grow beyond the confines of the aorta and invade adjacent structures. The majority of primary aortic tumors are of the intimal type, with equal distribution in the aortic segments. Staats and colleagues recently reported the clinicopathologic features of 26 aortic and iliofemoral sarcomas. Most of the aortic tumors originated in the abdominal (13) or thoracic segments (8). Interestingly, the diagnosis was not suspected clinically in any case. Poorly differentiated sarcomas were most common (13), followed by undifferentiated tumors (7). There were a small number of osteosarcomas, myxofibrosarcomas, and myxoid sarcomas that secondarily involved the arteries.[9] Secondary arterial involvement is also seen with head and neck, lung, musculoskeletal, colorectal, pancreatic, gynecologic, and retroperitoneal carcinomas or sarcomas.[10-13]

Primary and secondary tumors of the inferior vena cava (IVC) are shown in Table 194.1. Primary tumors of the superior vena cava (SVC) or peripheral veins are less common than those of the IVC.[1,5,14-16] Venous leiomyosarcoma is the most common primary tumor; it occurs more often than its arterial counterpart, is polypoid or nodular, and usually grows intraluminally, although it can extend through the adventitia and invade adjacent structures.[17,18] Similar to aortic sarcoma, distant metastases occur early and are present in at least half of patients at diagnosis.[1,19,20] These factors adversely affect survival.[1]

Retroperitoneal sarcoma is the most common malignancy to invade the infrarenal IVC, but it can invade any caval segment. Cancers of the viscera or solid organs invade the IVC segment in closest proximity. For example, cancers of the liver, pancreas, kidney, or adrenal glands invade the suprarenal segment.[17] Renal cell carcinoma (RCC) is the most common malignancy to exhibit intraluminal tumor thrombus, a feature present in 4% to 15% of patients. The thrombus is limited to the renal vein-caval

Abstract

Surgical treatment of malignancies involving the arteries and veins has become more aggressive, due in part to careful patient selection, improvement in surgical techniques and critical care, and the lack of curative adjuvant therapies. This chapter reviews the selection of patients, surgical principles and management, the approach to, outcomes and technical aspects of, resection and replacement of major central and peripheral arteries and veins.

confluence in nearly half of this group. Extension into the suprarenal IVC occurs in 40% of patients, and the remaining 10% present with right heart involvement.[21-27]

CLINICAL PRESENTATION AND EVALUATION

Lymphovascular invasion is important to the pathologic staging of most malignancies. Hematogenous spread at the cellular level is the primary mechanism of metastasis for certain cancers and sarcomas, but arterial obstruction by tumor emboli is a recognized presentation of arterial tumors, albeit rarer than non-neoplastic emboli.[8,28-31] Upper or lower extremity, or brain involvement, are the most common locations of malignant embolization.[32] At times intimal or mural aortic sarcomas are misdiagnosed as aneurysms, focal dissection, an inflammatory process mimicking vasculitis, or an atherosclerotic lesion. Interestingly there are reports of aortic sarcoma originating within an aneurysmal sac after EVAR or immediately adjacent to a polyester aortic graft.[33-36] Similar to other advanced malignancies, at the time of diagnosis, the most common symptoms are nonspecific, such as malaise, fatigue, and unintentional weight loss.

Primary venous leiomyosarcoma more commonly involves the IVC than the peripheral veins, presents in women more than men, and occurs over a wide age range, with a mean age at presentation of 50 to 60 years.[1,14,15,19,37] Similar to primary aortic sarcoma, early detection is rare. Abdominal pain is the most common symptom, although many patients present with nonspecific symptoms, and metastases are present in 50% or more of patients when the diagnosis is made.[5,15,18] Cardiac symptoms, hepatic vein outflow obstruction causing Budd-Chiari syndrome, obstruction of renal vein outflow, or invasion of retroperitoneal muscles or nerves may occur with primary or secondary venous malignancies. Lower extremity deep vein thrombosis or edema is more common with peripheral vein tumors.[38]

A multidisciplinary team is paramount to manage patients with primary or secondary arterial or venous malignancies. Involvement of a medical or surgical oncologist is needed to guide adjuvant and surgical therapies. For example, neoadjuvant treatment is now offered to select patients with locally advanced pancreatic adenocarcinoma and vascular involvement to improve their candidacy for surgical resection. If a response is noted, radical resection is undertaken; this may involve revascularization of the portal vein and/or hepatic artery (Fig. 194.1). Oncologic, hepatobiliary, urologic, orthopedic, neurologic, and cardiothoracic surgeons often team with the vascular surgeon in operative planning and execution. Evaluation is directed at definition of the tumor type, its locoregional extent and distant metastases, and the severity of arterial or venous obstruction. Moreover, patient comorbidity and performance status (physical fitness) affect decision making for operation. In general surgical therapy is offered to patients with localized disease, good cardiopulmonary, hepatic and renal function, and few if any limitations in daily activities (performance status score of 0 or 1).[16]

Computed tomography (CT) and magnetic resonance imaging (MRI) are the most common studies used to define location and extent of tumor, presence of distant metastases, and plan of operation. Arterial and venous phase imaging is important. Properly timed CT venography supplants the need for standard venography. MRI remains the imaging study of choice when there is an intracaval mass, in which case differentiation between tumor and bland thrombus is critical to patient management. Some groups, including our own, have used MRI to determine the likelihood of venous wall invasion from intracaval tumor thrombus. Psutka and Zini have both shown that residual adherent tumor thrombus to the caval wall increases the risk of recurrence and mortality.[26,27] Such preoperative differentiation influences operative planning and the need for caval replacement. Positron emission tomography (PET) is selectively used to define distant metastases for many primary and secondary tumors and has been used to diagnose aortic sarcoma.[39-41] Transesophageal echocardiography and ultrasound imaging are used selectively depending on tumor type and location, particularly if CT or MRI provide inadequate images of venous tumors. The Mayo Clinic group routinely obtains lower extremity ultrasonography of the deep veins for any patient with an IVC, iliac, or extremity tumor to exclude occult deep vein thrombosis. Recently, the authors have applied three-dimensional (3D) modeling for operative planning for complex tumors in close proximity to major vessels, soft tissues, bone, or nerves (Fig. 194.2).

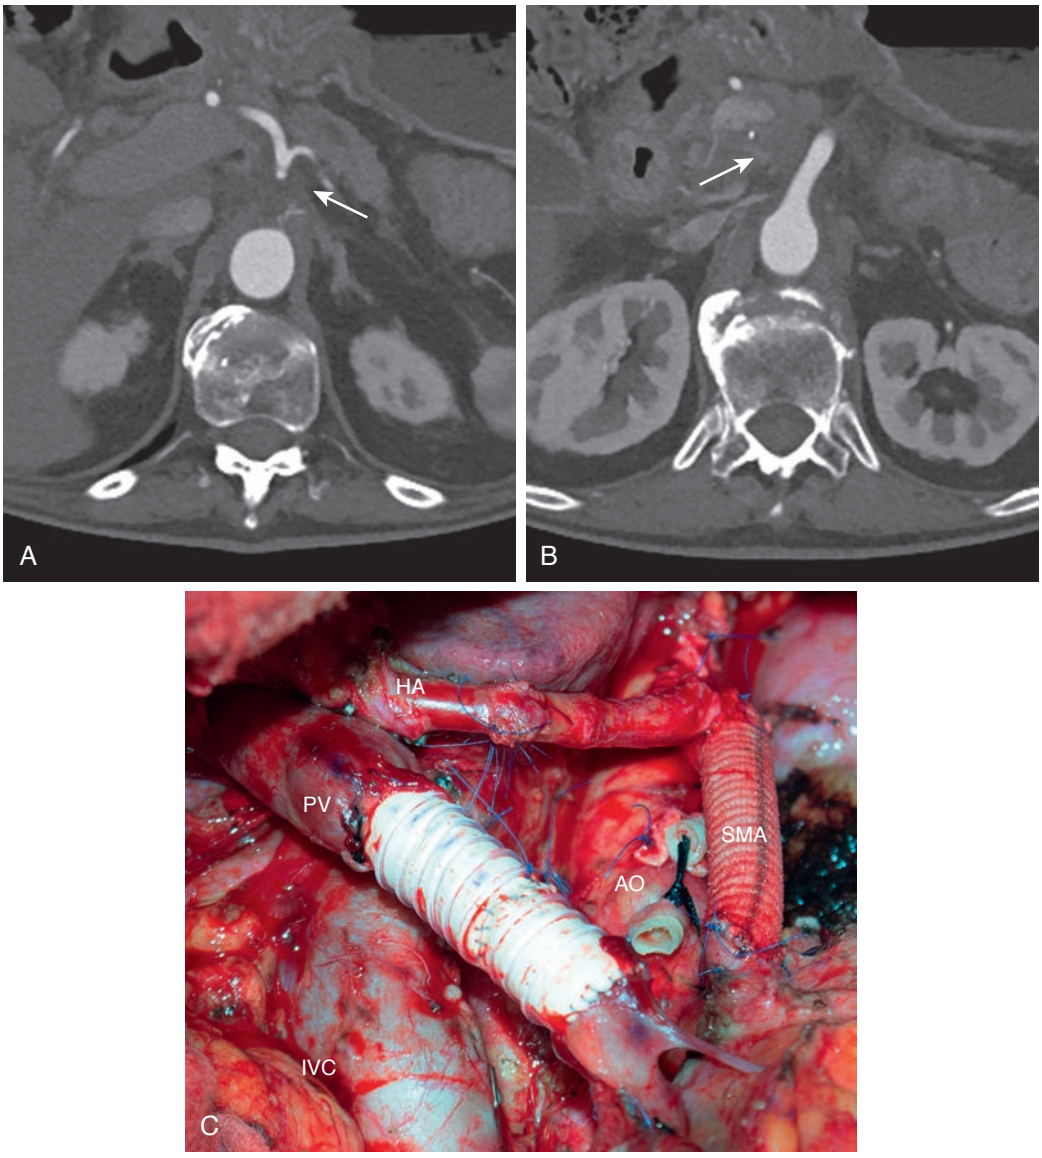

Figure 194.1 Axial computed tomography images showing encasement of the celiac artery (A, white arrow) and near-encasement of the superior mesenteric artery (B, white arrow) in a young, good-risk patient with locally advanced pancreatic adenocarcinoma who responded to neoadjuvant therapy. Tumor resection required reconstruction of the superior mesenteric artery (SMA). A superficial femoral artery graft was used to reconstruct the hepatic artery (HA) because of size match. The portal vein (PV) was reconstructed with a large-diameter externally supported polytetrafluoroethylene (PTFE) interposition graft (C). The portal vein was reconstructed first, with a longer graft to maintain liver blood flow; the hepatic artery was reconstructed later. The PTFE graft was foreshortened after the arterial reconstructions were completed. *IVC,* Inferior vena cava.

Medical risk assessment focuses on organ system function. Transthoracic echocardiography or cardiac stress studies, pulmonary function tests, and blood work for liver and renal function are commonly obtained. If major liver resection is anticipated, it is important to address the volume of liver remnant to avoid perioperative hepatic dysfunction. Physical fitness is essential if a major aortic, vena cava, or central artery or vein replacement is to be done. The risk of major adverse events and the capacity for patients to recover from surgery is negatively impacted if they have significant morbidities or limitations in daily activities (performance score ≥2). Patients with poor cardiopulmonary function or physical debility should not be offered operation in our opinion.

TREATMENT

The operative approach and treatment depend on the type, location, and extent of the tumor, the extent of venous obstruction, and the location of collaterals in patients with primary or secondary venous tumors. As with any vascular reconstruction, adequate exposure is essential, so the incision and approach must be chosen carefully and with input from the entire surgical team. 3D

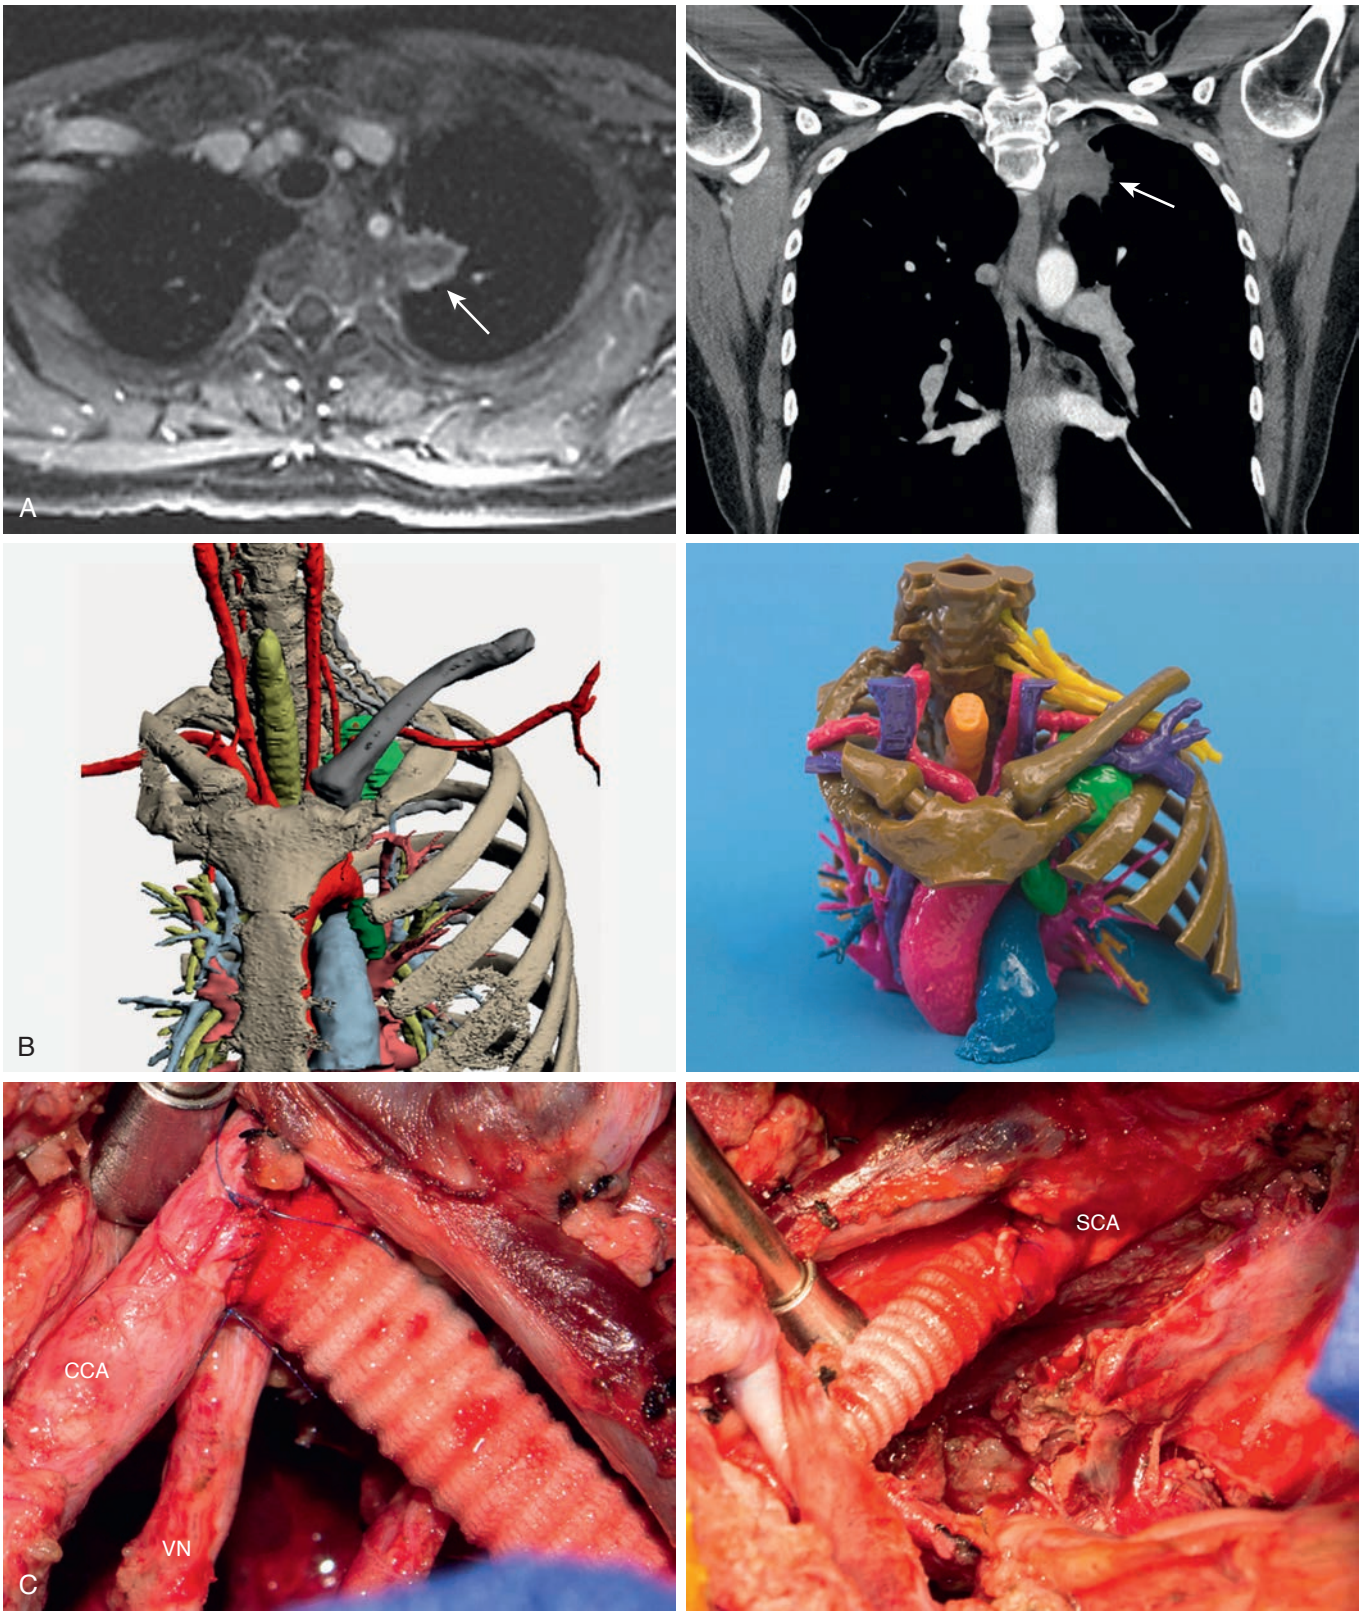

Figure 194.2 Left sided Pancoast tumor *(white arrows)* encasing the subclavian artery (A) and three-dimensional modeling (B) showing the relationship of the tumor *(green)* to the adjacent artery *(red)*, veins *(purple)*, brachial plexus *(yellow)*, and bony structures *(tan)*. modeling is helpful when the tumor is in a difficult area, such as the thoracic inlet or outlet, the mediastinum, or the pelvis. Choice of incision is straightforward for most neck, mediastinal, and extremity operations but varies when vascular reconstruction is needed in the abdomen. The selection of midline, bilateral subcostal, modified Makuuchi, or thoracoabdominal incisions is determined based on the size and location of the tumor, body habitus including the costal flare, extent of the anticipated vascular replacement, and the level at which control of the aorta, vena cava, or branch vessels is needed. For example, a bilateral subcostal incision can be used to approach the upper abdominal aorta, visceral and renal arteries, portal vein, or suprarenal vena cava if the costal margin is wide. A full midline incision provides similar access and may be preferable for individuals with narrow costal margins. Either incision can be extended with a sternotomy for patients with RCC or similar cancers when tumor thrombus involves the right heart. This combination of incisions is also useful for patients with malignant obstruction of the suprahepatic and retrohepatic IVC, where there is venous congestion of the liver (Fig. 194.3).[1,4,5,14,16,17,42] A Makuuchi incision is favored by some surgical oncologists when radical pancreatic resection and vascular reconstruction are necessary. A low right thoracoabdominal incision (eighth or ninth interspace) affords excellent exposure of the vena cava and liver for patients with large malignant tumors involving the retrohepatic IVC.

If vascular involvement is confined to only part of the aortic wall or the iliac or peripheral artery, a prosthetic or bovine patch is used for repair. Aortic, supra-aortic trunk, carotid, visceral, and iliac artery replacement is done with a prosthetic graft unless resection involves the aerodigestive tract. In this case our preference is for a cryopreserved artery allograft or superficial femoral artery (SFA).[43-45] In the authors' experience, the latter seems to resist infection or anastomotic dehiscence better than saphenous vein, particularly when the carotid artery requires replacement during the resection of head and neck cancer with involvement of the aerodigestive tract and for

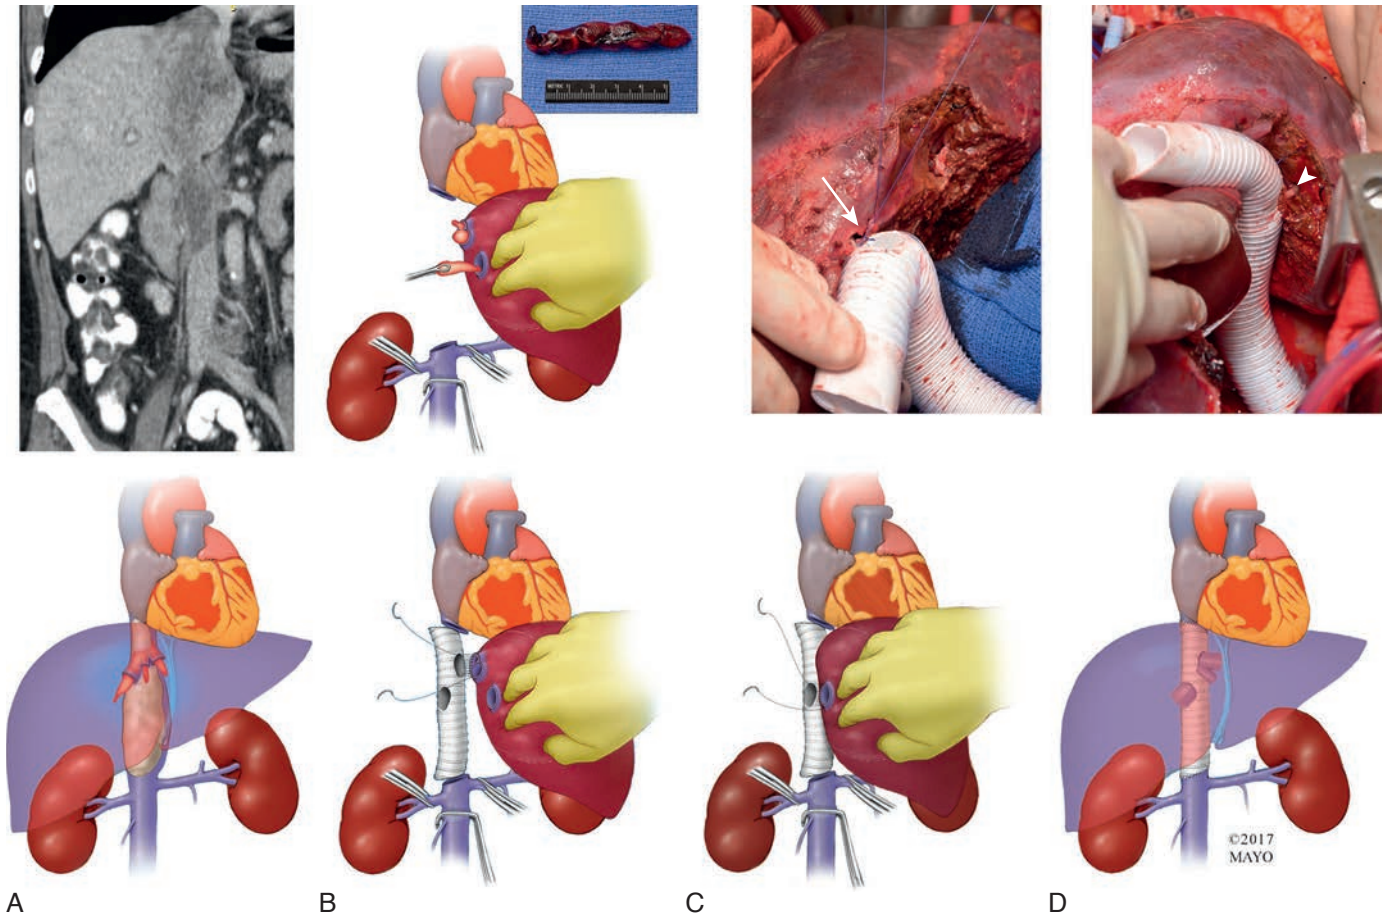

Figure 194.3 An infiltrative retrohepatic caval leiomyosarcoma extending from the cavoatrial junction to the renal vein; caval confluence as depicted vertically (A). The tumor invaded the hepatic veins, causing thrombosis, with resultant hepatic congestion. Operation was done with cardiopulmonary bypass. The tumor was resected and the liver rotated to allow removal of bland thrombus from each of the hepatic veins and some of their branches (B). The *left* and *middle* hepatic veins were reimplanted onto the externally supported polytetrafluoroethylene graft (*bottom* [B], and *top* [C, white arrow]). The right hepatic vein was reimplanted next (*bottom* [C] and *top* [D, arrowhead]). Note that the hepatic veins are not linearly oriented. The liver was placed in anatomic position, and the *upper* and *lower* caval anastomoses were completed (D), *bottom panel*.

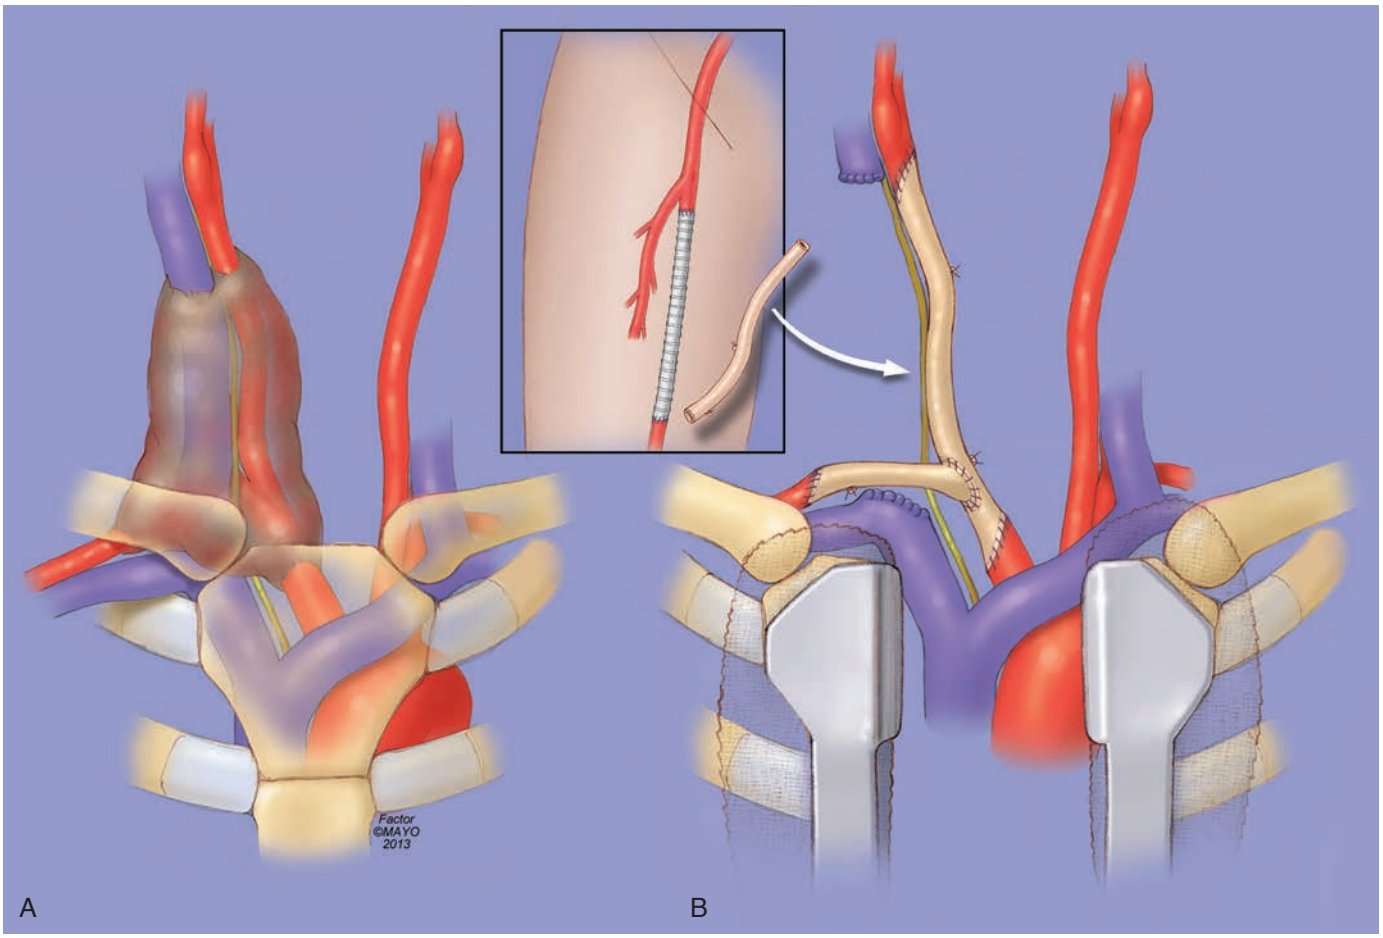

Figure 194.4 Patient with recurrent angiosarcoma encasing the common carotid, subclavian, and distal innominate arteries and the internal jugular vein, as shown schematically (A). The right superficial femoral artery (SFA) was harvested and used to reconstruct the carotid and subclavian arteries. The SFA was replaced with a prosthetic interposition graft (B). The left vertebral artery was dominant and the patient tolerated test balloon occlusion of the right vertebral artery; therefore, it was not reconstructed.

reconstruction of the hepatic and/or superior mesenteric artery in select patients with locally resectable pancreatic cancer. In these cases the SFA is replaced with a prosthetic interposition graft (Fig. 194.4). If a cryopreserved femoral artery allograft is used, it is best if the diameter is 7 mm or larger, as we have seen graft stenosis occur in smaller sized allografts. A few surgeons have used a thoracic aortic stent graft to facilitate resection of a tumor involving the aortic wall to obviate the need for aortic cross clamping. Tumor resection follows stent graft placement, and the aortic wall defect is buttressed with a patch.[46,47]

Our preference for vena cava or iliac vein replacement is a large-diameter externally supported PTFE graft.[5,16,17] The external support resists compression in the mediastinum or abdomen. Cryopreserved aortic grafts have been used by the authors to replace the IVC or iliac veins if concomitant intestinal resection is done. Others have used cryopreserved vein or bovine pericardial tube grafts in similar circumstances.[48-51] Portal vein replacement can be replaced with a prosthetic graft, or with left renal, jugular, femoral, or spiral saphenous vein conduits.[52-54] Patch venoplasty is preferred over large vein segmental resection and replacement whenever possible, and our preference is for a bovine pericardial patch. We accept as much as 60% involvement of the circumference of the IVC in which to resect and patch provided that the resection is limited to a small segment (4-7 cm length). It is imperative that the diameter of the patch be of adequate size to avoid stenosis. The diameter necessary is easily calculated based on the circumference of the normal vena cava, which geometrically is a cylinder. An IVC 20 mm in diameter in which 50% of the vein wall is resected will require a patch 30 mm in diameter (π or $3 \times$ vein diameter $\times$ % of the wall to be replaced. For this case, the calculation is made as $3 \times 20 \times 0.5$) (Fig. 194.5).[17]

Peripheral artery or vein replacement is done with a prosthetic graft or saphenous vein alone, in a spiral or panel graft configuration, or with a cryopreserved artery or vein. Choice of conduit is dependent on the size of the vessel, the length needed for reconstruction, and the availability of autogenous conduit (Fig. 194.6). If both artery and vein replacement is necessary, venous reconstruction is usually done first (Fig. 194.7). With chronic infrarenal IVC or long segment iliac or peripheral vein occlusion, vein replacement may not be necessary if collaterals are not

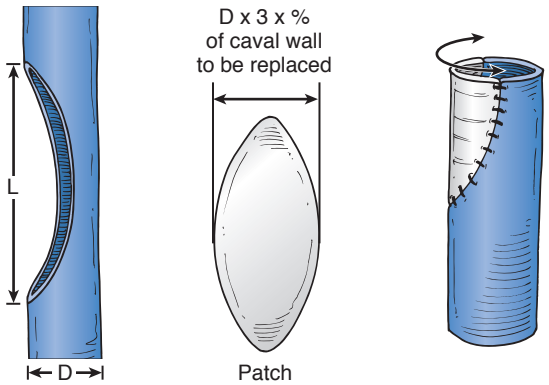

Figure 194.5 If closure of a caval defect will narrow the vein, a bovine pericardial patch is used. The diameter of the patch is estimated from the percentage circumference resected from the normal vena cava. See diagram for calculation. In most cases, the patch assumes a wide elliptical or circular configuration.

ligated during tumor resection.[21,55-58] In select cases, temporary arterial or venous shunting or bypass is utilized to maintain distal perfusion during resection of large musculoskeletal tumors before definitive vascular reconstruction.

REPLACEMENT OF THE INFERIOR VENA CAVA

At Mayo Clinic, any segment of the IVC is replaced if the majority of its circumference requires resection to achieve tumor-free margins and the vein is only partially obstructed by the malignancy. We prefer large-diameter, externally supported PTFE grafts and have found patency rates to be at least 90% in more than 110 patients who have now been treated at the Mayo Clinic.[5] Maximal diameter is 20 mm, which is sometimes smaller than the vena cava. Cryopreserved aortic allograft, femoral vein panel graft, and bovine pericardial tube grafts have been utilized in the few patients who required concomitant intestinal resection (Fig. 194.8). Others, including the University of California, Los Angeles (UCLA) group, prefer these conduits. The UCLA group favors smaller-diameter grafts because of the theoretical increase in blood flow velocity through the graft, which may enhance patency.[4] PTFE grafts are readily available and resist visceral compression. The rings of the graft are kept in immediate proximity to the anastomoses whenever possible to avoid late stenosis in the unsupported segment.

Infrarenal IVC replacement is straightforward, with the primary challenge being control of the iliac vein-caval confluence if resection extends to the caval bifurcation. There are a number of thin-walled or broad-based iliolumbar or sacral veins which cause troublesome bleeding if injured. This venous anatomy is highly variable, but often there is a large right iliolumbar vein at the junction of L5-S1. We long ago abandoned the use of arteriovenous fistulas to enhance patency for grafts in this position, given the good results seen with anticoagulation alone.[4,5,16,17,59] Resection of the pararenal IVC segment has been done without graft replacement but is hampered by a risk of renal failure, particularly if one kidney is resected with the tumor. Our preference is to reconstruct or reimplant remnant renal veins, including the left one, even if the branches of the left renal vein are preserved. The added operative time is minimal as compared with the consequence of renal failure from ligation of the left renal vein if a right nephrectomy has been done.

Special adjuncts are helpful when the retrohepatic or suprahepatic IVC requires resection and graft replacement, particularly if concomitant major liver resection and/or hepatic vein reconstruction is necessary. Total vascular isolation (TVI), selective use of venovenous or cardiopulmonary bypass (CPB) to maintain hemodynamics or protect the organs, choice of clamp position, ischemic preconditioning of the liver during hepatic resection, and ligation of the afferent and efferent lobar vessels during parenchymal division have all been used in our experience.[3-5,16,17,59-61] The specific steps with retrohepatic IVC replacement and concomitant liver resection are highlighted in previous publications by the authors.[17,59,61,62] TVI is initiated once the surgical team is prepared to transect the vena cava to complete the en bloc tumor resection. A temporary period of suprahepatic IVC clamping allows determination as to the need for venovenous bypass. Generally patients with good cardiopulmonary function tolerate systolic pressures of 100 mm Hg or higher without the need for venovenous bypass. If the initial test clamp results in lower pressures, intravenous volume loading is necessary. If the target of 100 mm Hg is not achieved within a few minutes, a cannula is placed in the infrarenal IVC at the gonadal vein confluence. Blood is circulated through an extracorporeal pump system to the jugular vein via a large-bore catheter. If the upper caval anastomosis is to the suprahepatic segment with incorporation of the remnant hepatic vein, the anastomosis will be challenging because the PTFE graft is stiff. Placement of the suprahepatic clamp in the immediate supradiaphragmatic extrapericardial position affords additional length and size of the vein orifice. A parachute technique may facilitate this anastomosis. One or more clamps are placed on the graft caudal to the anastomosis to allow hepatic venous drainage, but only after forebleeding is allowed by temporary release of the hepatic artery and portal vein clamp prior to completion of the anastomosis. Graft length is an important consideration, as the tendency is to cut the graft too long. This mistake is obviated by checking graft length during maximum inhalation and exhalation. We cut the graft primarily based on the inhalation length, as the upper and lower IVC will stretch. Reestablishment of blood flow is done after back bleeding and fore bleeding of the IVC has been performed with the patient in a head-down position, the lungs inflated to 30 mm Hg, and the graft filled with heparinized saline. The anastomosis is completed, the lower caval clamp is released, and the graft is de-aired to avoid embolism. To date, the warm liver ischemia time has been well tolerated by patients with these in situ reconstructive techniques.[3,16,60,61]

A few patients with infiltrative leiomyosarcomas or secondary tumors of the retrohepatic IVC occlude hepatic vein outflow and the liver becomes very congested. Mobilization of the liver and isolation of the suprahepatic IVC is risky because the liver parenchyma tears and bleeds easily. In these circumstances, cardiopulmonary bypass (CPB) and cooling have been utilized. The liver is fully mobilized once CPB is instituted. An atriotomy

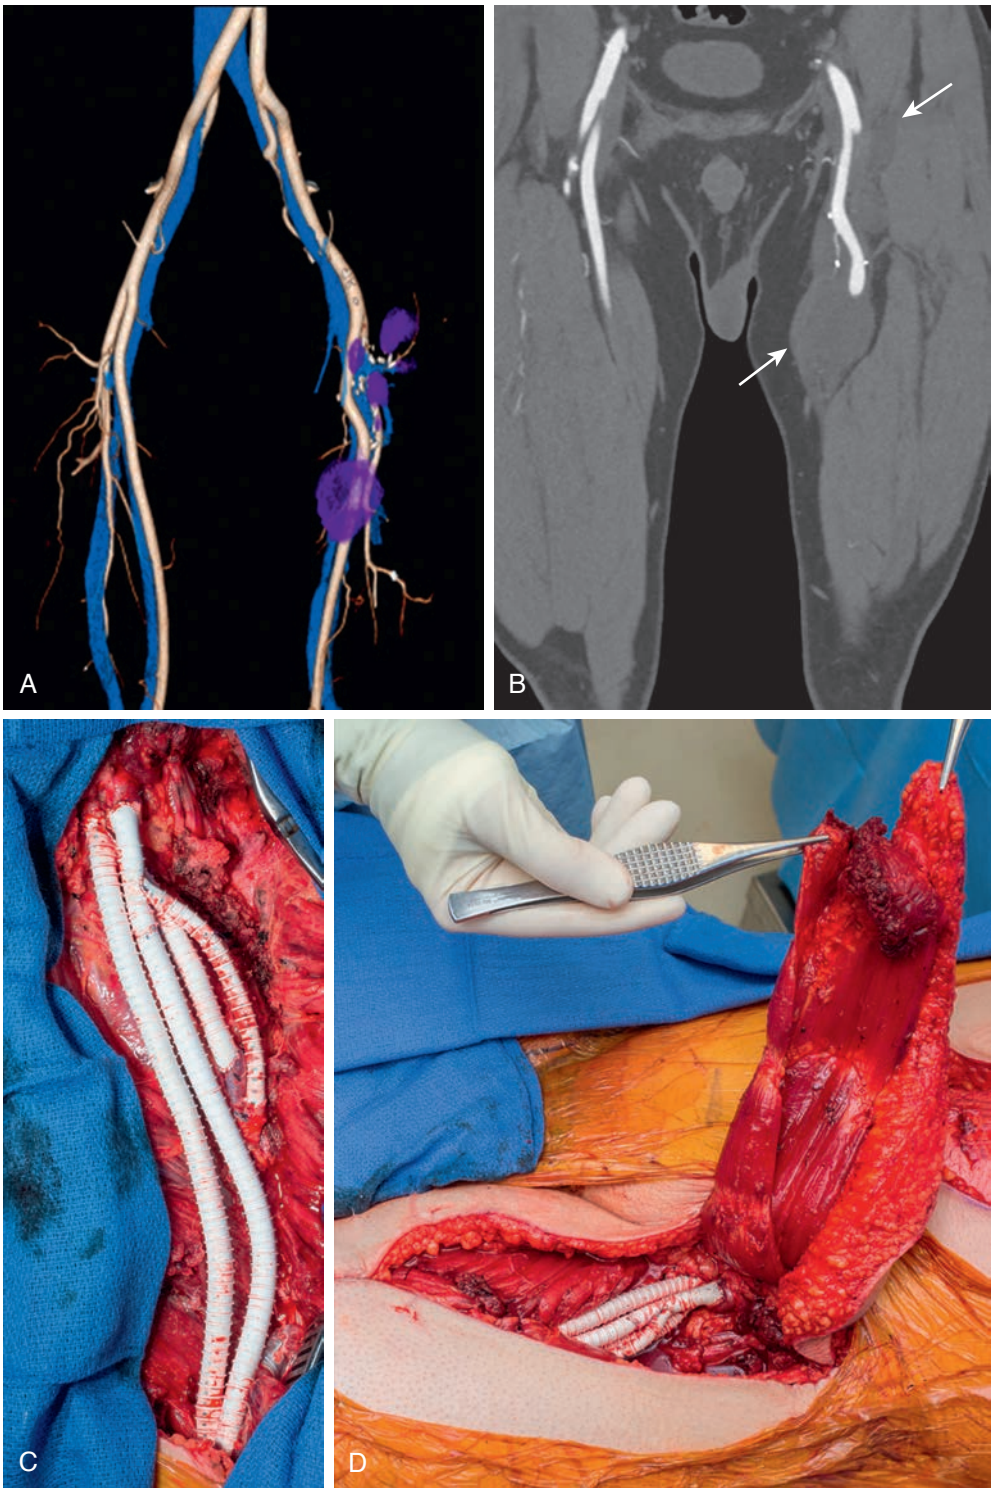

Figure 194.6 Patient with recurrent myxoid liposarcoma in the left groin and thigh, encasing the femoral arteries and veins (A and B). To achieve tumor-free margins (R0 resection), a wide resection was necessary. The common femoral artery and vein, deep femoral artery and vein, and superficial femoral artery and femoral vein required interposition grafts. Although autogenous reconstruction is preferable for peripheral veins, the patient did not have adequate conduit, necessitating the use of a prosthesis (C). Distal arterial and venous anastomoses were done first and the proximal venous anastomoses were completed next, followed by the common femoral artery anastomosis. A rectus abdominis flap was mobilized to cover the grafts and fill the soft tissue defect (D).

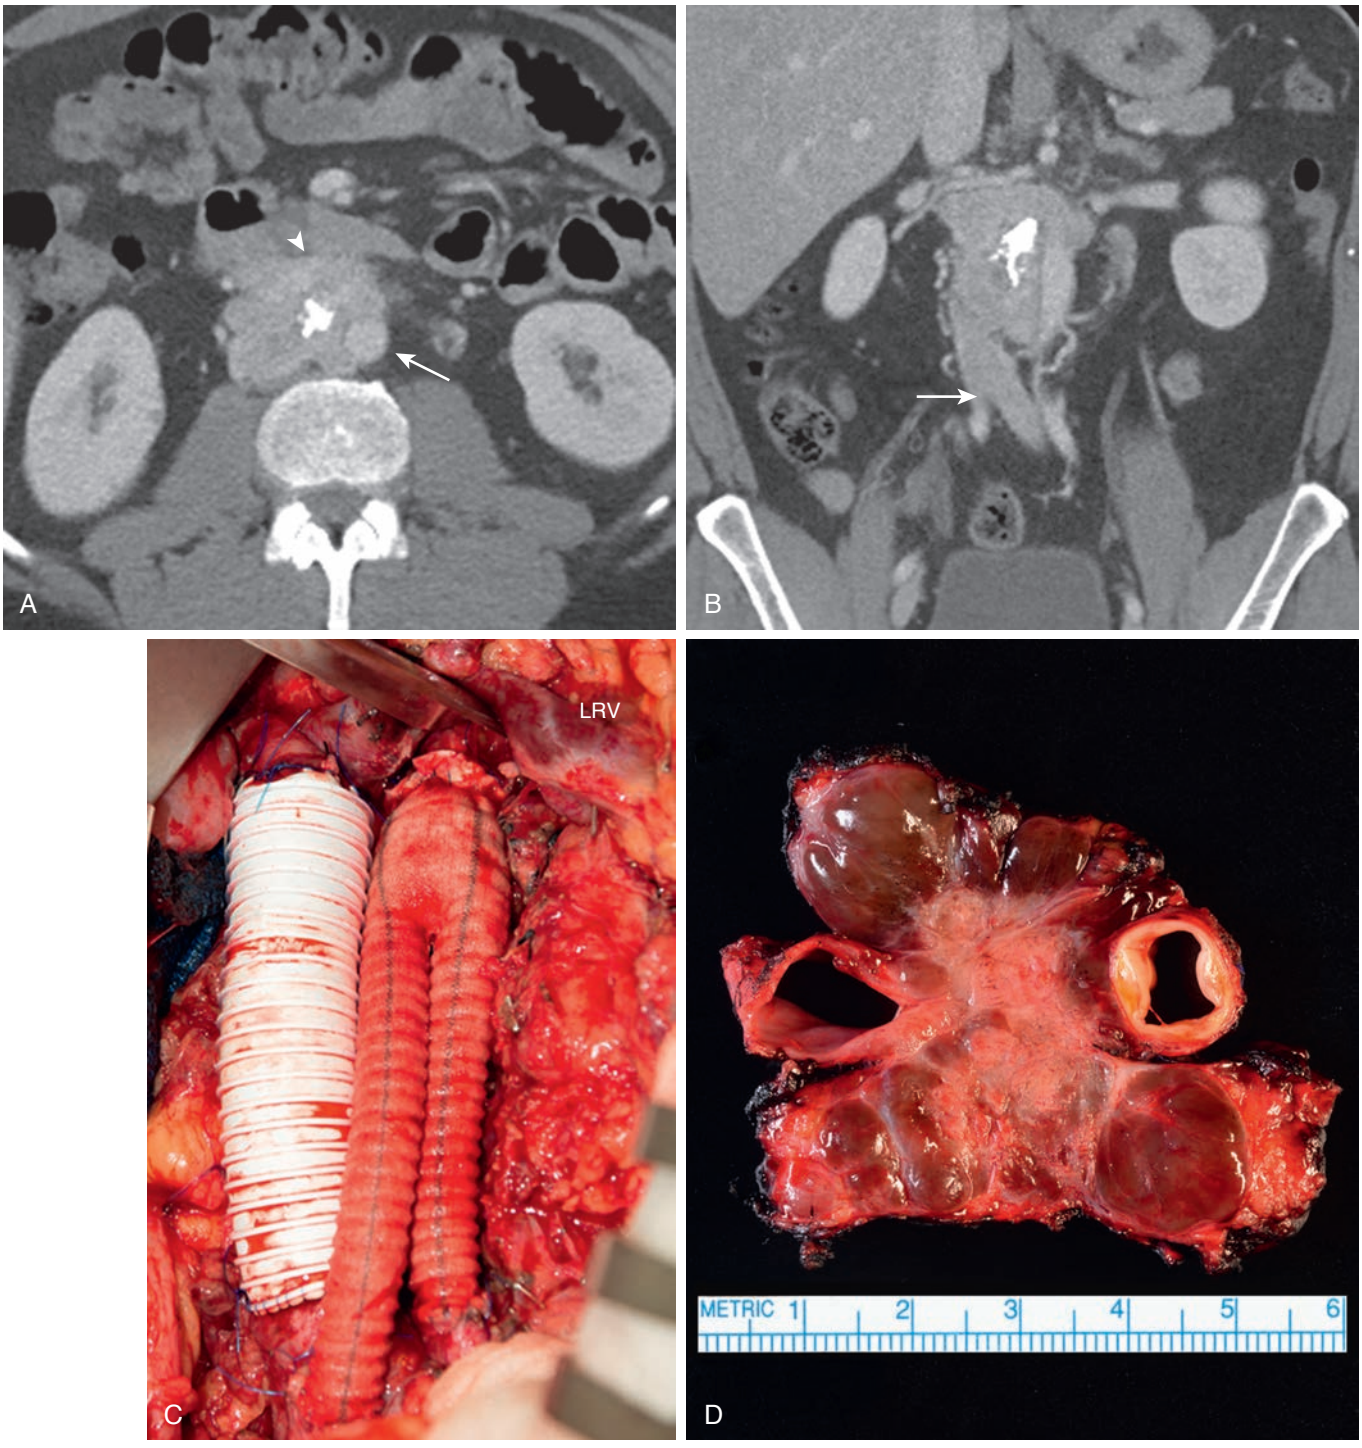

Figure 194.7 Paraganglioma encasing the infrarenal vena cava (A, *arrowhead*) with partial involvement of the aortic wall (A, *arrow*), as shown on CT (A) and (B), and on the pathologic specimen (D). The tumor extended to near the caval bifurcation, as shown by the *arrow* (B). The vena cava and the aorta required reconstruction (C). *CT,* Computed tomography; *LRV,* left renal vein.

allows examination of the upper extent of the tumor. The IVC is transected and the tumor and cava are resected with buttons cut around the hepatic veins. It is imperative that frozen sections show tumor-free margins. The remnant hepatic veins are reimplanted onto the caval graft; it is then placed in anatomic position and sewn to the cavoatrial junction and the infrahepatic IVC. The challenges are proper alignment of the hepatic veins on the graft, as they are not linear in orientation, and ensuring that the hepatic vein–graft suture lines and the raw liver surface are hemostatic in advance of the caval-graft anastomoses due to the inherent coagulopathy with CPB and hypothermia.

Others prefer ex situ hepatic resection and autotransplantation of the hepatic remnant if a complex vascular reconstruction is needed and the warm hepatic ischemia time is anticipated to be

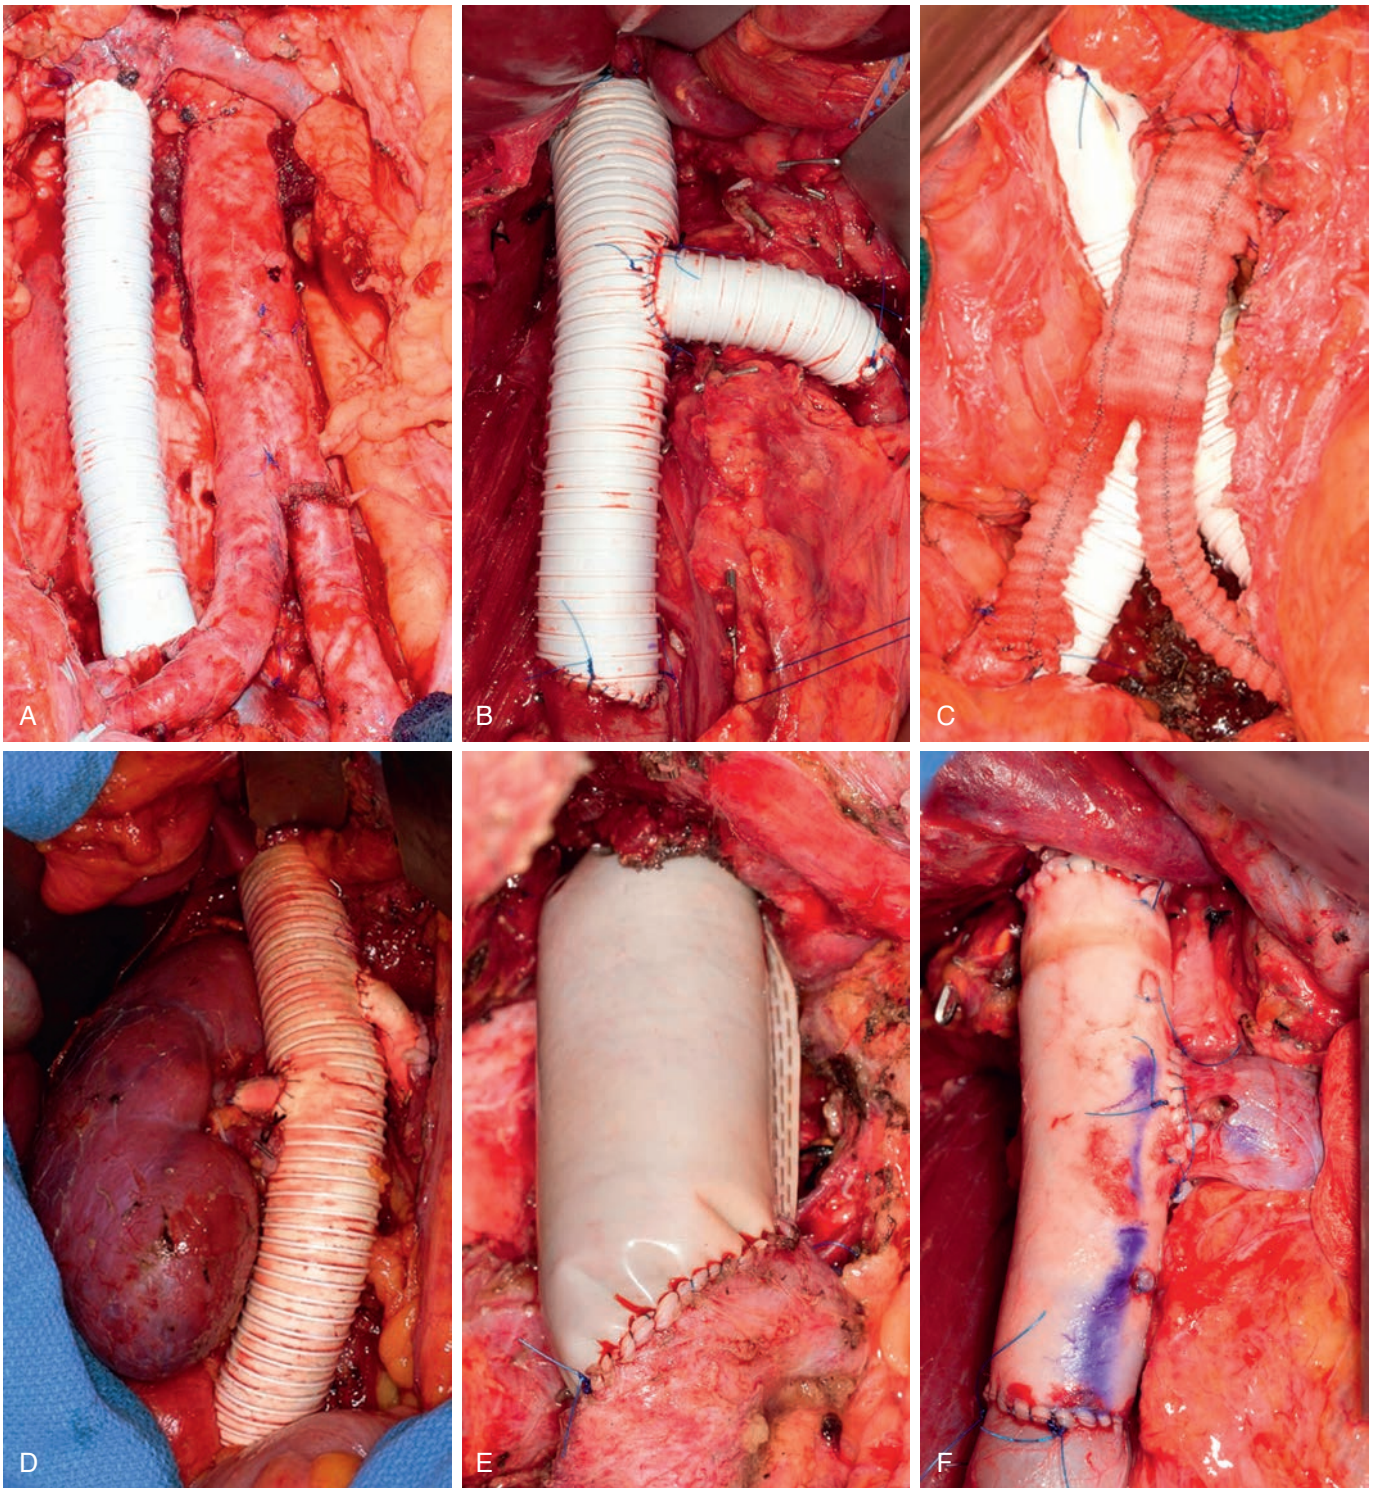

Figure 194.8 Inferior vena cava (IVC) and branch vein reconstructions can be done in many ways. (A) An infrarenal IVC graft. (B) Reconstruction of the infrahepatic and infrarenal IVC with a prosthetic interposition graft to the remnant left renal vein. (C) Bifurcated grafts used to reconstruct the infrarenal IVC, aorta, and common iliac arteries. Both renal veins were reconstructed together with caval replacement in (D). A bovine pericardial tube graft was used to reconstruct the infrahepatic IVC (E). A cryopreserved aortic allograft was used for caval replacement (F), as there was duodenal wall invasion. The remnant left renal vein was reimplanted.

long. Ex situ techniques allow time to perform difficult vascular anastomoses while protecting the liver but are fraught with higher perioperative mortality and liver failure rates than in situ reconstructions. Moreover, there is a low but real risk of liver failure, necessitating orthotopic liver transplantation. Further refinement in surgical technique, methods to mitigate ischemic liver injury, and new or better neoadjuvant therapies are needed to broaden applicability and improve outcomes in these patients.[3,16,60,61]

OUTCOMES

Patient outcome is dictated by operative risk; performance status; tumor type, location, and stage; and whether arterial and/or venous involvement is managed by primary closure, a patch, or an interposition graft.

Given the rarity of primary aortic or peripheral arterial malignancies, few surgical series are available.[12,28,32,63,64] The Mayo Clinic group reported outcomes in 13 patients diagnosed with primary angiosarcoma of the heart, aorta, or supra-aortic trunks spanning a 26-year period. Metastatic disease was present in 10 patients when diagnosis was made, and only 9 proved to have resectable disease. Of the nine patients, five underwent aortic resection and reconstruction and two each were treated by thromboendarterectomy or pericardiectomy and atrial septal resection with patch closure of the defect (Fig. 194.9). One patient had biopsy only. There were no early deaths but overall median survival was just 8 months. The surgically treated aortic sarcoma patients had median survival of 14 months, ranging from 1 to 75 months.[28] Carpenter et al. reported outcomes for 60 patients surgically treated for tumors arising from or secondarily involving the aorta or other major arteries.[12] Iliac artery involvement was noted in 37 patients (62%) and sarcoma was the most common pathology; of these, 12 patients required aortic resection, 8 were treated with graft replacement, and a patch or primary closure was used for the others. Early mortality was 5%. There were two intraoperative deaths and another from cardiac arrest within 24 hours of surgery. Two deaths were in patients with aortic tumors, and the third in a patient with sacral malignancy in which the aorta and iliac arteries required mobilization. The latter patient died from coagulopathy induced by bone and soft tissue hemorrhage. Graft patency was excellent over a mean follow-up of 20.5 months except for one patient with an SFA graft rupture and another with thrombosis of a prosthetic graft involving the common iliac artery.[12]

Comparison of outcomes for patients with IVC replacement is difficult because tumor types vary and surgeons lump patients treated by primary closure or patch angioplasty with those who need segmental resection and graft replacement. Moreover, the location of the IVC tumor influences risk.[18] The physiologic stress of a retrohepatic IVC graft replacement, particularly if hepatic veins require concomitant reconstruction, varies significantly from an individual who needs replacement of the infrarenal IVC. Mortality was 20% in the Kieffer series, but tumor size was large and 14 of the 20 patients had suprarenal IVC involvement, including 5 with invasion into the hepatic veins or heart.[15] By comparison, Ito reported no mortality among 20 patients surgically treated for PVL, but only 5 patients had graft replacement and only 1 had tumor above the hepatic veins.[14] Similarly, an Italian report indicated low mortality among 11 patients treated with graft replacement of the infrarenal IVC.[1,65] Contemporary series from Quinones-Baldrich et al., Hemming and colleagues, and Glebova and associates document low mortality despite increasingly complex operations (Table 194.2).[1-6,14,15,42,61,66,67] Overall 5-year survival has reached 50% in some series for primary or secondary IVC tumors. Among 124 patients from the Mayo Clinic who had segmental IVC resection and graft replacement, at 5 years, overall survival was 52%, disease-free survival 32%, and local progression-free survival 66%.[5] Other series report similar results. Although surgical resection may improve survival in select patients, more effective adjuvant therapies are needed if additional survival advantage is to be seen.

The greatest survival benefit is seen in patients surgically treated for RCC with intracaval tumor thrombus. Five-year survival rates between 40% and 60% are noted in several series, with sarcomatoid features, lymph node involvement, perinephric fat infiltration, distant metastasis, and residual tumor adherent to the IVC wall after thrombectomy adversely impacting outcome.[21-24,26,27,68-71] Extent of tumor thrombus is not as important as presence of metastases at time of operation or vascular margin status. Psutka and colleagues noted a 1.5-fold increase in mortality at 5 years if vascular margins proved positive on pathologic analysis, among a cohort of 304 patients. Five-year disease-specific survival reaches 40% to 71% for patients undergoing radical nephrectomy and IVC tumor thrombectomy in the absence of metastases, but falls considerably to 6% to 28% when metastatic disease is present.[25,26]

Concomitant liver resection increases the complexity of the operation significantly. Sarmiento and colleagues reported outcomes of 19 patients who underwent partial hepatectomy and segmental IVC resection and reconstruction. Cholangiocarcinoma was the most common tumor (nine patients), followed by metastases in five, sarcomas in three and hepatocellular carcinoma in two patients. Major hepatectomies (≥3 segments) were performed in 15 patients. Hepatic vascular isolation was needed in 13 patients, and all but 1 patient had IVC replacement with a PTFE graft. Despite a high complication rate (42%), there was only one perioperative death (5%). Median overall survival was 38 months.[61] These results are corroborated by a more recent publication by Hemming and colleagues.[3] Concomitant liver and IVC resection was performed in 60 patients, mostly for primary hepatic tumors. Graft replacement of the IVC was needed in 38 patients, 6 of whom required an ex vivo procedure, whereas the remaining 54 used varying degrees of vascular isolation. Perioperative mortality was 8%. Long-term survival was 89% and 35% at 1 and 5 years, respectively. These results support aggressive resection of hepatic tumors with IVC involvement.[3,60,61]

Adjuvant therapies have been slow to evolve for most primary or secondary IVC malignancies. Tyrosine-kinase inhibitors seem an effective treatment for patients with RCC, although they have not significantly impacted survival in patients with intracaval tumor thrombus.[72-75] An R0 tumor resection is always the goal, but select patients with retroperitoneal or IVC sarcomas may have their risk of locally recurrent disease lowered by radiation therapy. Some authors have shown benefit from combination of external beam and intraoperative radiation therapy in such cases.[76-79]

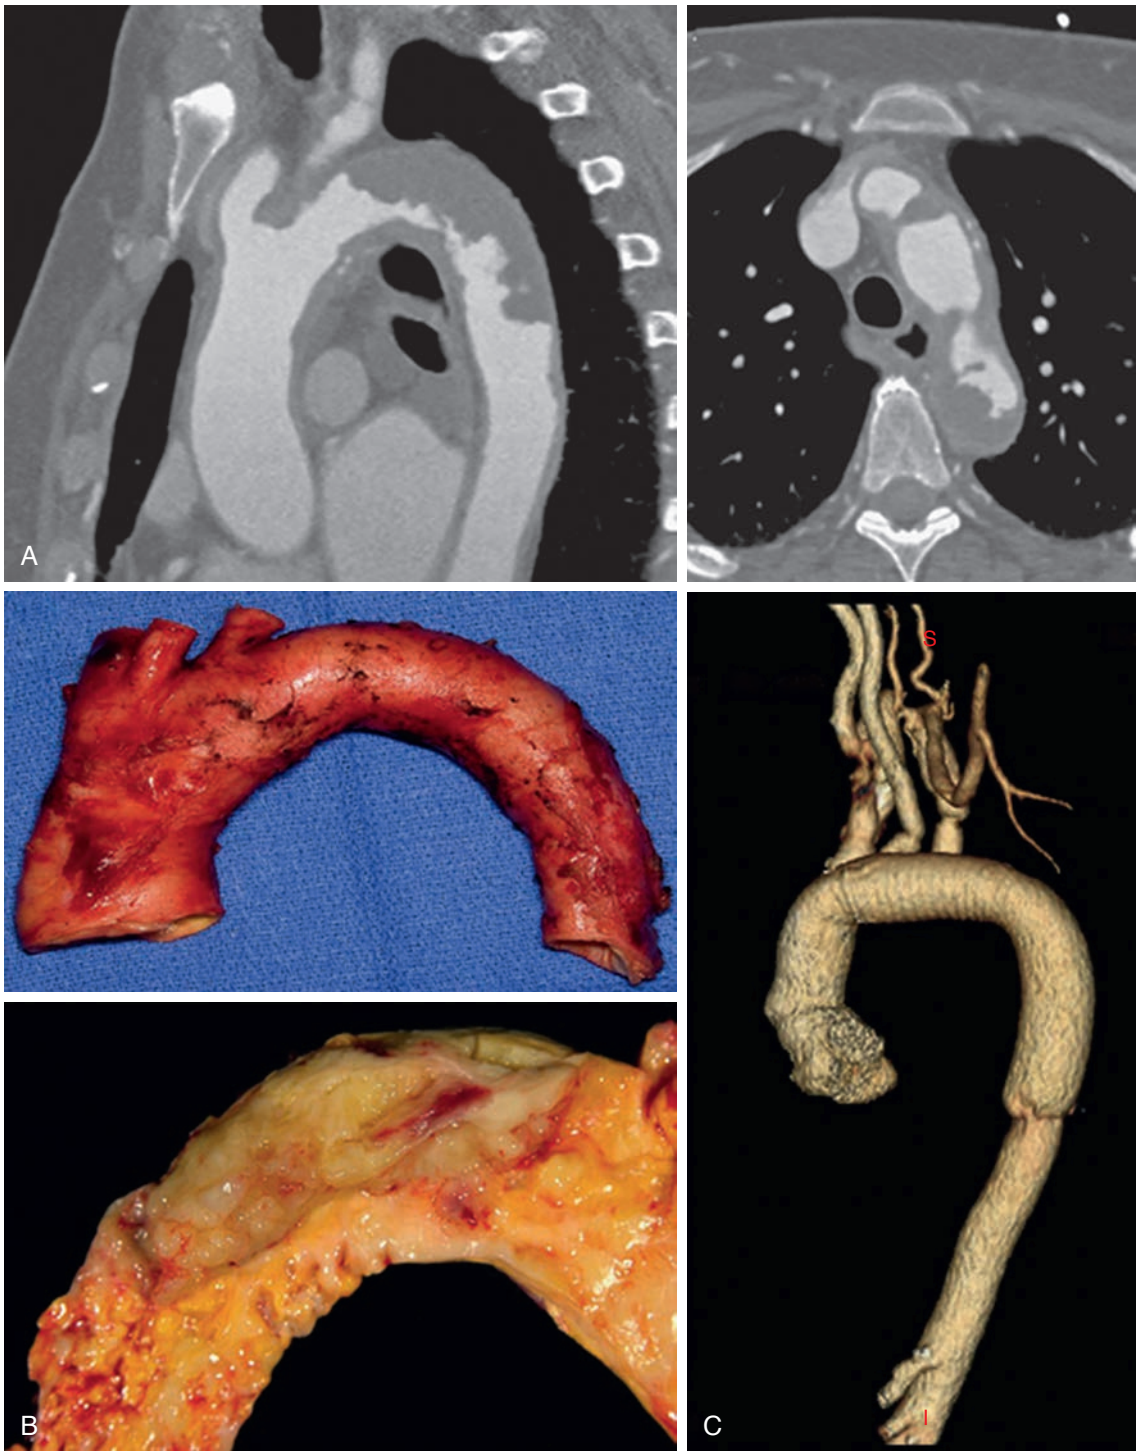

Figure 194.9 Sagittal and axial computed tomography (CT) images of an intimal sarcoma of the aortic arch and proximal descending thoracic aorta (A). Pathologic specimens (B) show no gross invasion through the adventitia but extensive intimal tumor. Postoperative CT angiogram (C) showing widely patent aortic graft with reconstructed supra-aortic trunks. (Modified from Fatima J et al. Primary angiosarcoma of the aorta, great vessels, and the heart. *J Vasc Surg*. 2013;57(3):756-764.)

Malignant obstruction of the SVC is most often caused by lung cancer with mediastinal adenopathy. Lymphoma, thyroid cancer, thymoma, and teratoma are the other etiologies. Most patients with malignant SVC obstruction are not surgical candidates, and treatment is palliative with stenting of the vein. If patients with localized disease undergo segmental SVC or innominate vein resection, our preference for venous reconstruction is a prosthetic graft (expanded PTFE).

Single-center experience with peripheral vein reconstruction for malignancy is rarer than that of the IVC. Sun and associates

TABLE 194.2 Contemporary Series of Primary and Secondary Inferior Vena Cava Malignancies

[a]Nine SVC and 26 IVC tumors. The locations in the nine patients with grafts are shown in parentheses.
[b]Eight entire IVCs replaced with hepatic/renal vein reimplantation; six had suprarenal and pararenal IVCs replaced with seven renal vein reimplantations; four had infrarenal and pararenal IVCs replaced with four renal vein reimplantations.
[c]Multiple segments in the remainder.
HCC, Hepatocellular carcinoma; *IVC,* inferior vena cava; *IR,* infrarenal segment; *PVC,* primary venous leiomyosarcoma; *RCC,* renal cell carcinoma; *SR/RH,* suprarenal–retrohepatic segment; *SH,* suprahepatic segment.

from the Mayo Clinic reported the results of 28 reconstructions in 27 patients with iliac (19), lower extremity (6), and upper extremity (3) venous tumors spanning the period between 2000 and 2015. Prosthetic grafts were used in 17 patients, vein grafts in 7, and a cryopreserved graft in 1, with the remaining 3 reconstructions done with a patch. Early outcomes were good, with no 30-day mortality and few graft-related complications (infection in three). At a median follow-up of 4.4 years, 2- and 5-year primary patency rates were both 61%. Graft thrombosis occurred in five patients, four with prosthetic grafts, yielding an overall freedom from graft thrombosis of 87% at 5 years.[38] Similar results have been reported by others.[80]

Bower TC, Nagorney DM, Cherry KJ, et al. Replacement of the inferior vena cava for malignancy: an update. *J Vasc Surg.* 2000;31(2):270–281.

The paper provides an in-depth analysis of the types and locations of the IVC tumors, analysis of outcomes, and detailed surgical techniques.

Fatima J, Duncan AA, Maleszewski JJ, et al. Primary angiosarcoma of the aorta, great vessels, and the heart. *J Vasc Surg*. 2013;57(3):756–764.

The Mayo Clinic experience in 13 patients diagnosed with primary angiosarcoma of the heart, aorta, or supra-aortic trunks spanning a 26-year period. Five of the nine patients underwent aortic resection and reconstruction and two each were treated by thromboendarterectomy or pericardiectomy and atrial septal resection with patch closure of the defect. There were no early deaths but overall median survival was just 8 months. The surgically treated aortic sarcoma patients had median survival of 14 months, ranging from 1 month to 75 months.

Hemming AW, Mekeel KL, Zendejas I, Kim RD, Sicklick JK, Reed AI. Resection of the liver and inferior vena cava for hepatic malignancy. *J Am Coll Surg*. 2013;217(1):115–124.

A large series of 60 patients treated with concomitant liver and inferior vena cava resection for primary and secondary hepatic tumors. A detailed technical description of different variations of the operation is provided. Ex vivo reconstruction was performed in six patients, and the other 54 procedures were performed with varying degrees of vascular isolation. The IVC was reconstructed in 38 patients using a tube graft. Perioperative mortality was 8% and actuarial 1- and 5-year survival rates were 89% and 35%.

Pouliot F, Shuch B, LaRochelle JC, Pantuck A, Belldegrun AS. Contemporary management of renal tumors with venous tumor thrombus. *J Urol*. 2010;184(3):833–841.

This paper summarizes the contemporary management of patients with renal cell cancer and venous tumor thrombus. The authors provide comparative outcome data between the largest studies with regard to median survival, disease-specific survival, and impact of metastases or no metastases on disease-specific survival.

Quinones-Baldrich W, Alktaifi A, Eilber F. Inferior vena cava resection and reconstruction for retroperitoneal tumor excision. *J Vasc Surg*. 2012;55(5):1386–1393.

The UCLA group describes 47 patients treated with IVC resection and tumor excision between 1990 and 2011. The majority of tumors were sarcomas, of which 30 were primary to the IVC. Eleven patients had primary repair, 9 had patch angioplasty, and 27 had circumferential resection and IVC replacement with a PTFE graft. Eighteen of the reconstructions with grafts included more than one caval segment. There was no mortality and a 10.6% major morbidity rate.

PANCREATIC MALIGNANCIES

Pancreaticoduodenectomy

Pancreatic cancer is currently the fourth leading cause of death within the United States with 53,000 new cases and 41,780 deaths estimated for 2016.[1] Improving long-term survival remains the goal of care. Therefore surgery remains the pivotal portion of multidisciplinary care. Currently, preoperative resectability can be classified as follows: *unresectable* (metastatic disease/encasement of the superior mesenteric artery [SMA] or hepatic arteries, lack of venous reconstructive options); *borderline resectable* (superior mesenteric vein [SMV]/portal vein [PV] tumor-vessel interface ≥180 degree of vessel wall circumference, and/or reconstructable occlusion; SMA tumor-vessel interface <180 degree of vessel wall circumference; celiac artery [CA] tumor-vessel interface <180 degree of vessel wall circumference); or *resectable.*[2] Recent reports of successful SMA and hepatic artery reconstruction during resection of a pancreatic head malignancy (at times with total pancreatectomy) may provide successful surgical strategies in some patients with arterial involvement. Therefore venous resections, as well as arterial reconstruction, need be in the armamentarium of the pancreatic surgeon. Herein presented are the details of vascular reconstructions for resection of the pancreatic head.

When there is potential for a venous resection/reconstruction one should consider an artery-first approach.[3,4] Our preference is to dissect and ligate all SMA branches/perivascular connective tissue to the pancreas prior to undertaking SMV/PV clamping or venous resection. In brief, this technique can be accomplished by rotating the specimen to the left by widely mobilizing the right colon to fully expose the duodenum in its entirety and dividing the perivascular connective tissue along the SMA in a parallel fashion from caudal to cranial. Attachments between the SMA and uncinate are divided to expose the lateral border of the PV–SMV. After the specimen has been freed from the SMA the only tissue remaining should be venous attachments. Benefits include not only the potential for lower blood loss and

Abstract

Vascular resections and reconstructions are not uncommon during oncologic operations. Surgeons undertaking tumor extirpation should be aware of the potential need for vascular interventions and technically proficient in vascular procedures prior to entering the operating theatre. Herein, this chapter focuses on the technical aspects of vascular resection and reconstruction for pancreatic, hepatic and biliary malignancies as well as soft tissue sarcoma.

facilitation of an en-bloc resection but also increased mobility of the specimen and ease of venous resection.

Venous Resection and Reconstruction

The surgeon should have a clear understanding of the need for venous reconstruction based on high quality preoperative cross-sectional imaging (triple contrast phase along with thin cuts through the pancreas). Obliteration of the tumor/vessel fat plane interface or narrowing of the SMV/PV is suggestive of vascular abutment or involvement. True venous involvement of the SMV, PV, or their confluence can be confirmed either at the time of tunneling under the pancreatic neck or following the creation of the tunnel (at the time the surgeon is controlling vessels from the SMV/PV, SMA to the head of the pancreas and uncinate process). Vein resections can either be performed by excising the right lateral portion of the SMV or PV or a segment of the SMV, after gaining venous control. Generally, options to proceed include locally resecting a portion of the right lateral aspect of the SMV/PV (tangential resection) and repairing either with interrupted sutures in a transverse fashion or with a saphenous vein patch (Fig. 195.1), segmental resection and primary anastomosis, or segmental en-bloc resection of tumor and vein followed by placement of an interposition graft.[5] More recently, data suggest SMV or PV resection with primary end-to-end reconstruction or transverse venorrhaphy results in a greater patency rate as compared to lateral/longitudinal venorrhaphy, patch venoplasty or interposition grafting.[6]

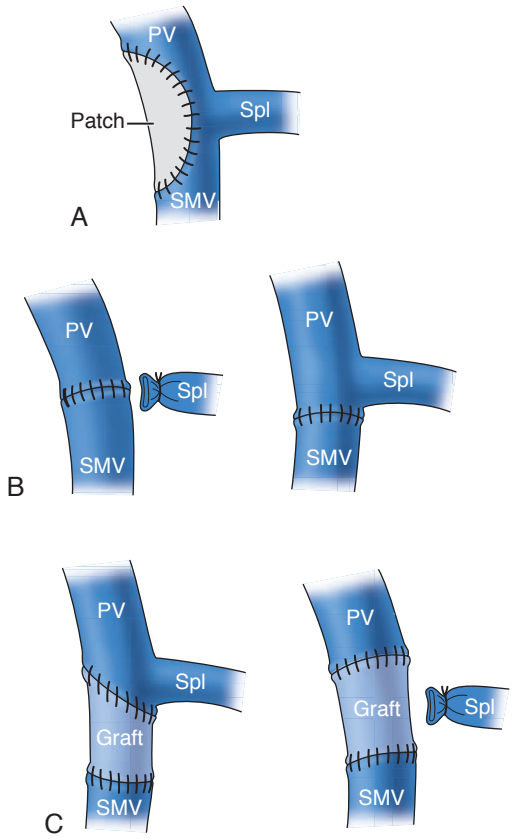

Figure 195.1 Venous Reconstruction Options Following Superior Mesenteric Vein/Portal Vein Resection During Proximal Pancreatectomy (A) tangential resection with patch repair, (B) primary anastomosis with/without splenic vein grafting, (C) interposition grafting with/without splenic vein grafting. (From Tseng JF, Raut CP, Lee JE, et al. Pancreaticoduodenectomy with vascular resection: margin status and survival duration. *J Gastrointest Surg*. 2004;8:935–950.)

As a general principle, it is of paramount importance to critically analyze the site of tumor infiltration of the vein preoperatively and intra-operatively. Wide mobilization of the liver and retroperitoneum will allow approximately a 3-cm gap to be bridged by a primary end-to-end repair. Proximal vein involvement can typically be handled more easily, as the vessel diameter is large enough to create a sufficient anastomosis. However, in cases of venous involvement distal to the first jejunal branch, the decreasing diameter of the SMV may limit the technical possibility to perform a venous resection.[7] Occasionally, however, the SMV, PV, SV, and confluence will all be involved by tumor. This pattern of venous invasion may be found when resecting tumors of the pancreatic neck or medial aspect of the head of the pancreas. In such cases when all three venous structures are involved, a total pancreatectomy with SMV to PV reconstruction can be considered. In this setting, the venous gap may exceed 3 cm and interposition grafting may be required.

Please note, for all proximal pancreatectomies, the patient should have the groin sterilely prepped into the field and covered to allow access to the great saphenous vein (GSV) if venous reconstruction should be required.

Tangential Superior Mesenteric Vein/Portal Vein Resection With Saphenous Vein Patch

Tangential (right lateral SMV/PV partial resection) has become our preference when there is involvement of the medial aspect of the SMV/PV junction opposite to the splenic vein. Although certain circumstances preclude this technique and a formal segmental resection must be performed, if possible a tangential resection should be utilized. Key technical aspects of this procedure include proximal and distal control of the SMV/PV and splenic vein with vascular clamps, achieving a grossly negative margin of vein and constructing a vein patch. If there is a question of leaving a positive margin, a segmental resection should be utilized. Additionally, if only a small portion of the vein is required for resection the vascular clamps can be applied in a "V" format, angling in behind the involved area of vein. Note, if a larger portion of the vein is required, a Satinsky clamp can be applied parallel to the vein.

The GSV should always be harvested prior to PV clamping in order to expedite the reconstruction and limit the amount of portal flow disruption. It is paramount to plan and prioritize sequential steps to allow for safe and efficient venous repair. GSV harvest is accomplished by exposing the previously prepped groin and creating a longitudinal incision medial to the femoral artery. The GSV is then identified at its junction (saphenofemoral junction) with the femoral vein, mobilized distally for an appropriate length (5-6 cm), and ligated proximally and distally; this segment of GSV is then removed and placed in heparinized

saline. Note: close communication with the anesthesia team at the time of PV clamping is important to avoid potential hypotension and any diminished mesenteric venous flow.

To complete the vein patch, the GSV should be opened longitudinally, cut to size and spatulated. The valves should be lysed to avoid directional flow issues. Following clamping, the patch is then grafted using 5/0 or 6/0 prolene suture in a running technique (see Fig. 195.1). Finally, an air knot of 1/3 the diameter of the PV (growth factor) is tied in order to allow for venous distention.

Segmental Resection and Primary Anastomosis

Segmental resection with primary end-to-end anastomosis has proven to have the highest patency rates of all reconstruction methods. Certain factors must be appropriate in order to complete a primary end-to-end anastomosis following a segmental resection. First and foremost, the anastomosis must be created without tension. This can be facilitated by mobilization of the SMV (along the root of the small bowel mesentery) and PV (superior to the pancreas) by ligating and dividing small branches along the length of these vessels. Additionally, further length on the PV can be gained through hepatic mobilization. Therefore the right and left liver should be mobilized by incising the triangular and cardinal ligaments along with the hepatocolic and falciform ligaments. If further length is required, the midgut can also be mobilized by creating a dissection plane immediately anterior to the wall of the aorta and IVC. Such preparatory steps should precede the interruption of portal venous flow to avoid venous congestion.[9]

Proximal and distal control of the PV and SMV is then obtained with pediatric vascular clamps, the vein transected, and the specimen removed. The previous mobilization maneuvers should permit a tension-free primary anastomosis. Once an appropriate length is achieved, the anastomosis is undertaken utilizing a running 5/0 or 6/0 prolene suture on the back wall and simple suture repair on the front wall. Note: travel distance between each suture should be conservative. Finally, an air knot of 1/3 the diameter of the PV (growth factor) is tied in order to allow for venous swelling and to prevent an hour-glass formation of the anastomosis. Typically, a segmental defect of ≤3 cm can be repaired with a primary anastomosis using these principles (Fig. 195.2).

Segmental Resection and Interposition Grafting

For segmental resections of the PV or the SMV longer than 3 cm, we recommend the use of a vascular conduit as an interposition graft. Conduit selections include: autologous vein (left renal vein, internal jugular [IJ] vein), cryopreserved vein, bovine pericardium, peritoneum, and synthetic grafts. However, cryopreserved vein, bovine pericardium, peritoneum, and synthetic grafts are not considered optimal conduits for PV reconstruction. Our conduit preference for interposition grafting in the setting of pancreatectomy is autologous vein utilizing the left renal vein or splenic vein.

Left Renal Vein Graft

Traditionally, the left renal vein has been used to repair venous structures (PV, IVC or hepatic vein) during resection of hepatic hilar cholangiocarcinomas. Extrapolating this technique to the pancreas offers distinct advantages for venous reconstruction. Importantly, literature has shown the safety of distal left renal vein ligation, when ligated as close to the IVC as possible, therefore allowing the left kidney to drain through the gonadal and adrenal veins.[10] Advantages to this conduit include the ability to expose the vein within the same operative field and eliminating a second operative field as would be required to harvest the IJ vein.[10] Additionally, the caliber and wall thickness of the vein is similar to the PV, therefore providing ease in handling and suturing.[10]

Distally, the vein must be divided at the junction of the left gonadal and left adrenal veins. If chosen as a conduit it is critical to leave these veins intact to ensure adequate left renal drainage. Proximally, the vein is then divided flush with the IVC (Fig. 195.3). Division of the vein is undertaken with a linear (transverse anastomosis) stapling device. Generally, this conduit provides a 3- to 4-cm venous interposition. Following harvest, the venous segment should be maintained in heparinized saline until reconstruction. Interposition reconstruction should then be undertaken with 5-0 or 6-0 prolene suture in a running technique in an end-end fashion without spatulation (see Figs. 195.1 and 195.2).

Internal Jugular Vein Graft

IJ vein graft remains a valid option for segmental reconstruction. However, unlike the left renal vein, a separate surgical field is required. Harvest of the IJ vein is performed with the patient's head turned away from the surgeon and the neck slightly extended. An incision on the anterior border of the sternocleidomastoid muscle (SCM) is created and taken down to the carotid sheath. This can be facilitated by retracting the SCM laterally. Next, the carotid sheath should be entered and the facial vein ligated between ties. Next, the vagus nerve should be identified, keeping it free from injury. An appropriate length of IJ vein is then chosen and ligated between ties. Following harvest, the venous segment should be maintained in heparinized saline until reconstruction.

Interposition reconstruction should then be undertaken with 5-0 or 6-0 prolene suture in a running technique in an end-end fashion without spatulation (see Figs. 195.1 and 195.2).

Splenic Vein Preservation Versus Ligation

Splenic vein preservation is possible. However, preservation of the splenic vein significantly limits the mobilization of the PV and may prevent primary anastomosis of the SMV/PV following segmental resection if the tumor is opposite the splenic vein orifice. Thus, total pancreatectomy with SMV/PV end-to-end anastomosis may be the best option when all three vessels are encased. However, if there is excess distance to bridge then choosing a segment of splenic vein from the

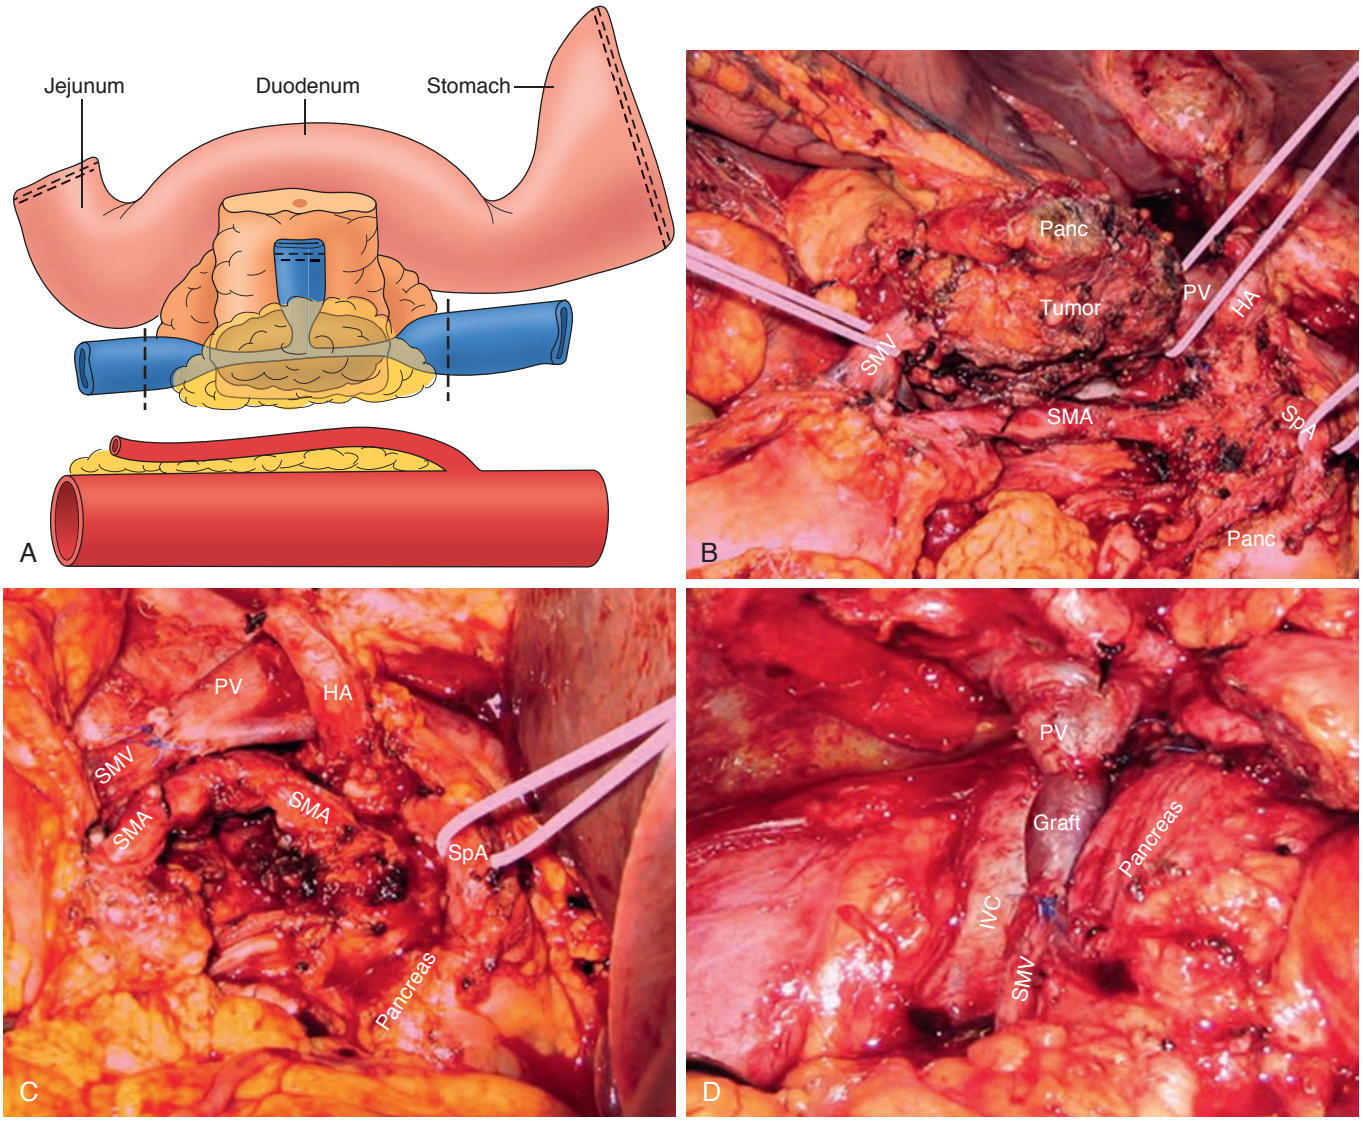

Figure 195.2 (A) Schematic of the completed dissection, tumor remains only adherent to SMV/PV. (B) Completion of dissection, tumor remains only attached to SMV/PV. distal pancreas to use as a secondary splenic vein graft can be performed.[5]

Arterial Resection

To date, the oncologic benefit of arterial resection for pancreatectomy remains unclear. Historically, arterial resection was associated with high morbidity and has thus been considered a contraindication. More recently, Perinel et al. have published results of a cohort of patients who underwent planned arterial resection and reconstruction during pancreatectomy. This cohort was then compared to those who required only venous resection and those who required no vascular resection. The primary selection criteria for arterial resection was the possibility of achieving a complete resection based on the extent of axial encasement, the absence of tumor invasion at the origin of celiac trunk and SMA, and a free distal arterial segment to allow for reconstruction. Six SMA, two celiac trunk, four common hepatic artery, and two replaced right hepatic artery resections were undertaken with the preferred arterial reconstruction being a splenic artery transposition. There were no statistically significant differences in the incidence, grade, and type of complications in the three groups. Planned arterial resection for PDA may now be able to be performed safely. However, that said, 7/14 and 2/14 patients in the arterial resection group developed metastatic and two loco-regional recurrences, respectively.[11]

Please note, this study is presented as hypothesis generating and should not be taken as standard of care. A clear limitation to

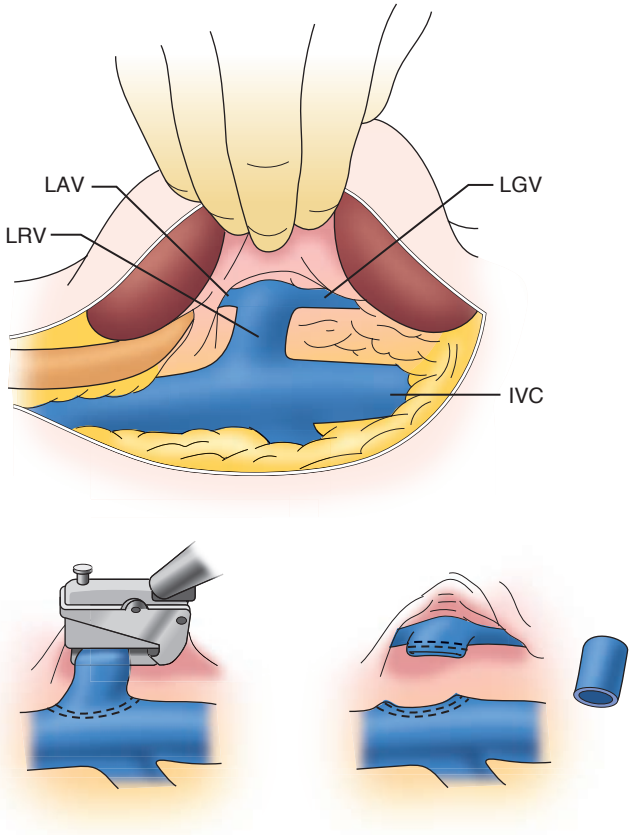

Figure 195.3 Left renal vein conduit. *IVC,* Inferior vena cava; *LAV,* left adrenal vein; *LGV,* left gonadal vein; *LRV,* left renal vein. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

this data remains the small sample size and heterogenous patient population, therefore contributing to unclear oncologic benefit.

Postoperative Considerations and Oncologic Outcomes

Postoperatively, patients do not require anticoagulation with heparin; however, it is our practice to start antiplatelet therapy (aspirin) on the first postoperative day and continue such antiplatelet therapy indefinitely. Doppler ultrasound imaging on postoperative day 2 or 3 is useful to detect any flow abnormalities that may require additional anticoagulation. Reported rates of venous thrombosis after reconstruction range from 0% to 44% and vary according to the repair[6]: longitudinal venorrhaphy was recently documented as 25%, patch repair 31%, and interposition grafting 44%. Transverse venorrhaphy and primary repair had a 0% thrombosis rate at a median follow-up of 316 days.[6]

With respect to oncologic efficacy, literature has shown equivalence between those who undergo SMV/PV resection to those who do not. In an assessment of long-term survival, 110 patients who had undergone SMV/PV resection were matched and compared to 181 patients who did not require venous resection. Median survival was 23.4 versus 26.5 months ($P = .177$), respectively.[5] Additionally, in a more recent study, comparing outcomes between patients who did and did not undergo venous resection at the time of pancreaticoduodenectomy, postoperative complications (55.7% vs. 50%), R0 resection (65% vs. 76%), and median overall survival (21.6 months vs. 19.7 months) were found to be similar.[12] Therefore in properly selected patients, venous resection during pancreaticoduodenectomy should be undertaken if technically feasible.

Celiac Axis Resection/Appleby Procedure

Involvement of the celiac axis by pancreatic body tumors is no longer considered an absolute contraindication to resection. In highly selected patients, resection is feasible and relies on collateral circulation through the gastroduodenal artery (GDA) to maintain hepatic arterial perfusion. However, we would note that in the setting of locally advanced pancreatic adenocarcinoma, we recommend the commencement of systemic therapy prior to the consideration of surgical exploration. Our current algorithm implements FOLFIRINOX or Gemcitabine/Abraxane followed by serial cross-sectional imaging. In the lack of an objective response, further neo-adjuvant radiotherapy may be employed.

That being said, if resection is deemed appropriate and the celiac axis remains grossly involved with tumor, an Appleby procedure can be performed. This allows for en-bloc resection of the common hepatic, celiac, and splenic arteries in combination with a distal pancreatectomy and splenectomy. Of paramount importance, adequate flow through the GDA must be determined prior to celiac axis resection and preserved to allow for continued hepatic arterial perfusion via retrograde flow to the proper hepatic artery.

The general operative principle for this procedure is the assessment of resectability by determining adequacy of retrograde blood flow through the GDA by isolating the celiac axis, common hepatic artery, and GDA. The common hepatic artery is then clamped. Flow in the proper hepatic artery and GDA is assessed by palpation and Doppler flow. The presence of a strong pulse/signal will allow resection to proceed.

Once deemed resectable, the common hepatic artery is clamped and divided. Transfixing sutures are placed at the superior and inferior borders of the pancreas and the pancreas is divided at the pancreatic neck. The celiac axis should then be exposed, clamped, and divided utilizing a prolene suture ligature. Standard distal pancreatectomy, splenectomy can then ensue.

HEPATIC AND BILIARY MALIGNANCIES

Despite advances in novel chemotherapeutics, biologic agents and immunotherapy, the best chance for cure and long-term survival for hepatic and biliary malignancies is surgical resection with negative margins. Even with improvements in regional hepatic therapies, patients who are deemed unresectable have overall worse survival than those who have a chance at curative

resection. However, regional nodal involvement often determines oncologic outcome beyond a technically successful resection. Historically, vascular invasion for hepatic and biliary tumors was considered a contraindication to surgical resection and thus conceived with high skepticism, as the risks of an operative intervention were felt to far outweigh the benefits.

However, with technical advances over time, combined hepatectomy and vascular resection as a means to obtain negative margins for many hepatobiliary malignancies has become acceptable. Most of the published literature of vascular resection and surgical outcomes comes from hilar cholangiocarcinoma (Klatskin tumors) due to the infiltrative nature of this malignancy (involvement of adjacent vascular structures within the hilum). Therefore this chapter uses hilar cholangiocarcinoma as an example to demonstrate the fundamental elements and operative approach of oncologic vascular surgery and reconstruction in hepatic and biliary malignancies.

Cholangiocarcinoma is the most common cancer of the biliary tree, accounting for 3% of gastrointestinal cancers.[9] Although many present with advanced disease, 50% to 70% of patients will be considered for curative resection. These particular cases present unique challenges as the disease can extend longitudinally along the hepatic ducts and obtaining a negative margin is often difficult. Resection of the extrahepatic biliary tree in conjunction with hepatic resection has become the standard of care.[10,11] The infiltrative nature of the tumor and the anatomic proximity of a Klatskin tumor to the PV, hepatic arteries, and IVC predisposes it to vascular involvement. Therefore hepatic surgeons must be facile in perihepatic vascular reconstruction of the PV, hepatic artery, or retrohepatic IVC in cases of locally advanced cholangiocarcinoma.

It goes without saying that these combined resections are associated with higher morbidity and mortality rates. Given the high morbidity of such surgical resection and complex decision making in this disease, management at high volume centers within a multidisciplinary team experienced in both surgical and perioperative management of these diseases is highly recommended.

General Considerations and Surgical Principles

In the management of hilar cholangiocarcinoma, it is of highest importance to define tumor resectability preoperatively. Management of these tumors with vascular reconstruction begins with a standard oncologic work-up, including preoperative cross-sectional imaging with either triphasic computed tomography (CT) or magnetic resonance imaging/cholangiopancreatography (MRI/MRCP) to assess the extent of vessel involvement. Variant vascular anatomy and ductal vascular relationships must be defined for preoperative planning for successful resection and vascular reconstruction. It is paramount to confirm vessel accessibility above and below the tumor level for vascular anastomosis. Additionally, it has become our practice to also obtain a preoperative duplex ultrasound to assess for vascular involvement.

The general principles of vascular reconstruction apply. It is essential to preoperatively address the need for vascular access, ability to establish proximal/distal control, and select appropriate conduits for vessel reconstruction in each patient individually. In general, guidelines for liver resections include a future liver remnant (FLR) of greater than 0.6% of total body weight (greater in the pretreated or cholestatic liver).[11,12] It is therefore recommended to obtain volumetric assessment preoperatively to avoid postoperative complication and liver insufficiency/failure, even more so in planned resections in conjunction with vascular reconstruction. In cases of borderline FLR, preoperative portal vein embolization (PVE) has been used as an important adjunct. In such cases, PVE should be performed 4 to 6 weeks before resection to allow time for adequate hypertrophy.

Portal Vein Reconstruction

Reconstruction of the PV in conjunction with hepatectomy was first described in the Western literature by Blumgart in 1990 for hilar cholangiocarcinoma.[15] Several years after, a "no-touch en bloc resection" technique[16,17] for hilar cholangiocarcinoma was described by Neuhaus and his colleagues.

Studies have shown histologic invasion in greater than one-third of cases in which the PV has been resected.[18] Although occult invasion does not often occur, the distance between the leading edge of cancer cells to the outer layer of the adventitia is usually less than 1 mm in most cases. With that, PV resection is the most common vascular resection performed for hilar cholangiocarcinoma and considered a means to obtain negative margins and thus a better chance of long-term survival. Preoperative planning and understanding the portal venous anatomy as well as the position of the hepatic artery in relation to it is key for successful outcomes.[19,20]

In general, primary end-to-end anastomosis is preferred compared to interposition grafting. To perform a primary anastomosis, complete mobilization of the proximal main PV to the level of the pancreas is recommended (as described above under pancreatectomy). For right-sided hepatectomies, a minimum of 1.0 cm segment of the PV prior to branching point is required for clamp placement and anastomosis.[9] Anastomosis of the left PV can almost always be performed in an end-to-end fashion as the left PV is accessible and should be performed before the liver itself is transected. If needed, anastomosis can be performed after parenchymal transection (Fig. 195.4).

As left-sided resections usually require a more extended resection, the right posterior sectoral branch becomes the general target for anastomosis. This reconstruction is usually performed after transection of the liver. If the main PV does not reach, common autologous vein grafts including left renal, femoral, jugular, and even hepatic vein from the resected liver can be used (see Fig. 195.3).[21-25] If no native veins are available, synthetic or cryopreserved grafts can be used but, if possible, should be avoided due to risk of infection and thrombosis.

Long-term survival when using PV resection depends entirely on the ability to achieve negative margins. Therefore with aggressive surgical care, the number of resectable and, therefore, curable patients has increased over time. Morbidity of combined resection with concomitant vascular reconstruction has improved

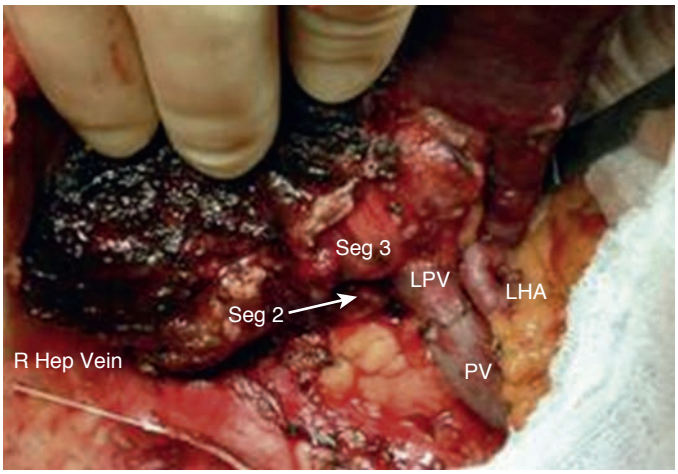

Figure 195.4 The tumor has been resected with a right trisectionectomy with bile duct resection and PV resection. over the last decade. Several studies have shown that patients undergoing combined hepatectomy and PV resection with negative margins have similar outcomes to patients with negative margins undergoing hepatic resection alone.[9,18-20] Most recent reports have shown improved outcomes with perioperative mortality up to 33% in early studies in the 1990s and early 2000s to current reports of 0% to 5%, similar to liver resections without PV resection.[18,29,30]

Hepatic Artery Resection

In contrast to PV resection, data on hepatic artery reconstruction is more limited and long-term survival benefits have not been clearly described. However, an increasing number of series have successful outcomes of hepatectomies and PV/hepatic artery reconstruction in a selected patient population.

Most cases in which a hepatic artery resection in indicated, the artery is involved at its bifurcation and thus necessitates combined PV resection. Prior to any arterial reconstruction, it is of highest importance to review the anatomic variation in case native vessels are needed. As with the PV reconstruction, assessment of adequate clamping space for proximal and distal control sites and options for suitable grafts need to be made preoperatively. Arterial reconstruction should be performed after completion of PV reconstruction, which is usually done after the specimen is removed and the liver is transected. To perform a tension-free end-to-end primary anastomosis, the artery must be fully mobilized.[31] The preferred conduit for interposition graft is the GSV (Fig. 195.5).[32] Other options include the radial or splenic artery, however these should only be considered in the absence of a suitable saphenous vein.

Although originally studies demonstrated worse long-term outcomes with a higher operative mortality of up to 55%,[34,35] more recent outcomes from high volume centers with experience have shown acceptable results combining arterial and PV reconstruction. Nagino et al.[23] report the largest series of 50 patients who underwent combined PV and arterial reconstructions with an operative mortality rate of only 2%. With advanced microsurgical techniques, 32 of their cases were performed in a primary end-to-end, fashion, 11 with a saphenous vein and radial artery interposition graft, and 2 using a left or right gastric artery. R0 resection was achieved in 66%, with 1-, 3-, 5-year survival rates of 78%, 36%, and 30%, respectively.[23]

Inferior Vena Cava Resection

IVC involvement has traditionally been a contraindication to resection for hepatic and biliary malignancies given the poor postoperative outcomes. However, with improved techniques for liver resection and perioperative management, tumors involving the IVC and hepatic veins are now considered resectable in select patients with hepatic malignancies with acceptable morbidity and mortality.

Caval reconstruction depends, as with any other vascular reconstruction, on the degree and extent of involvement. If feasible, primary resection with a side-bite clamp with primary anastomosis or patch repair can be considered.[36] Otherwise, complete replacement of the vena cava with a synthetic or biological graft should be considered. For complete caval replacement generally speaking, the IVC should be exposed above and below the tumor and resection can be performed along with the parenchymal resection after vascular control has been obtained. Primary end-to-end repair may be feasible with a resected portion up to 3 cm. However, larger defects should be reconstructed using synthetic or biologic graft material. Reconstructive options include an interposition graft with a large caliber (18-22 mm) polytetrafluoroethylene (PTFE) ringed graft or a bovine pericardium patch if the caval defect is less than 1/3 the circumference. Contrary to what one might think,

there is no clinical evidence that using synthetic material leads to higher risks of infection in these vascular reconstructions.[37-40]

IVC resection and reconstruction has been associated with higher morbidity and mortality[38,40] rates but this risk has been accepted given its benefits in experienced hands and lack of alternative curative approaches. The largest series by Hemming and colleagues[42] included 60 patients over a study period of 16 years. In their study, defects of greater than 5 cm were repaired with autologous vein, bovine pericardium, or Gore-Tex. More than half of their patient population required full reconstruction with a Gore-Tex graft. Perioperative mortality was 8% and 3-year survival 35%.[43] Others have reported similar perioperative mortality rates ranging from 11% to 19% with a 5-year survival of 22% to 38%.[37-47] These results demonstrate that combined liver and IVC resection proves to be beneficial in fit and highly selected patients. Nevertheless, these radical resections should only be executed at highly specialized centers with experienced hepatobiliary surgery and liver transplantation and capacity of perioperative ICU and interventional radiology.

Renal cell carcinoma has a predilection for tumor growth into the IVC. For local involvement, tumor thrombectomy after proximal and distal control of the IVC can be performed. However, for more extensive tumor involvement, vena caval resection and reconstruction may be required.

SOFT TISSUE SARCOMA

Soft tissue sarcoma (STS) is a rare, heterogeneous group of tumors of mesenchymal origin, comprising over 50 histologic subtypes and representing 1% of all adult cancers.[48] The underlying oncogenesis of these tumors varies widely amongst the various subtypes. The most commonly affected site is the extremity (approximately 40% of cases)[49]; however, STS may arise anywhere in the body. STS is often locally aggressive and as such often involves multiple anatomic structures. Complete surgical resection is the mainstay of treatment and the only potentially curative therapy. Owing to the infiltrative nature of these tumors, local recurrence had historically been the pitfall of treatment[50-52] and highlights the need to achieve wide, microscopically negative margins. Management is best handled at high volume centers within a multidisciplinary team experienced in both surgical and medical treatment of this disease.

The surgical management of STS is further complicated when major vasculature is involved. Any major blood vessel or vascular bundle may require resection in order to remove all disease. Amputation was historically considered the ideal procedure to achieve local control.[53,54] Since the hallmark study by Rosenberg and colleagues in 1982 demonstrating similar oncologic outcomes of limb-preserving surgery in combination with adjuvant radiation as compared to amputation alone,[55] limb preservation has become the modern standard of care. It is often the case that a major blood vessel must be resected in order to achieve this goal. Limb preservation thus necessitated the development of techniques to reconstruct major blood vessels after extensive en-bloc oncologic resections. Recent literature has defined this field as "oncovascular surgery."[56] Both resection and reconstruction require careful planning among a team of experienced oncologic and vascular surgeons given the complex anatomy and locations of these tumors.

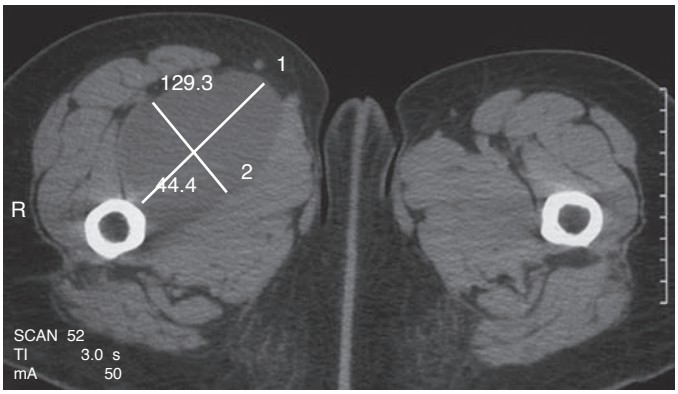

Figure 195.6 Preoperative CT image demonstrating a well-demarcated liposarcoma of the medial compartment of the right thigh. Surrounding soft tissue structures are well delineated from tumor. (From Karakousis C. Tumor in the medial thigh. In: *Atlas of Operative Procedures in Surgical Oncology*, New York: Springer Science + Business Media; 2015:327, Chapter 48, Fig. 48.7.)

General Considerations and Surgical Principles

Management of STS requiring concomitant vascular reconstruction begins with a standard oncologic workup, including appropriate staging. Each case should be individualized to the specific histologic type and managed within a multidisciplinary team. When vascular reconstruction is necessary, cross-sectional imaging with either contrast-enhanced CT or MRI is sufficient to delineate anatomic details such as involved vessels, modification to normal blood flow patterns, development of collaterals, and presence of intravascular thrombus (Fig. 195.6). MRI is particularly useful in defining involvement of soft tissues adjacent to vascular structures.[56,57] Adjuvant imaging modalities such as duplex ultrasonography can be helpful in select cases but often do not add significant information to the operative plan.

Considerations that are essential to address preoperatively include the need for vascular access, ability to establish proximal/distal vascular control, possible endovascular adjuncts, and specific strategies for reconstruction of the involved blood vessels.[56] Technique, extent of vascular resection, and choice of conduit vary widely among the literature and are often based on surgeon preference.[58-70] The most common materials utilized for oncovascular reconstructive surgery are summarized in Table 195.1. Short- and long-term patency rates of vascular bypass in STS resection are comparable to those performed for atherosclerosis,[58-70] thus emphasizing that the presence of STS itself does not significantly alter the vascular outcome of these procedures. Endovascular adjuncts may be performed pre- or postoperatively to optimize conduit patency and outcomes. Preoperatively, embolization of vessels perfusing hostile surgical fields such as large pelvic tumors has been employed to help manage predicted intraoperative bleeding.[71] Postoperative endovascular interventions may also be utilized to provide secondary patency and extend the life of a functioning vascular conduit.

TABLE 195.1 Materials Utilized for Arterial/Venous Reconstruction

Autologous vein
• Great saphenous vein • Femoral vein • Splenic vein • Jugular vein • Left renal vein
Cadaveric, cryopreserved vein
Cadaveric, cryopreserved artery
Bovine pericardium
Synthetic conduit
• Polytetrafluoroethylene (PTFE) • Polyethylene terephthalate (Dacron)

The extent of vascular resection and subsequent reconstruction is based upon the extent of the lesion, the predicted patient morbidity, and the preoperative venous anatomy. When curative resection is the goal, all involved vascular structures must be completely removed to achieve negative margins. In difficult anatomic regions where dissection may lead to massive hemorrhage and vascular involvement is unclear, the decision can be made to shave the tumor away from major vessels as opposed to a formal resection (Fig. 195.7). Although in some instances safer, this technique may leave behind residual microscopic disease along the adventitia. For arterial resections, reconstruction must always be performed given the inevitability of limb ischemia if adequate perfusion is not restored. If less than 50% of the vessel circumference is resected, patch angioplasty is an acceptable option. More extensive lesions require formal arterial bypass.

Venous resection with subsequent reconstruction is less definitively managed, with multiple options based on the clinical scenario. Veins which are chronically occluded or in the periphery of the surgical field can be sacrificed via ligation without significant effect on preservation of the limb[72,73] and is well tolerated (Fig. 195.8). Likewise, preoperative imaging displaying abundant venous collaterals can allow for ligation of major veins with similarly good outcomes.[59,66,67] Without evidence of collaterals or preoperative occlusion, the decision to reconstruct major veins is debated in the literature. Proponents of venous reconstruction cite that it adds very little morbidity to the overall procedure, while simultaneously acting as prophylaxis to severe postoperative venous hypertension with sequelae similar to that of a post-thrombotic syndrome.[61] Arguments against venous reconstruction make note that if assessed in the early postoperative period, venous conduits are often occluded,[69] although this is not a consistent finding in all series.[62] Authors have also argued that incidence of postoperative edema does not vary with or without venous reconstruction.[69] Furthermore, even in cases where edema from venous ligation is present, it can often be managed with standard medical treatments such as limb elevation and compression.[67,74] If a flap repair is used to cover the surgical defect, functional venous collaterals may also develop in the postoperative period and render venous reconstruction unnecessary.[75] Overall, it is acceptable to perform venous reconstruction when indicated but is not a surgical necessity.

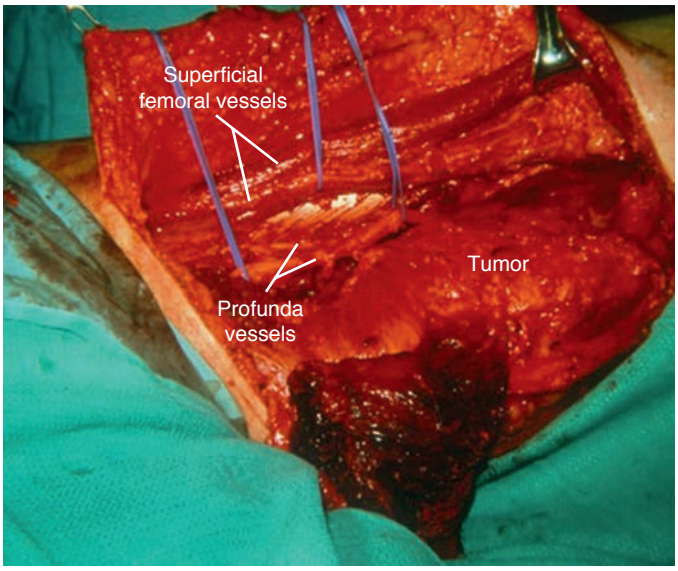

Figure 195.7 Dissection of a medial thigh sarcoma away from the superficial femoral and profunda femoris arteries. (From Karakousis C: Tumor in the medial thigh. In *Atlas of Operative Procedures in Surgical Oncology*, New York, 2015, Springer Science + Business Media; Chapter 48, p. 327, Fig. 48.8.)

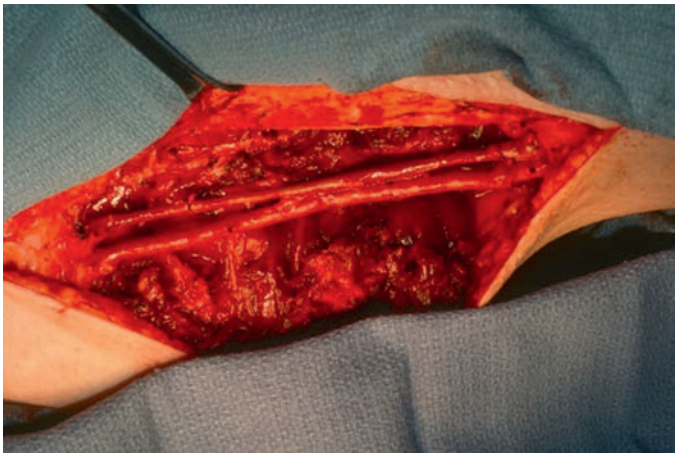

Figure 195.8 Resection of the femoral artery and vein with isolated arterial reconstruction. In the setting of chronic occlusion or well-developed collaterals, veins may be ligated without significant impact on limb preservation. (From Karakousis C. Tumor in the anterior thigh. In: *Atlas of Operative Procedures in Surgical Oncology*, New York: Springer Science + Business Media; 2015:321, Chapter 47, Fig. 47.19.)

Extremity Soft Tissue Sarcoma

The extremity is the most common location of STS, and in approximately 3% of cases a major neurovascular bundle is involved.[56] Historically, 47% of STS cases localized to the extremity resulted in amputation.[75] At that time, incomplete resections and local recurrence rates exceeded 60%[75] and thus did not provide a satisfactory oncologic outcome. Since the advent of adjuvant radiotherapy, amputation rates more recently approximate 0% to 8% as limb-sparing procedures evolved

to become the standard of care.[62,76] Importantly, limb salvage with vascular reconstruction offers comparable local tumor control,[62,68,69] and overall survival[76] as compared to amputation. Functional outcomes and quality of life are improved with limb-sparing procedures,[77] which is particularly important given the relatively young mean age of patients with STS.

Any major upper or lower extremity vessel may be involved in STS, and thus thorough knowledge of both the vascular anatomy and possible bypass options is a prerequisite to optimal patient outcomes. In order to achieve negative margins, the extent of the resection may be more significant than originally planned based on preoperative imaging. Thus, the ability to be flexible in regards to an operative plan is also paramount. The predominant site of STS is the lower extremity and therefore the vast majority of resections subsequently involve a lower extremity bypass. Upper extremity vascular resection and reconstruction is rare, but when performed most commonly involves the brachial artery.[68] Most if not all permutations of arterial reconstructions of the extremity are represented in the literature.[68,69,74] A list of common arterial reconstructions are represented in Table 195.2; however, various combinations may be required to restore adequate limb perfusion.

Choice of conduit in vascular reconstruction of the extremity after STS resection is based upon surgeon preference. For arterial reconstructions, most centers utilize autologous vein whenever possible as it provides lower rates of infection.[62,77] The GSV is the most commonly used autologous conduit given its length and ease of accessibility; however, several reports have illustrated good outcomes with the femoral vein as well.[68,78] When possible, the graft should be harvested from the contralateral limb so as not to worsen limb edema on the side of the primary resection, which commonly disrupts native venous tributaries and lymphatics. To date, there are no published studies demonstrating improved patency of venous over synthetic grafts after STS resection as has been the case in similar non-oncologic vascular procedures. The failure to recapitulate this finding is likely based upon underpowered sample sizes when studying this rare disease, and as such autologous vein should be considered a superior conduit overall. Anecdotally, synthetic conduits have been employed in a larger proportion of venous reconstructions as compared to arterial; however, autologous vein is also a suitable option for venous repair as well.

Outcomes with respect to vascular reconstructions for limb preservation are exceedingly good, as evidenced by limb salvage rates of over 90% in nearly all published studies. Five year arterial patency approximates 55% to 80%.[61-63] Venous patency rates are more variable and less well characterized. In general, thrombosis is more common in venous reconstructions secondary to the low flow state of this system. The clinical significance of these events is typically negligible, as most episodes of venous thrombosis are successfully managed with systemic anticoagulation alone. The most common morbidities related to vascular reconstructions after STS resection are wound infection, skin flap necrosis, limb edema, hematoma, and graft thrombosis.[61-63] Early arterial thrombosis is quite rare but necessitates reintervention to restore perfusion to the extremity, which typically involves revision and/or complete reconstruction of the vascular conduit.

Patients with STS who undergo limb-preserving surgery with adjuvant radiotherapy have similar long-term outcomes as those who undergo limb amputation. Five year overall survival approximates 40% to 65%.[61-63] The success of STS resection is incumbent upon complete removal of disease, and as such most reports achieve R0 (margin negative) or R1 (microscopically positive margin) resections in nearly all cases.[61-63] This has only been made possible by modern advances in vascular bypass, which permit safe clearance of even questionably involved structures. At one time, local recurrences plagued the surgical management of STS. With current limb-preserving techniques and radiotherapy, local recurrence has diminished from over 60%,[3] to approximately 16%.[61-63]

Retroperitoneal Soft Tissue Sarcoma

Retroperitoneal STS represents a particularly challenging surgical disease, which is only further complicated when the aorta, IVC, or both are involved. Retroperitoneal STS comprises 15% of all cases of sarcoma.[56] As with other anatomic locations, these tumors are locally aggressive and invade nearby vital structures. These tumors are often asymptomatic until they achieve a sufficient size to cause compression of local structures, and as such typically involve multiple organs. Multivisceral resections (defined as the removal of two or more organs) are frequently required to achieve negative margins.[59,67] When the aorta or IVC are involved, additional concerns arise as both structures must be resected if a curative surgery is planned.

Preoperative workup must focus specifically on identifying the extent of vascular and solid organ involvement. Tumors may present anywhere from the aortic hiatus and retrohepatic IVC superiorly to the common iliac bifurcation inferiorly. Extension into the pelvis makes adequate exposure and safe dissection more difficult, and in some cases impossible. When the aorta or IVC are involved, consideration must be given to the possible need for cardiopulmonary or veno-venous bypass. The potential need for postoperative renal replacement therapy (RRT) must also be considered if the renal vasculature requires resection or a formal nephrectomy is a possibility. Therefore we favor obtaining preoperative split function renal testing. Based on the extent of the tumor, a tentative but specific operative plan must be developed in order to make preparations for the vascular reconstruction.

With respect to vascular reconstruction, involvement may comprise the artery alone, vein alone, or a combination of the two. Similar to vessels in the extremity, if less than 50% of the

vessel circumference is resected, angioplasty (primary or patch) is a reasonable option.[64] Both synthetic and autologous materials can be used for this purpose.[64] In the setting of bowel resection, which is common in retroperitoneal STS, some centers opt to avoid synthetic materials.[64] Good results have been reported with the use of cryopreserved autologous vein, saphenous vein, femoral vein, and IJ vein.[64] If greater than 50% of the vessel circumference is involved, a formal resection and reconstruction must be performed to avoid compromising flow. Both the aorta and the IVC may be reconstructed utilizing autologous or synthetic conduits.[70] Given the large diameter of both vessels, synthetic conduits are generally the first line choice. These offer several advantages, including avoidance of donor site morbidity, ease of matching vessel diameter, and a shorter procedure. When large en-bloc resections are required, concomitant replacement of the aorta and IVC can be performed and has been done so with favorable results.[18] Similarly, reimplantation of one or both renal vessels on either side of the conduit can be performed if necessary.[70] For situations in which IVC reconstruction is exceedingly difficult or dangerous, the IVC can be ligated. Up to half of these patients will develop subsequent venous hypertension and lower extremity edema if collaterals are poor.[79] Similarly to reconstructions in the extremity, the two exceptions to this are if occlusive thrombus is present proximal to the resected vein segment preoperatively, or significant venous collaterals have been identified on cross-sectional imaging. In either of these scenarios, the IVC can be ligated without significant sequelae.

Postoperative management after retroperitoneal STS resection has the potential for high morbidity given the multivisceral component, extensive dissection required to achieve negative margins, and prolonged time spent in the operating room to perform the necessary vascular reconstruction. Mortality is notably rare[67] but is certainly a more significant concern as compared to resection of extremity STS. Patency of the reconstructed aorta and IVC is very good as a result of the large diameter of these vessels, with overall graft patency rates of approximately 90% at 2 years follow-up.[69] Common early postoperative morbidities include hemorrhage, wound infection, prolonged ileus, and renal insufficiency.[69] Hemorrhage may resolve without intervention or may be a harbinger of significant complication, in some cases necessitating revision of the vascular conduit.[67] Late complications include abscess formation and ureteral stenosis.[67]

Oncologic outcomes for retroperitoneal STS involving major blood vessels are comparable to those of the extremity only if complete resection with negative surgical margins is achieved. In other words, patients with retroperitoneal STS after R1 resections have worse outcomes than patients with R0 resections. In the largest series to date assessing retroperitoneal STS resection with major blood vessel involvement, R0 resection yielded 2- and 5-year survival rates of 90% and 66.7%, respectively. However, patients with an R1 resection had a mean survival of 21 months, and R2 resections had 8 months mean survival.[20] Local recurrence in this series approximated 18% for complete resections.[67] Neoadjuvant and adjuvant therapies vary widely among centers, but nearly all patients will receive some variant of adjunctive treatment.

Chronic exertional compartment syndrome (CECS) is a nonatherosclerotic cause of claudication that is often referred to a vascular surgeon. As the name implies, it is exercise-induced leg pain that usually presents in young, active patients such as athletes and military personnel. Symptoms are generally confined to the compartment of the leg that is affected and are reproducible to timing, distance, and the intensity of exercise.

HISTORY

CECS was first described in 1912 by Edward Wilson during an expedition to the South Pole.[1] In his diary he described his symptoms, which are consistent with anterior compartment syndrome. Various descriptions were offered until G. E. Mavor published his article regarding a professional soccer player in Aberdeen, Scotland, who complained of pain in the anterior compartments of both legs during exercise. In addition, he had paresthesias associated with the pain in his foot. Mavor ultimately performed the first published fasciotomy for CECS. Interestingly, his repair was completed with a fascia lata graft to close the defect. The operation worked so well that after he performed it on the contralateral leg, the patient was able to resume his soccer career.[2]

ETIOLOGY

The exact mechanism is unknown but CECS is believed to arise from increased compartment pressure (ICP) resulting in transient muscular ischemia within the enclosed myofascial space during endurance training.[3,4] In contrast to an acute compartment syndrome, in which the pressure remains elevated, in CECS the pressure dissipates over time and the symptoms resolve. Theories that have been proposed to explain the development of ischemia include arterial spasm, microcirculatory obstruction, and arteriolar and venous collapse due to pressure disturbances.[5] Studies on normal muscle reveal a 20% increase in muscle size secondary to increased blood volume and exercise.[6] In addition, fascial thickening and hypertrophy have been postulated to account for this syndrome.[7] However, some studies, including those by Amendola, have found that pain is not related to ischemia on nuclear medicine blood flow imaging; in their study of patients with CECS utilizing MRI did not

Abstract

Chronic exertional compartment syndrome is a nonatherosclerotic cause of claudication in the young patient. It is present in highly active athletes and soldiers, involving increased intracompartmental pressures (ICMPs) during activity. Its diagnosis relies on a heightened clinical suspicion, physical examination, and compartment pressure measurements after exercise. Treatment involves a fasciotomy of the affected compartment.

claudication in young patients
compartment pressure
non-atherosclerotic leg pain

find ischemic changes in all of the patients with elevated pressures.[8]

EPIDEMIOLOGY

Risk factors include anabolic steroid use, with resultant muscle hypertrophy and abnormal biomechanics during running that favor increased load bearing by various compartments of the leg.[9,10] The estimated prevalence of CECS in patients with exercise-induced leg pain is 10% to 60% in relation to the diagnostic criteria utilized.[11] In a study of 150 athletes with exercise-induced leg pain, CECS was the most common condition (34%), followed by stress fracture of the tibia, accounting for 25%.[12] Most patients with CECS present with pain in the anterior and lateral compartments and 70% to 80% of these will have bilateral symptoms. Studies have not revealed a difference in males and females and the median age of presentation is 20 years.[13] The condition is often seen in military personnel and recruits. Waterman and colleagues reviewed the military health database over an 8-year period and identified 611 patients who underwent 754 surgical procedures. Of these procedures 77.4% involved only the anterior or lateral compartment. Symptom recurrence after treatment was 44.7%, and 27.7% of these individuals were unable to return to full activity. Surgical failure was associated with perioperative complications, activity limitations, and persistence of preoperative symptoms. The investigators concluded that CECS was a substantial contributor to lower extremity disability in the military population.[14]

In a systematic review among athletes, runners and soccer players were most prone to develop CECS. In addition, the presence of deep posterior compartment syndrome in this young population is associated with higher rates of surgical failure.[15]

DIFFERENTIAL DIAGNOSIS

A history of reproducibly developing pain in a compartment of the leg with exercise in a young, active person is typically seen. The pain can be described as burning or aching. In patients referred to a vascular specialist, the main diagnosis that should be considered is popliteal entrapment syndrome (PES). Although patients may describe similar symptoms as seen in CECS, often a diminished pulse is not noted with provocative maneuvers; subsequent noninvasive studies will generally fail to identify popliteal compression. Other etiologies of exercise-induced leg pain—such as stress fracture and medial tibial stress syndrome (shin splints)—can be ruled out by physical examination and x-ray imaging. Other nonatherosclerotic etiologies that should be considered include cystic adventitial disease of the popliteal artery and thromboangiitis obliterans (Buerger disease). Both of these conditions, along with atherosclerosis, are not generally seen in this young, active population.

ANATOMY

The leg is divided into four compartments: anterior, lateral, superficial, and deep posterior. The structures located within the anterior compartment include the deep peroneal nerve, anterior tibial artery, tibialis anterior, and extensor muscles of the toes. The lateral compartment contains the superficial peroneal nerve and the peroneus longus and brevis muscles. The superficial posterior compartment contains the gastrocnemius and soleus muscles and the sural nerve. The deep posterior compartment contains the tibial nerve, posterior tibial artery, peroneal artery, tibialis posterior muscle, and flexors of the toes.

CLINICAL PRESENTATION AND DIAGNOSIS

CECS should be suspected in a young, active patient with reproducible symptoms that occur with endurance training and resolve with rest. In this patient population, in addition to the symptoms already described, exercise history may reveal neurologic symptoms based on the involved compartment. For example, for the most common compartments affected, the patient may describe weakness with dorsiflexion (anterior compartment, deep peroneal nerve), numbness of the dorsum of the foot (lateral compartment, superficial posterior compartment), or, more rarely, weakness of plantarflexion (posterior compartment, tibial nerve).

Physical examination is unrevealing at rest. The individual compartments may feel firm or be tender to deep palpation, and fascial hernias may be present as well.[3] Neurologic examination should focus on the suspected, specific compartment and nerve involved to identify chronic irritation. The pulse examination and resting ankle-brachial indices will be normal in these individuals.

The definitive diagnosis of CECS is established by invasive measurement of intracompartmental pressures (ICMPs). A handheld device is available (Stryker catheter, Kalamazoo, Michigan) that allows rapid measurement (Fig. 196.1). With this device, the pressure can be measured in the compartments of interest. The classic diagnostic criteria described by Pedowitz are as follows: ICMP before exercise 15 mm Hg; 1 minute after exercise, greater than 30 mm Hg; and 5 minutes after exercise, greater than 20 mm Hg.[16] The exercise regimen described in studies is often variable and inconsistent. A more recent protocol developed by Roscoe in the United Kingdom involves continuously measured ICMP before, during, and after participants exercise on the treadmill. A standardized exercise protocol was utilized, and the investigators compared patients with a suspicion for CECS with healthy volunteers. The protocol included measuring beyond 5 minutes of exercise and to maximal tolerable pain as the individuals tested went through three phases of exercise carrying a weighted backpack and with varying grades on the treadmill. When the investigators compared their technique, they found a higher sensitivity and specificity for the diagnosis of CECS.[11]

Recent studies have investigated the use of MRI to diagnose CECS. Ringler performed a validation study with MRI in 76 patients referred for pain induced by a lower extremity exercise; as a result, 23 patients met the clinical diagnostic criteria for CECS. Utilizing a T2-weighted intensity ratio of 1.54 and correlating with ICMP measurements, the sensitivity of MRI

Figure 196.1 Intracompartmental pressure measurement.

was 87% and specificity was 62%. Others have also had promising results with MRI and described the benefit of visualizing fascial thickening and edema as well muscle hypertrophy.[17] Other modalities such as near-infrared spectroscopy (NIRS) have been investigated as well. This technique is able to noninvasively measure the tissue oxygen saturation with a sensitivity similar to that of MRI.[18] All of these modalities are promising, but ICMP is the current "gold standard" for the diagnosis of CECS.

MANAGEMENT

Nonsurgical

Most patients are initially offered a trial of decreasing or stopping the physical activities that trigger the symptoms. Cessation of eliciting activities usually resolves all symptoms; but in this patient population, who are often high-performance athletes, it is not a realistic option. Multiple nonsurgical interventions have been described for the treatment of CECS, including the use of insoles and orthotics to correct excessive pronation, running on softer surfaces, physical therapy, icing, warm therapy, nonsteroidal anti-inflammatory drugs, and even local lidocaine injections.[10,13,19] All nonsurgical treatments have had little success; surgical intervention with compartment decompression is the only reliable option that can return these patients to prior activity levels.

Surgical

Surgical compartmental release is accepted as the only effective treatment of CECS. The goal of the intervention is to decrease the ICMP by increasing the volume of the affected compartments. Multiple fasciotomy techniques have been used, including subcutaneous and endoscopic fasciotomy, as well as fasciectomy, with similar results. This outpatient procedure can be performed under local, regional, or general anesthesia. A compressive dressing is usually applied in the operating room, and we prescribe graded compression stockings (15-20 mm Hg) for the first 14 days after the surgery for patient comfort.

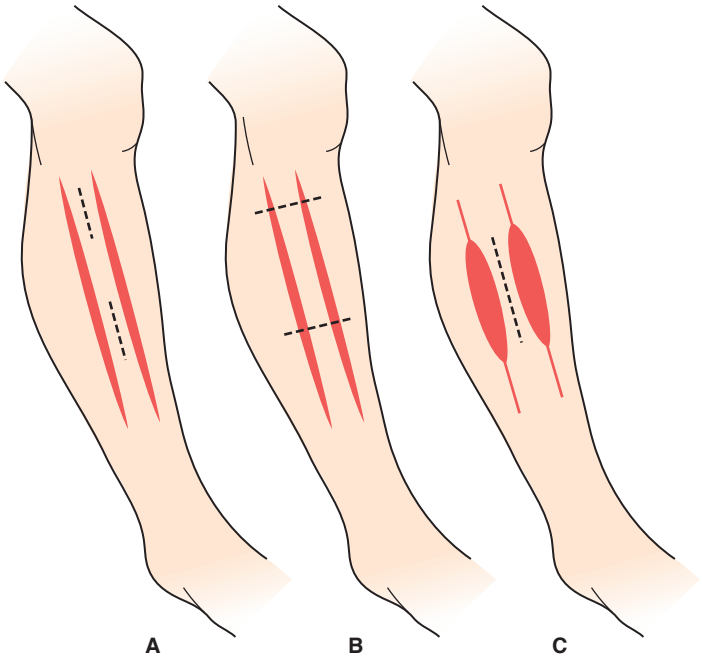

Figure 196.2 Schematic representation of alternate anterior and lateral compartment release techniques. See text below for details. *Dotted line:* skin incision.

Anterior and Lateral Compartment Fasciotomy

Following the technique described by Rorabeck in 1983, the compartments are released by using two 4-cm vertical skin incisions separated by a 15-cm skin bridge. The incisions are centered between the fibula and the crest of the tibia and a plane is developed between both incisions. Decompression of the anterior and lateral compartments is achieved by retracting the skin and incising the fascia 1 cm medial and lateral to the intermuscular septum (Fig. 196.2A). A similar decompression can be achieved by performing a single 5 cm skin incision over each compartment and incising the underlying fascia subcutaneously with Metzenbaum scissors (Fig. 196.3). Another technique employs two transverse skin incisions to perform subcutaneous

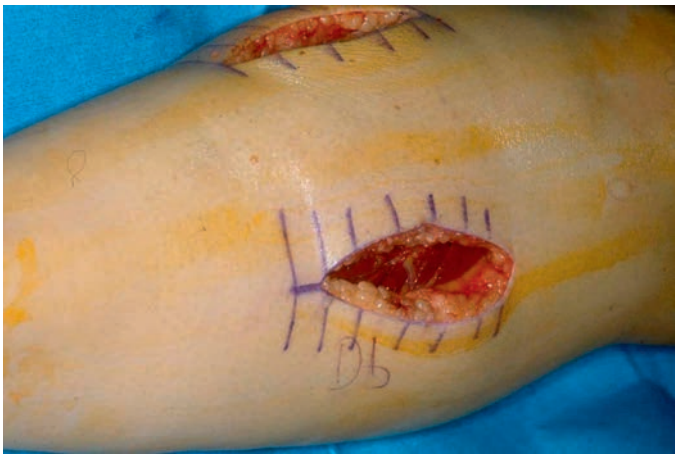

Figure 196.3 Anterior and lateral compartment fasciotomy.

fasciotomy of the anterior and lateral compartments (see Fig. 196.2B).

Open fasciectomy of the anterior and lateral compartments is performed using a single incision lateral to the edge of the tibia. After raising subcutaneous flaps of appropriate length, the fascia of both the anterior and lateral compartments is exposed and an approximately 6- by 2-cm ellipse of fascia is removed. This procedure is usually combined with fasciotomies performed by incising the fascia proximally and distally in order to achieve complete compartment release while the fascia overlying the intermuscular septum is left intact (see Fig. 196.2C).

Posterior Compartments Release

One or two vertical incisions are made behind the posteromedial edge of the tibia. The greater saphenous vein and the saphenous nerve are identified, mobilized if needed, and protected during the procedure. The fascia is incised and, in order to decompress the deep posterior compartment, the tibial attachments of the soleus are taken down so as to expose the deep posterior compartment fascia. The fascia overlying the deep posterior compartment is incised, exposing the flexor digitorum longus and decompressing the compartment.

Endoscopic Compartmental Release

Similar to the technique of subfascial endoscopic perforator surgery (SEPS), endoscopic compartmental release has been described. A transverse incision is made in the proximal leg just medial to the fibular head and a dissection plane is created into the loose areolar tissue just superficial to the fascia where the balloon dissector is inserted. The balloon is advanced to the distal leg and inflated in order to create a cavity within the fascial cleft. The fascia overlying the anterior and lateral compartments is released under direct visualization.[20]

To release the superficial and deep posterior compartments, a skin incision is made proximally on the medial aspect of the leg; the balloon is advanced into the loose subcutaneous tissue just above the fascia, inflated, and removed after developing the cavity. Using endoscopic scissors and under direct visualization, the fascia overlying the superficial posterior compartment as well the fascia of the deep posterior compartment are released directly off the edge of the tibia.[20]

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

The patient is instructed to perform range-of-motion and stretching exercises, and we do not place limitations on weight bearing postoperatively. Patients are encouraged to ambulate early after the procedure. Vigorous activities such as running and participating in team sports are not recommended for the first 2 weeks to ensure skin healing. Activities are gradually advanced and the patient is expected to return to full activity in 6 to 8 weeks.

The most frequent complication is postoperative neurologic dysfunction, specifically superficial peroneal neuritis, which affects up to 5% of patients. Infection, seroma, hematoma, DVT and wound dehiscence are rare in this patient population.

OUTCOMES

Although surgical treatment is accepted as the only effective treatment option for CECS, outcomes are not universally positive. Furthermore, there is no standardized tool, questionnaire, or metric to report the efficacy of the intervention, making the evaluation of success across published cases series difficult. Earlier reports described resolution of symptoms in almost 100% of cases, but recent papers report success rates below 50%.[21,22] In the military population, 25% of patients are unable to return to active duty even after surgical treatment.[14] Interestingly, 84% of patients are satisfied with the results of the procedure at short- and midterm follow-up.[15] Overall, the estimated clinical success rate of compartmental release for CECS is around 66%.[15]

Recurrent symptoms are reported by 5% to 10% of patients, and approximately 6% of patients undergo revision surgery.[23] Incomplete or inadequate compartment decompression as well extensive scarring are the usual reasons for revision surgery.

Multiple studies have investigated predictors of surgical failure after all of the described procedures (fasciotomy, fasciectomy, endoscopic fasciotomy), which have yielded similar results. Based on anatomy, the diagnosis of CECS of the posterior compartment is associated with the poorest outcomes.[23,24] Satisfaction after the procedure and return to the previous level of activity does not correlate with preoperative ICMP values.[23] However, chronicity and a longer duration of symptoms are associated with worse outcomes. Poor outcomes have also been found among female athletes, but the underlying reason for this finding is unknown.[24]

CECS is an unusual cause of claudication in the young patient, and every vascular surgeon should understand the presentation, diagnosis, and treatment of this pathology. In contrast to older patients with claudication due to atherosclerosis, the symptoms of CECS occur with more strenuous exercise, and we should understand that cessation of activity is not a reasonable recommendation for this patient population. However, it is also

important to appreciate that even though the procedure is not complex, the surgical outcomes are not uniformly positive.

INTRODUCTION

A service line strategy has long been used by medical centers to counter inefficiency in provision of multidisciplinary care, improve quality, and capitalize on high-frequency diseases with well-reimbursed treatments. Common examples are neuroscience, cancer, and wound care services. The concept of a vascular service line has existed since World War II,[1] and organized cardiovascular (CV) centers have existed in civilian hospitals since the 1980s.

However, service line strategies involving multiple specialties can be a challenge in academic medical centers (AMCs), where departmental silos can splinter the care of a single patient. For example, vascular disease can be managed by vascular surgery, vascular medicine, interventional radiology, and cardiology.[2] These difficulties may also arise in community hospitals, where turf battles between private groups may exist.

Currently, the multispecialty CV center remains a priority of health system leaders,[3] but the forces shaping their evolution are changing rapidly in the contemporary healthcare environment. Successful multispecialty CV centers are adapting, whereas others are losing market share. Vascular diseases in particular represent a strategic priority for CV centers because of the projected growth in demand for services, disruptive technology, prevailing poor care coordination, and a lack of integration with cardiac disorders.[4] In this chapter, we will review early examples of multispecialty CV centers and the impact of changes in market forces, consider development and operational aspects, appraise trends within existing CV centers, and look ahead into the future.

Abstract

A service line strategy has long been used by medical centers to counter inefficiency in provision of multidisciplinary care, improve quality, and capitalize on high-frequency diseases with well-reimbursed treatments. However, service line strategies involving multiple specialties can be a challenge in academic medical centers, where departmental silos can splinter the care of a single patient. For example, vascular disease can be managed by vascular surgery, vascular medicine, interventional radiology, and cardiology. These difficulties may also arise in community hospitals, where turf battles between private groups may exist. The multispecialty cardiovascular center remains a priority of health system leaders, but the forces shaping their evolution are changing rapidly in the contemporary healthcare environment. The successful cardiovascular center of the future must be multidisciplinary and patient centered, empower physicians and other leaders to participate fully in governance and business decisions, design quality of care guidelines, abandon siloed care, and move to collaborative models.

EARLY EXAMPLES OF MULTISPECIALTY CARDIOVASCULAR CENTERS

An early concept of a vascular center was described by Elkin and DeBakey in 1943:

> *The problem of supplying competent specialized care by experienced personnel for large numbers of casualties with vascular injuries was solved in World War II by the establishment in the Zone of Interior of vascular centers to which surgeons experienced in vascular surgery were attached and in which other surgeons could be trained. To these centers were sent patients with vascular injuries and diseases. The establishment of these centers made it possible to carry out the necessary treatment of such patients with an economy of equipment, personnel, and effort which would have been impossible had the patients been scattered through a large number of hospitals. It also permitted the observation of patients with vascular injury and disease in numbers far beyond those of any similar previous experience. Careful and detailed records were kept and analysis of data derived therefrom permitted deductions and conclusions which could not be gained from the small series of cases previously observed by surgeons in civilian practice.*[1]

Even in the midst of war, these surgeons had the foresight to recognize and address the challenges and opportunities facing a service line strategy, all the while paying equal attention to the clinical care, teaching, and research missions. The War Department set up the first vascular center at Ashford General Hospital in West Virginia. It was, indeed, a true multispecialty CV center consisting of a surgeon, assistant surgeon, two medical officers, a cardiologist, a physiotherapist, and an officer to supervise reconditioning after treatment had concluded.

Modern CV centers do not have to deal with the volumes of military injuries that Ashford General Hospital did but instead must navigate an increasingly complex environment with a shifting regulatory landscape, decreasing reimbursement, demands for transparency and quality measures, and interspecialty competition. However, CV centers are well suited for multispecialty collaboration. Emphasis on one organ system, high volumes and visibility, and a major source of revenue for health systems have led to initiatives to undertake new care models with reimbursement tied to varying incentives through novel strategies, such as Medicare demonstration projects. With increasing employment of all CV specialties by health systems, the task of getting multiple specialties to agree on protocols and quality metrics has become possible. Modern vascular centers that employed CV specialists arose in the 1980s and include the Mayo Vascular Center.[5]

The birth of the Mayo Vascular Center in 1987 arose from the recognition that because multiple clinical departments were involved in the diagnosis and treatment of most vascular diseases, diagnostic testing suites and physician clinics became physically and administratively distinct and spread across the campus. As the Mayo Vascular Center developed a national referral base, these separations introduced significant inefficiency. The strategic vision of the founders of the Center prioritized a "one-stop" patient experience and openness to any interested specialties. This represented an early recognition of patient satisfaction as a quality metric, as well as the potential for competition between specialties in the vascular space.

Initially, large private health systems were unable to duplicate the Mayo experience, which is unique both geographically as well as organizationally, following a foundation model for physician-hospital alignment.[6] However, as the fee-for-service model evolved into the health maintenance organization (HMO) era in the 1980s and 1990s, then to the present value-based payment (VBP) system in which cost containment and value are emphasized, academic, private, and foundational model CV centers have found success, and their strategic visions have dramatically changed and increased in complexity.

FORCES SHAPING THE EVOLUTION OF CONTEMPORARY MULTISPECIALTY CARDIOVASCULAR CENTERS

The United States spends more than any other country on healthcare, and by 2020 US healthcare expenditures are projected to exceed 20% of the gross domestic product.[7] Inefficiencies in US healthcare are widely viewed as opportunities to contain costs, particularly in the government-sponsored Medicare and Medicaid programs. Regulators and the public are increasing focus on value, transparency, and definitions of quality. Total demand for CV services is increasing rapidly as the population ages, while a specialty physician shortage looms.[4,8] What started out as a marketing tactic aimed at increasing market share has now evolved into a holistic focus on quality, efficiency, transparency, patient satisfaction, and cost, almost all driven by changing reimbursement systems. Health systems still continue to fight for market share to compensate for diminishing revenue. This is the difficult environment in which the contemporary multidisciplinary CV center must succeed. Hospital systems and physicians alike should weigh the advantages and disadvantages before undertaking the process of CV center formation (Table 197.1).

Changes in Demographics and Care Delivery

The number of board-certified vascular surgeons in the United States has remained relatively stable, and in 2010 there were, by one estimate, fewer than 3000. This number is projected to grow linearly over the next 3 decades to approximately 3500 in 2040.[9] Simultaneously, the general population will continue to expand rapidly, and the elderly population even more quickly over the coming years. Vascular surgeons are one of the smaller physician workforces, yet they take care of a disease that is part of the leading cause of death in the United States. A vascular surgeon shortage looms, and this has and will continue to shape the makeup of the vascular provider pool and the

TABLE 197.1 Pros and Cons of Establishing a Multidisciplinary Cardiovascular (CV) Center

Pros	Cons
• Common CV disease process • Demand for CV care is increasing • Ease of access for patients with multiple medical problems • Ease of access for referring physicians • Improved relationship and influence with payers • Decreased duplication of services and expenses • Improved quality oversight • Consolidated marketing strategy • Development of a CV scorecard to measure success	• Consolidation of services may require capital expenditures for physical facility • Physician engagement may be difficult due to diminished autonomy and interspecialty conflicts • May be seen as hostile to medical education and research • Change in reporting structure (especially academic medical centers) • Difficulties in aligning compensation among specialists • Challenges to aligning procedural privileging • Patients still require other services so not completely self-reliant

modes of delivery of vascular care.[8] Because vascular care is also provided by cardiologists, interventional radiologists, and vascular medicine specialists, a multidisciplinary CV center makes an ideal organization in which to provide comprehensive services to patients with a common pathology (Table 197.2).

Although still relatively rare before the age of 50 years, by age 80 the prevalence of peripheral arterial disease (PAD) rises to 20%. By 2030, 180,000,000 people are estimated to have at least one risk factor for PAD.[9] Thus, as the elderly population continues to expand faster than younger segments,

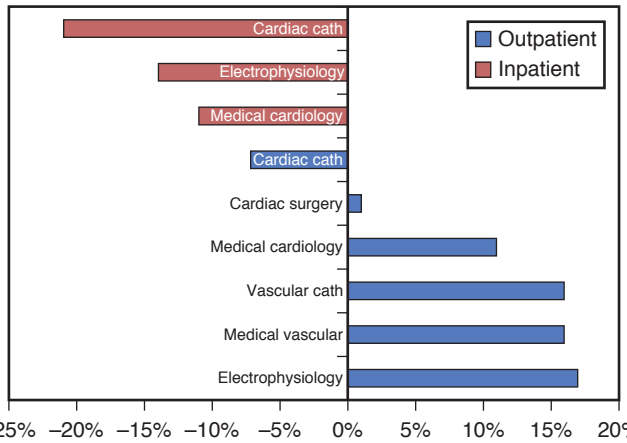

Figure 197.1 Cardiovascular Volume Growth Projections by Subservice Line 2013 to 2018.

the prevalence of PAD will continue to increase sharply, and the number of PAD procedures will increase accordingly (Fig. 197.1). Furthermore, these elderly patients are living longer, requiring treatment over longer periods of time, and all the while accumulating more comorbidities that affect PAD treatment outcomes.[10]

Despite these demographic changes, management of these aging and increasingly complex patients moves more and more into the outpatient arena. The rate of inpatient PAD interventions declined from 209.7 to 151.6 per 100,000 Medicare beneficiaries between 2006 and 2011, whereas the rate of outpatient interventions increased from 184.7 to 228.5.[11] With the shift to outpatient care, significant increases in office-based procedures are also occurring.

Paradoxically, medical innovation has largely focused on inpatient treatments. Costs for inpatient care continue to rise and make up the "lion's share" of Medicare expenditures for PAD[12]; this highlights the disconnect between increasing outpatient volumes and a focus on inpatient care. Given the push by multiple stakeholders, it is likely that financial incentives for outpatient care, preventive medicine, and population health management will drive the design of multispecialty CV centers in the future. For example, the safety, patient satisfaction, and financial viability of endovascular procedures performed in the outpatient setting has already been established.[13]

Competition

Market forces have played a significant role in the evolution of many multispecialty centers that focus on common or historically well-reimbursed diseases including CV, orthopedic, and neurologic diseases, especially in the outpatient arena (Fig. 197.2). For example, in the 1990s, the number of programs offering coronary artery bypass grafting (CABG) increased by 30%. More than 80% opened within 30 miles of an existing program, and 55% opened within 10 miles. Every new program established in a freestanding "heart" facility opened within 20 miles of an existing program. New cardiac surgery programs established from 1993 to 2004 led to little increased access

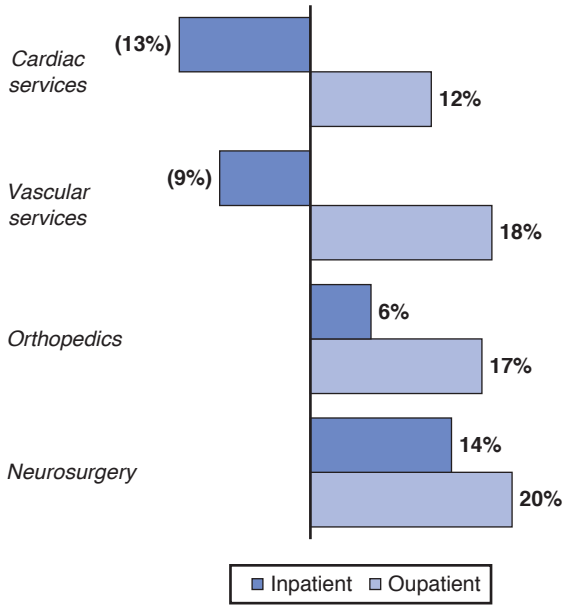

Figure 197.2 **All Payer Growth in Major Service Line Volume Projections 2014 to 2019.** The left side shows negative growth and the right side shows positive growth.

and substantial duplication of services.[14] At the same time, CABG volume overall was decreasing and there was mounting evidence that centers with lower CABG volumes had poorer outcomes.[15] Ultimately, the competition in this environment made it very difficult for many CABG programs to maintain durable independent success.

The evolution of disruptive technology, such as endovascular aneurysm repair (EVAR), has also increased competition among multispecialty CV centers. In many regions, as EVAR diffused from early adopters to academic centers to the community, the total volume of EVAR cases became distributed over an increasing number of centers. Again, this was in spite of data suggesting that high-volume centers had better outcomes.[16] The rapid growth of programs in proximity, decreasing procedural volumes, and the need for volume at individual centers to maintain quality outcomes and financial success has led to intense competition but has not necessarily improved access to specialty care in all communities.

Reimbursement and Quality of Care

Assorted reimbursement models have been proposed and implemented rapidly as our healthcare system struggles to balance cost, outcomes, and value. Pay-for-performance models offer only modest incentives for quality improvement over fee-for-service models and drive the use of evidence-based practice while emphasizing patient satisfaction. The assumption is that higher quality leads to fewer encounters, more durable outcomes, and therefore lower cost, an assumption that may not be valid and also one that depends heavily on the definition of quality. The definition of quality can vary significantly, particularly if one moves from an individual perspective to a community or population perspective. Individual patient outcomes have always been the physician's measure of quality. Quality and value were viewed as synonymous. However, in this era of cost containment, the definition of value has evolved to include much more. Not only are patient outcomes a part of this new value equation but so is patient (customer) satisfaction and experience, efficiency, and cost management. To this end, calculating the value of a multispecialty CV system has become important to the public, payers, and regulators.

As part of the trend toward financial transparency and value estimation, Medicare in 2008 began the Physician Feedback Program. Not yet publicly reported, this program collects data on quality, cost, and resource use on a hospital and provider level and provides participants with their data in comparison to their peers. In addition to this reporting, a VBP modifier is in development, which would provide for differential payment for fee-for-service Medicare services based on quality of care and costs incurred by providers. With all this currently or soon-to-be publicly available data, multispecialty CV centers must balance meeting metrics while staying true to their core mission.

DEVELOPMENT OF A MULTISPECIALTY CARDIOVASCULAR CENTER

To position themselves to provide for population health, successful health systems are altering their strategies. Optimizing CV specialist access at high-volume, critical locations is important so that there is a balance between offering access at outreach sites yet not short changing primary sites.[17] Ideally, the right patients should be seen by the right specialist at the right time in the most cost-effective manner. Although "on demand" presence is rarely possible because of limited physician capacity, considerable management skills are needed to use CV specialists appropriately. This may include streamlining scheduling practices, reducing no-shows, and prioritizing patient convenience by offering hours convenient for them.

When multiple specialties are involved, there is always going to be jockeying for an advantage between groups. Managing these highly charged conflicts takes a skillful leader. Experience, temperament, and trust are prime attributes to seek in any leader, but especially in a complex, changing environment. A physician co-leader working with an administrator may provide the best value (Fig. 197.3). Almost 75% of surveyed CV centers had either a "dyad" (physician leader and an administrator) or a "triad" (administrator and two physician specialists) leading the center.[18] The team leading a CV center, as a whole, must possess critical skills such as project management, strategic and operational awareness, financial proficiency, and competence in addressing quality of care issues. The biggest challenges are aligning incentives and achieving shared values and expectations so that all stakeholders agree to be accountable to each other. It is essential that these are written down and agreed upon by all members.

In AMCs the duality of reporting to the academic department as well as the CV center creates confusion regarding accountability.[2] Although it may be possible to eliminate the duplicate reporting in nonacademic, highly integrated health systems,

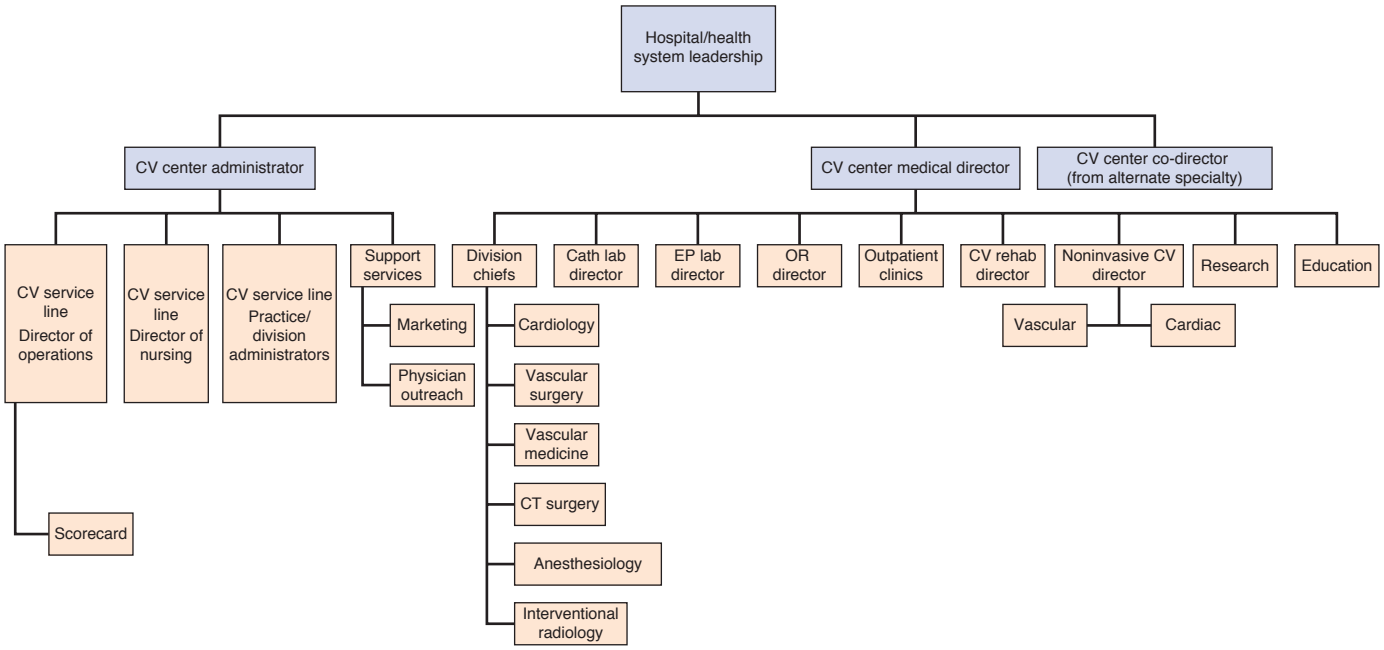

Figure 197.3 Suggested governance of a CV center (dyad or triad). *CT,* Cardiothoracic; *CV,* cardiovascular; *EP,* electrophysiology; *OR,* operating room.

long-standing barriers and fear of disruption of traditional cost-accounting systems make it difficult in AMCs.

Another pitfall in a CV center is agreeing on privileges for procedures because procedural volumes required for "competence" vary by specialty. Agreement must be reached by reviewing relevant specialty guidelines and favoring a higher bar, then negotiating to train each other to achieve competence. This can happen only if incentives for compensation are transparent, fair, based upon valid benchmarks, and agreed upon unanimously. After internal competition between specialties is eliminated or minimized, all specialists can concentrate on growing the business regardless of who does the work.

Finances and Compensation

As more CV specialists become fully employed by health systems, the financial management must itself be completely integrated. A dedicated budget and a single profit and loss statement for all CV operations must be in place. This allows the pressures on revenues such as increasing costs, decreasing reimbursement, more risk-based payments, and changing payer mix to affect all specialties. Although volume, commonly measured by work relative value units, is still the dominant component of physician compensation, an increasing share is tied to quality of care and performance. If the CV center is designing a compensation system to align multiple specialties, shared incentives must be encouraged so that some percentage of compensation is based on team, unit, service line, or system performance. Similarly, at-risk incentives may include metrics such as quality measures, use, readmissions, patient access, cost control, good citizenship, and outreach activities. As an example, if there is a group performance incentive, a CV specialist who travels to an outreach site and generates referrals for others in the group while her own procedural productivity suffers should share equally in the group bonus if productivity targets are met or exceeded. These incentives should be perfectly transparent to all the involved clinicians. Multispecialty collaboration is unlikely to succeed if a specialty or individual feels that their income is more at risk than the others.

Operational Issues

A culture of excellence is vital for a CV center to succeed but requires a commitment from physician and nursing staff. Because of the competition for CV patients both locally and regionally, CV centers need to differentiate themselves based upon quality outcomes, price, access, reputation, and rankings. Achieving well-known designations for excellence requires the organizational commitment of everyone from leadership to support staff, in addition to investment in personnel and computer resources. Common CV sought designations include: US News and World report (Heart and Heart Surgery category),[19] Health Grades,[20] which gives out specialty awards annually, Thomson Reuters, which publishes hospitals that meet certain CV benchmarks with its top 100,[21] Intersocietal Accreditation Commission accreditation for vascular laboratories, echocardiography and nuclear medicine,[22] and American Heart Association recognition for ST-elevation myocardial infarction referral centers. Many insurance companies and professional society databases also confer various awards for excellence in specialty care.[23] These designations require sophisticated computer programs and staff to enter, collect, analyze, and report data.

The governance structure of the CV institute must ensure that responsibility and accountability for the service line is designated to clearly appointed personnel. The "dyad" model combines the clinical experience of a physician with a skilled administrator. The difficulty in executing a vision or strategic plan occurs because of ambiguous lines of responsibility.

Regardless, the structure must allow proper representation of all parties (see Fig. 197.3).

There are several options for designing an operations hierarchy. Several layers of vertical bureaucracy existing in most hospitals are not well suited to single service line organizations. A matrixed structure allows expedited decision making, quicker execution of strategic plans, and better patient outcomes and quality of care. However, this reporting structure consists of a CV leader but no clear and direct responsibilities for all the divisions or departments within the service line.[24] This model requires all parties to be cooperative at all levels, and obtaining consensus may delay time-sensitive decisions. In an integrated operating structure most, if not all, reports occur directly to leaders of a service line or subservice line within a CV center. This structure is more complex because of the number of personnel and functions reporting to very few individuals, but decision making can be more efficient. There is no "one-size-fits-all" governance hierarchy that will work in every system. The management structure chosen must fit the local culture while satisfying basic organizational needs.

AMCs have traditionally operated with a hierarchical structure partly because the decision-making power rests with a dean and a department chair and partly because AMCs are cautious about taking risks with new models of care. However, foundation model-based institutions such as the Mayo Clinic have changed to patient-centric, integrated models of care in view of the move to value-based reimbursement, more emphasis on quality of care, increased transparency, and regulatory pressures. In bringing several specialties in CV centers into a single service line, many challenges are faced because of disruption of the existing power structure, medical education, resident training, and most importantly internal competition and compensation models. Not all AMCs are well suited for disruptive change.[25] Skilled leadership is required to integrate clinical, research, education, and administrative functions into a tightly knit, efficient unit focused on patient care, best outcomes, growth, and external competition.

THE CURRENT STATE OF MULTISPECIALTY CARDIOVASCULAR CENTERS

A recent survey of CV center administrators showed that AMCs, nonteaching community hospitals, and teaching community hospitals each constitute one-third of all CV centers.[18] Half of CV centers are associated with greater than 500 beds, and 60% are either regional or multistate systems, suggesting the need for organizational resources and capacity. It must be recognized that the creation of a larger entity such as a CV center poses new challenges in terms of governance and operations to any healthcare system, which should be anticipated (Table 197.3).

To better understand the current status of multidisciplinary CV centers in this country, existing community and AMC program administrators and lead physicians were contacted for telephone interviews. Designations for current CV centers range

TABLE 197.3 Challenges and Solutions for Cardiovascular (CV) Centers

Challenge	Possible Solutions
Appropriate leadership	1. Select a knowledgeable, representative, and accepted leadership unit in place 2. Establish a culture of integrity, transparency, and accountability 3. Mission and vision statements after input from all stakeholders 4. Responsibilities are specific and not ambiguous
Organizational chaos	1. Require physician leadership training 2. Integrate employed and affiliated physicians 3. Fashion a systemwide service line 4. Integrate inpatient and outpatient services 5. Control costs associated with newly formed service line associated center
Interspecialty silos and conflicts	1. Minimize internal competition while maximizing referrals and volumes for all 2. Avoid cannibalization 3. Design a transparent, fair compensation system that rewards not only individual productivity but team goals
Turf battles	1. Affirm a multispecialty team approach to cardiovascular diseases 2. Broad agreement to train each other when possible 3. Train multidisciplinary nurse specialists, patient schedulers, and other care givers 4. Cross specialty strategy, privileging, and quality of care committee 5. Educate trainees on the advantages of cooperation
Integration	1. Common charge-master and pool technical and professional revenue 2. Single profit and loss statement 3. Cross specialty practice guidelines and value analysis 4. Compensation incentives partly based upon group or subservice line performance and system goals 5. Physicians completely embedded in the governance model
Variation in care among specialties	1. Standardization of clinical and operational protocols 2. Institute a standing multidisciplinary quality assurance (mortality and morbidity) and case monitoring conference 3. Participate in national registries such as Vascular Quality Initiative (VQI) by the Society for Vascular Surgery or National Surgical Quality Improvement Program (NSQIP) by the American College of Surgeons or similar program

from "center of excellence" and "service line" to "institute," implying varying degrees of integration. Service lines tend to bring together specialties with a common clinical focus under one administrative umbrella, with the aim of initiating cost-savings maneuvers and promoting collaboration among specialists. Centers of excellence seem to venture beyond operational integration and clinically cooperate on various levels with regard to physical facilities, scheduling, and referrals. Institutes imply the highest level of integration with financial interdependence between the member specialties and an increased level of collective fiscal responsibility by the specialties.

The impetus to establish a multidisciplinary CV center varies but was generally consistent with the reasons stated earlier. Administrators tended to cite business reasons as motivators, such as greater procedural volume, access to patients, and better bargaining power with payers. Improved system accessibility for patients and better patient outcomes were also mentioned. Although physicians claimed these same patient-centered inspirations, preservation of specialty specific referrals and practice patterns remained important to them. Despite this, most CV centers were inclusive of cardiology and vascular surgery; cardiothoracic surgery, interventional radiology, neurology, neurosurgery, and vascular medicine were involved on a more varying basis. Overall, CV centers seemed to have a higher level of integration when a variety of physicians were engaged at the inception of the CV center and improved patient care was the ultimate objective.

The presence of a common CV center administrator was a typical theme, but this person's responsibilities and decision-making authority varied from functioning as a simple coordinator to one with full strategic and operational capabilities. Physician leadership was always incorporated to some degree but ranged from one to several directors, typically from a variety of specialties. Commonly, a cardiologist was the appointed physician leader. The amount of physician responsibility also ranged from an assigned title to involvement in operations including active planning and frequent team meetings.

Many CV centers approached were still in a state of continued development and refinement of their programs. The more recent adapters tended to have service line–type programs by aligning the involved specialties through administrative functions. This included managing personnel issues and processing requests for new equipment acquisition, among many other tasks. Individual specialties maintained their separate financial structures and oversight programs (quality, physician recruitment, reimbursement, etc.). Clinical activities were typically also independent, although there were some CV centers whose specialists shared a common outpatient clinic or inpatient procedural area.

In general, academic divisions contacted continued to report and be accountable to their respective departments. It was rare to encounter an AMC where individual divisions had traded the traditional departmental structure for a disease-based configuration, unless special circumstances existed, such as a previously established multispecialty practice or the availability of a large amount of external funding. Departments also seemed unwilling to sacrifice their components (and sometimes the more lucrative ones) to a disease-specific center. Community hospitals tended to have similar concerns, with specialists remaining loyal to their private practices and groups, rather than wanting to create a whole new financial structure and give up total operational and fiscal control.

No matter the base structure of a CV center, most have developed some type of tool for measuring success. Key performance indicators (KPIs) are the norm in CV centers operated by both academic and community hospital systems,

TABLE 197.4 Key Performance Indicators in Creating a Cardiovascular (CV) Scorecard

Focus	Focus of Metrics	Examples of Metrics
Customer	1. Patient 2. Employee 3. Referring physician	• Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS), care pathways, average wait times to access • Attrition rate, satisfaction survey metrics • Referral rates, survey metrics
Clinical/education	1. Quality 2. Research 3. Education	• Outcomes by specialty, shared performance measures, concurrence with guidelines, door to door times, core measures met • Grant volumes and dollars, presentations, publications • Peer-reviewed publications • Scientific presentations—local, regional and national • Performance in "in-training" and board examinations • Results of accreditation site visits • Outcomes of National Resident Matching Program (NRMP)
Organizational	1. Leadership 2. Strategy/business development 3. Financial performance 4. Marketing initiatives 5. Operational efficiency	• Quality of care indicators, financial performance, market share • Market share, payer mix, physician alignment • Inpatient and outpatient volumes, accounts receivables, physician productivity, monitoring of value based payments, net profitability measures by specialty, return on investment • Patient intake by geographical area and zip code, success of differentiation strategies, online analytics (bounce and conversion rates) • Case mix index, supply chain efficiency, readmission rates, no show rates, unit or procedure room use rates, staff productivity

whether they are administrative or clinical (Table 197.4). A scorecard should be built based on the organization's mission, vison, and values in order to better communicate strategy to the key stakeholders. KPIs should be reviewed regularly to gauge success. Examples of CV scorecard projects are endless and may include increasing local/regional market share, improving patient throughput in the ambulatory setting, employer of choice programs, and reintervention rates for endovascular interventions.

Healthcare marketing is a specialty and in competitive markets is a multi-million dollar budget item for CV centers. Although there are several important metrics in gauging success of marketing plans, market share is a critical number to follow over time. Market penetration is monitored by analyzing patients served, discharges, and revenue in specific regions. Occasionally in CV centers that exist largely in name only, without true integration in operations and finance, care givers themselves may be unaware that a named CV center exists, making one wonder how effective their marketing plans have been. This emphasizes the importance of staff engagement on all levels to promote a healthier patient experience and the success of centers of excellence.

FUTURE DIRECTIONS

With mergers and acquisitions of hospitals and health systems will come consolidation of services focused on reducing variations in care and eliminating wasteful tests and procedures, all to produce better quality healthcare with reduced cost.[26] Specialties providing care to the vascular patient will be persuaded to work together with greater efficiency, and physicians will be credentialed according to experience and skills rather than specialty-specific requirements. Difficult as it may be, sharing of knowledge must be mutually acknowledged as being a necessity. Best practices and specialty guidelines must be shared and disseminated throughout all clinical areas.

On the surface, the multidisciplinary CV center seems well suited to achieve success in bundled and accountable care reimbursement models. By giving providers defined payments for "episodes of care," bundling emphasizes clinical performance and the use of evidence-based medicine but also rewards efficiency of care delivery and multispecialty cooperation. Systems that can achieve quality outcomes with the least redundancy and waste should succeed. Furthermore, by including continuums of care in certain "episodes" (e.g., defining an episode as admission through a surgery and then 90 days postdischarge), systems are forced to invest not only in procedural or inpatient care but also postacute and outpatient care. The Bundled Payments for Care Improvement Initiative (BPCI) sponsored by the Center for Medicare and Medicaid Innovation (a product of the Affordable Care Act) has targeted 48 disease areas in which to roll out bundled payments; fully one-third are CV diseases.

The Accountable Care Organization (ACO) model further broadens the scope of cost-containment efforts to the community and population level. Instead of individual episodes of care, disease outcomes at the population level are emphasized. Successful treatment of chronic outpatient diseases and delivery of effective preventative care are rewarded. In addition to the quality care delivery and system efficiency incentivized by bundled payments, effective resource use across a community, geographic region, or population is rewarded by the ACO. The Centers for Medicare and Medicaid (CMS) recently reported that since 2012, Medicare ACOs have grown to more than 477 nationwide and currently are serving nearly 8.9 million beneficiaries.[27] Besides large health systems, physicians are leading consolidation of single or multispecialty vascular and cardiac groups and are also well positioned to succeed in competing for the CV patient. A national survey of ACOs showed that 51% were physician led and 33% were jointly led by physicians and hospitals.[28] Furthermore, physicians constituted a majority of the governing board in 78% of ACOs. Each of these evolving reimbursement models rewards a different type of multispecialty CV system, and development of a successful center requires intimate knowledge of the local and national reimbursement environment and the direction in which it is likely to move.

Patients increasingly affected by cost shifting to higher deductibles will move toward being better consumers, seeking out online reviews about quality and price transparency. Nonemergency procedures performed in the expanding outpatient arena will compete for price and quality. Similarly, Hospital Consumer Assessment of Healthcare Providers and Services (HCAHPS) metrics now used as part of value-based reimbursement will likely also begin to be used in outpatient centers. CV centers of the future will also join the technology revolution by allowing vascular patients to access their electronic medical records, including imaging and test results. Consumer expectations for access to care are also changing quickly. The ease of access to services at one click for transportation, groceries, laundry, and retail care has changed consumer behavior to where "on-demand" access is expected. Similarly, online scheduling convenience will be expected and require upgrading scheduling platforms and physician portals. The concept of a "just in time" strategy to decrease waste and improve efficiency will become common as health systems grapple with innovative ways of using technology to increase access to vascular specialists at multiple locations.

CONCLUSION

Factors that should lead to the long-term success of any CV center are those that characterize the best health systems today: enlightened leadership, excellent patient care, demonstrated outcomes and quality, cutting-edge research and innovation, and committed physicians who have access to the latest technology.

The successful CV center of the future must be multidisciplinary and patient-centered, empower physicians and other leaders to participate fully in governance and business decisions, design quality of care guidelines, and abandon siloed care, and move to collaborative models. Only then will there be a truly shared commitment to collaborative growth in the construction of the CV center of the future.

The Advisory Board is a health care organization best practices consulting firm mostly made up of large health systems. Its Cardiovascular Roundtable group uses its resources to study the cardiovascular services market and produce guidelines and solutions to a variety of cardiovascular service line issues, such as this document, which is concerned with assembling a cardiovascular network.

Lucas FL, Siewers A, Goodman DC, Wang D, Wennberg DE. New cardiac surgery programs established from 1993 to 2004 led to little increased access, substantial duplication of services. *Health Aff (Millwood)*. 2011;30(8):1569–1574.

This paper describes how in the 1990s into the 2000s, the proliferation of cardiac surgery programs, which occurred as overall cardiac surgery volumes decreased, resulted in the establishment of new programs in urban areas which already were served by existing programs, and market share was divided by competition rather than expanded overall. Underserved areas did not benefit from the services of new programs, and saturated market became more competitive.

INTRODUCTION

Endovascular procedures were traditionally performed in the hospital where the patient was observed overnight following the procedure; this gradually transitioned to the patient being discharged on the same day.[1] Once the safety and efficacy of these procedures was established for the hospital-based setting, studies were conducted by multiple investigators that documented the safety, cost efficiency, and efficacy of conducting endovascular procedures in a dedicated outpatient office.[2-4] The deficit reduction act of 2005 included the provision for the Center for Medicare and Medicaid Services (CMS) to reimburse endovascular procedures in the office setting. Same-day discharge of the patient after these procedures helps reduce the cost of the procedure.[1] Other insurance companies followed CMS and now provide the same coverage. Thus, endovascular procedures can now be conducted in outpatient vascular centers. There are three types of outpatient centers that a patient may consider

Abstract

In 2005, the deficit reduction act allowed the reimbursement of procedures performed in office-based endovascular labs. Initially, the majority of procedures were performed to manage hemodialysis access. Subsequently, peripheral angioplasty and related procedures became reimbursable through the Center for Medicare and Medicaid Services (CMS). This has resulted in more than 500 labs opening in the country managed by vascular surgeons, interventional cardiologists, radiologists, and nephrologists. Of the commonly performed endovascular procedures, only endovascular repair of abdominal aortic aneurysm and carotid stent are not reimbursable when done in the office. There is no accreditation requirement by CMS for reimbursement, but individual states have different requirements. The physician receives a global fee that is a combination of a technical component and a professional component.

for endovascular procedures: a hospital-associated outpatient center, an ambulatory surgery center, or an office-based vascular center.

Outpatient vascular centers can be established by a hospital or by office-based practitioners. In hospital-developed outpatient centers, the hospital is paid under the outpatient prospective payment system, and each physician bills separately for professional services rendered. At a privately owned ambulatory surgery center (ASC), the "facility fee" is paid to the ASC for the surgical procedure and the provider is paid the "facility rate" based on the surgical procedure performed. In an office setting, Medicare and other insurance companies pay at the "nonfacility" rate. This nonfacility fee is a combination of technical and professional fees. An office-based center or laboratory is defined as a procedural suite within an office and is an extension of the office where patients are seen and treated. The office-based center is not specialty specific and the elements described in this chapter can be applied to all specialties. Office-based centers are currently owned by vascular surgeons, interventional cardiologists, interventional radiologists, and interventional nephrologists.

REGULATIONS

Office-based centers, in contrast to ASCs, do not have well-defined regulations guiding their operation. Instead, the centers are mostly regulated by state law (Table 198.1), because there are currently no federal guidelines for an office-based center. These regulations mostly pertain to anesthesia, radiology, and the Occupation Safety and Health Administration (OSHA).

Anesthesia

Regulations pertaining to anesthesia depend on the degree of sedation administered to the patient. In most states there is no requirement for an anesthesiologist to be present for minimal to moderate sedation. Many states, including New York,[5] require the presence of anesthesia personnel if moderate to severe sedation is needed for the procedures being performed. Different accrediting bodies may also have specific requirements regarding anesthesia that must be followed for the center to be accredited.

Radiology

Each state has different regulations governing the radiology suite in the office. Not all states require lead lining of the lab if a C-arm is being used. Some states mandate that only a certified radiology technician can operate the C-arm. The lab should follow the state law related to C-arm inspection, lead lining, staffing, and training regulations. In addition, there may be regulations governing the integrity of lead aprons and dosimeters.

Occupation Safety and Health Administration

OSHA regulations need to be followed diligently. This requires compliance training, policies and procedures, employee handbooks, and forms for recording incidents (needle sticks, etc.). The complete set of regulations can be found at www.osha.gov.

TABLE 198.1 Comparison of Ambulatory Surgery Center and Office-Based Labs

	ASC	Office-Based Lab
Payment methods	Bill facility fee and professional fee	Global payment (nonfacility)
Procedures allowed	All ASC approved procedures can be performed	Limited number of procedures
Physician usage	Other practitioners can use	Only practitioners seeing the patients in that office
Ownership	Multiple physicians can own it	Lab must typically be owned by physicians who are seeing patients and operating on them
Licensing	CMS and state license required	No license needed
Capital investment	Higher capital outlay for construction and equipment	Reasonable capital outlay
Oxygen requirements	Built in gas/oxygen supply and wall suction required	Oxygen cylinder
Size of facility	Bigger facility required	Depending on expected volume, smaller space can suffice
Regulations	Comply with federal and state laws	Comply with state laws
Services cost	Higher professional services cost at outset	Minimal cost
Staffing cost	Higher staffing cost; different staffing ratio	Office staff can be used in addition to added personnel
Monthly cost	Higher monthly costs	Lower cost
Accreditation requirements	Accreditation required	Not required except in certain states
Certification requirements	Certificate of Need required in many states	No Certificate of Need required
Transfer regulations	Transfer agreement required	Not needed, desirable if the practitioner is not a surgeon

ASC, Ambulatory Surgery Center; *CMS*, Center for Medicare and Medicaid Services.

COMPONENTS FOR SUCCESS

Office for Patients

Office-based outpatient interventional centers are defined as locations where patients traditionally see physicians or surgeons to discuss and diagnose their clinical needs. The office must

have the basic requirements of space and personnel, such as examination rooms for patients to be seen, and nursing staff to provide patient care, among other requirements.

Noninvasive Vascular Lab

A noninvasive vascular lab is needed to support the office-based practice and the endovascular laboratory suite. An ultrasound machine that can reliably perform imaging of the venous system and peripheral arterial system including the aorta, carotids, and visceral arteries is required. The same machine can be used to access arteries and veins in the endovascular suite. Different probes may be required to access the tibial and radial arteries. A Doppler machine to do wave forms and measure ankle and toe pressures is required to assess circulation in the extremities. Additionally, the appropriate equipment is required to conduct photoplethysmography of digital vessels to check the digital circulation in patients with the Reynaud phenomenon, vascular steal in dialysis patients, and occlusive disease in diabetics. The lab should be certified by the Intersocietal Accreditation Commission or the American College of Radiology.

Endovascular Lab

Almost all the percutaneous endovascular procedures currently being performed in the hospital can be safely conducted in the office-based lab.[6,7] Because there are limited resources in the office as compared to hospital, patient selection is crucial in optimizing results and intent to cause no harm. The absolute contraindications to treating a patient would be the need for general anesthesia, the need for hospital admission due to comorbidities, the need for prolonged observation postprocedure, or severe allergy to dye.[4] Relative contraindications for patients would include the weight of patient exceeding 400 pounds or a patient with decreased pain tolerance, if conscious sedation is not available. Endovascular repair of an aortic aneurysm and carotid stenting cannot be performed in an office-based lab and are not reimbursable in the office-based setting. In a pilot study (not published), endovascular repair of infrarenal aneurysms was safely done in the office-based lab in appropriately selected patients. However, until a larger study is conducted, this procedure should not be performed in the office-based setting.

Types of Procedures

Hemodialysis Access–Related Procedures (See Chapter 177)

Catheter insertions (temporary or permanent): Insertion of catheters should be avoided as much as possible[8] because of inherent complications like infection and stenosis caused by the catheters. Patients needing urgent dialysis without a functioning access will need catheters and these can be easily placed in the office setting.

Catheter removal: If the state regulations allow, a midlevel operator can be trained to remove catheters.

Fistulogram: There is no indication for doing a fistulogram on a predetermined schedule.[9] The following indications should be used for the procedure: (1) decreased blood flow, (2) increased venous pressure, (3) increased bleeding after removal of the needle, (4) ultrasound-proven hemodynamically significant stenosis, (5) inability to access the vein, (6) increased recirculation time, or (7) decreased urea clearance.

Fistulogram intervention (See Chapter 178): Once a fistulogram is performed, the most common intervention carried out is angioplasty of stenosis. Routine placement of stents is not recommended. Two covered stents, the Flair[10-12] (Bard Peripheral Vascular, Inc., Tempe AZ) and Viabahn stents (W.L Gore and Associates, Inc., flagstaff AZ), are approved by the Food and Drug Administration (FDA) to be used at the site of stenosis in graft vein anastomosis. Stents should be used only if there is elastic recoil after angioplasty, recurrent lesions within 3 months of the procedure, or in treating grade 2 or 3 hematomas. A stent should not be placed at the site of cannulation. Intrastent stenosis is very difficult to treat; therefore, following current best practices is advised. Additional concerns for stent use include migration or fracture of the stent. The use of laser atherectomy of stenosis at the dialysis access stent is currently not FDA approved, so it should not be done. If large branches are stealing the blood from the main access, coil embolization can be done[13] and may help improve blood flow through the main vein. Finally, if the fistula is not maturing, a fistulogram and angioplasty are appropriate. There is no reimbursable code for balloon-assisted maturation of a fistula.[14,15] Patients should not have balloon angioplasty at scheduled intervals without medical necessity.

Percutaneous thrombectomy: If a dialysis graft or fistula thromboses, it can be declotted using percutaneous,[16] chemical, and mechanical thrombectomy.[17] In cases of thrombosis in arteriovenous grafts,[18] angioplasty of graft vein anastomosis is almost invariably required[19] post thrombectomy.

Central venous stenosis management: Many patients present with swelling of the arm or other manifestations of higher venous pressure because of central venous stenosis. The narrowing may occur due to previous catheters or the presence of a pacemaker/defibrillator on the ipsilateral side.[20] Correction of these areas of stenosis requires large high-pressure balloons. Bare metal and covered stents are used more frequently in treating central vein stenosis.[21]

Inflow arterial stenosis: Blood flow in the access may be diminished due to proximal arterial stenosis. This can be corrected by angioplasty using a retrograde approach through the access or by using an antegrade approach via the femoral artery.

Peripheral Arterial Procedures

Diagnostic arteriogram: An arteriogram may be performed for carotid artery disease, renal artery stenosis, lower extremity ischemia, or visceral ischemia. A diagnostic arteriogram can be performed and billed for any vessel in the body except the coronary arteries. The procedure can be done via a femoral, brachial,[22] radial,[23] or tibial approach. Femoral artery access is

the most common approach. Prior to the procedure, kidney function should be assessed and in cases where renal function is compromised, an appropriate hydration protocol should be used. In patients with moderate to severe renal impairment, CO_2 angiography should be performed.[24] In cases of morbid obesity or hostile groin, a brachial or radial approach can be used. The complication rate is higher with the brachial approach compared to the radial approach.[22] Closure devices are used based on physician preference. Although there is no significant decrease in postprocedure bleeding when these devices are used, the time to discharge is often diminished.[25]

Arterial Intervention

Carotid: Stenting is not reimbursable.

Renal: Renal angioplasty and stent can be performed using appropriate indications.[26]

Visceral: Angioplasty and stenting of superior mesenteric and celiac arteries can be performed with results comparable to open procedures.[27]

Aorta: Angioplasty of the aorta is seldom indicated.

Iliac artery: Angioplasty and stenting of iliac arteries results in satisfactory long-term results. Atherectomy at this anatomical location is not proven to be clinically beneficial and is not reimbursable.[28]

Superficial femoral artery, popliteal artery, and infrapopliteal arteries: Intervention in this segment of blood vessels is the most common procedure performed in many labs, often done to relieve critical limb ischemia. Documentation of prior noninvasive vascular lab studies is desirable to justify the intervention. Angioplasty,[28] stenting,[29] and atherectomy[30-32] are all performed in these vessels. Stents crossing the knee joint are not advised because of increased incidence of stent fracture. There are currently no FDA-approved stents for infrapopliteal arteries. Various atherectomy devices are used, including directional, orbital, or laser devices. Long-term results using these devices are not currently available, because most of the data ends at 1-year post procedure. In the latest advances, drug eluting balloons,[33] new design stents, and drug-coated stents[33-36] are showing promising results. A retrograde tibial approach is being used to cross lesions when an antegrade method fails or in cases where the patient has a hostile groin.[37-39]

Upper extremity arterial stenosis: Stenosis in the subclavian,[40] axillary, brachial, radial, and ulnar arteries can be managed by angioplasty and stent when indicated. There is currently not enough data to support atherectomy in these arteries.

Venous Procedures

Venous stenosis in the iliac and femoral veins due to post-thrombotic obstruction or external compression, that is, May Thurner syndrome, can be detected using venography and intravenous ultrasound (IVUS). There is an increasing body of literature supporting the use of angioplasty and stenting of these lesions (see Chapter 161). Neglen et al.[41] have shown long-term patency of venous stents and sustained clinical symptom relief. Ganelin et al.[42] demonstrated the safety of this procedure in an office-based setting. Currently there is no FDA-approved stent to treat venous stenosis, but there are two ongoing trials testing the efficacy and safety of vein-specific stents. The stents needed are usually large, 14 to 28 mm in size. This also requires stocking larger balloons that are not usually kept in the lab. IVUS is proving to be more accurate than venography in diagnosing venous stenosis.[43] Results of thrombolytic therapy of iliac vein thrombosis in the office have been reported, and will likely soon be considered safe in the office setting. Finally, vena cava filters can be inserted and removed safely in the office-based lab.[44]

Port Insertions

Ports for chemotherapy, nutrition, or antibiotic therapy can be inserted as long as the patient is not on Coumadin. In many hospitals, ports are exclusively inserted by interventional radiologists or operating surgeons. However, ports can also be placed in office-based labs, where same-day service can be provided for port insertion.[6]

Venous Center

Use of an outpatient venous center to primarily manage superficial venous reflux has gained wide acceptance among physicians and patients. These centers specialize in endovenous ablation, microphlebectomy, sclerotherapy, and evolving new techniques like foam and glue injections for truncal venous insufficiency.[45] The venous center can be developed with or without an accompanying endovascular center. However, improved efficiency can be gained when venous centers are combined with an endovascular center, because patients who do not have complete symptomatic relief after ablation of veins causing superficial venous reflux may benefit from further intervention. They may also be candidates for interrogation of iliac and femoral veins using venogram and intravenous ultrasound and subsequent treatment with angioplasty and stenting. Providing treatment for all types of vascular conditions at one location improves the safety and convenience for the patient, because their physician is the same for both procedures.

Additional Services

Vascular Medicine

Management of peripheral vascular disease starts with medical management and may end in surgical intervention in some patients.[46] Even after intervention it is crucial to have optimal medical management. All vascular surgeons devote greater than 80% of their time to medical management of patients with peripheral artery disease (PAD). However, in a busy practice, a vascular medicine specialist can dedicate 100% of their time to managing the risk factors in patients with PAD, freeing the surgeon to dedicate more of their time to surgery. A vascular medicine specialist can coordinate programs dedicated to helping patients stop smoking and control weight with supervised exercise. With the continuous advent of new drugs and the need to treat hypertension, diabetes, and hyperlipidemia, it is challenging to keep up with all the medical advances. Most, though not all, patients have primary care physicians. However,

increasing regulatory demands prevent these doctors from spending enough time with patients whose health could be improved with closer monitoring of their risk factors. A vascular medicine service supporting the office-based lab can ensure patients are provided the most current medical treatment available and provide the personalized care these patients need to improve their health.

Wound Care Center

Ideally a vascular center would work closely with a wound care center.[47] Patients seen in the office with wounds can have the extremity revascularized in the office-based setting followed by wound care in the wound care center. If the practice is large enough, it can also own the wound center. Wound centers may also direct new patients into the vascular practice. If the limb can be revascularized in the office-based lab, followed by wound management in the wound care center, this can avoid a hospital admission, which is inherently more expensive.

Screening Program

Providing a screening program to patients for various endovascular diseases should be part of the comprehensive services provided to the patient population with peripheral vascular disease.[48] Screening for aortic aneurysms, PAD, and carotid disease is routinely done, both by primary care physicians and cardiovascular specialists. Since 2007, Medicare reimburses for abdominal aortic aneurysm (AAA) screening in men over 55 years of age with a family history of AAA, all men above the age of 65, and women 65 years or older with a family history of AAA or history of smoking. Specific screening guidelines vary among clinical societies. PAD screening and carotid screening are often done in tandem. In the life-line screening program, the prevalence of PAD and carotid artery disease was 4.1% and 3.9% respectively.[49] As many as 18.8% of patients with PAD also have carotid artery disease. Most patients who have an abnormal ankle brachial index will have mild atherosclerotic disease. Although mild disease can be managed medically, patients with severe disease will need endovascular intervention. Providing a screening program for endovascular diseases in an office-based laboratory increases the awareness of disease among patients in addition to positioning the practice as a leader in managing PAD, both of which benefit the practice.

Building a Center

Business Plan

Before embarking on developing an outpatient office-based endovascular suite, it is crucial to have a business plan.[4] This involves collecting clinical data, financial analysis, creating a pro forma, and projections. The physician needs to assess at the current volume of percutaneous procedures in each category that can be performed in the office, and anticipate what new procedures will be offered once the endovascular suite is opened. Each procedure has a different code and reimbursement that needs to be determined and incorporated into the business plan. A realistic expectation of growth based on the last 3 years of clinical practice should be determined. The capital expense and cost of disposable items and devices needs to be calculated and accounted for based upon the anticipated volume of patients. The largest expenses relate to the purchase of a building, capital equipment, cost of devices, and the cost of labor. If it is a new practice it may be advisable to build the practice prior to opening an office-based lab.

Building

The endovascular center needs to be in conjunction with the existing office space. A typical center is usually 2500 to 3500 square feet in area. The center will need the following areas: (1) a reception area, which can be combined with existing reception spaces; (2) a preoperative and recovery room with one or two reclining chairs for dialysis patients, and three to five beds for peripheral and venous procedures; (3) an endovascular suite that is lead lined, one or two depending on the anticipated patient volume; (4) a storage area for equipment and supplies; (5) a decontamination area; (6) a manager/coordinator's office; and (7) a nurses station.

Equipment

One of the biggest challenges facing the startup of the lab is financing. Most labs choose to buy the necessary equipment outright. However, many companies are willing to lease the capital equipment to the lab. Depending on the financial strength of the group, equipment can be procured in either manner. A list of equipment necessary for the endovascular suite and venous center can be found in Tables 198.2 and 198.3, respectively. For radiology equipment, another consideration is the choice between a C-arm and a fixed system, which depends on personal preference, types of cases anticipated, and the cost of the equipment. Currently available C-arms with vascular software provide adequate image quality for almost all procedures done in the office. One limitation is morbidly obese patients. C-arms have in increased risk of radiation to the patient, physician, and staff. Therefore, appropriate measures[50] should be taken to limit the radiation exposure.[51] Fixed systems may be better for renal intervention, procedures in morbidly obese patients, and carotid angiography. However, for dialysis-related cases a fixed system is harder to use because of positioning of the patient in relationship to the x-ray tube. It is better to buy new equipment rather than used or refurbished equipment, because the success of the center depends upon the functionality of these pieces of equipment. Purchase of equipment to perform ultrasound is highly recommended because ultrasound guidance for entering vessels during arterial and venous procedures is known to decrease complication rates. One of the complications of these procedures is postprocedure bleeding, and the most common cause for transfer to the hospital is bleeding after femoral artery catheterization. Thus, it is highly recommended that ultrasound be used to access arteries and veins,[52] but it is rarely required during fistulograms.

Supplies and Medications

Various supplies and medications are required for a functional endovascular center (Tables 198.4 and 198.5). The amount and brand of theses supplies to be stocked is at the discretion

of the endovascular center and the procedures that the center plans to perform.

Staffing

Acquiring new staff for the endovascular or venous center depends on the current number of staff members in the office. Some of the tasks, like scheduling, billing, and patient registration, can be performed by the current staff. The staff needed exclusively for the lab include a manager (if there is no business manager in the office), a registered nurse, a scrub technician, a radiology technician/medical assistant trained in using the C-arm, and another medical assistant to interact with patients

and carry out miscellaneous duties in the pre- and postprocedure area. If an anesthesiologist is providing sedation, they will have their own staff.

Electronic Health Record, Picture Archiving, and Communication System (PACS)

Data management in the office is currently being mandated by government and private insurance companies. It is important to have an electronic health record (EHR) and data management tool that can seamlessly interact. The data management tool should be able to provide patient demographics, risk factors, clinical findings, procedures performed, outcomes, and participate in a registry. For the functioning of the lab, the data management system should be able to track procedures, inventory, supplies used per procedure, clinical monitoring, image management, and billing. The clinical, business, and quality indicators have to work seamlessly. Total transparency is critical to the success of the lab; payers will need to see this data to reimburse for services provided by the office. Because there is no peer review for office-based procedures, payers are inherently suspicious of doctors performing unnecessary procedures. Only a strong data management program can help challenge that bias. All of the images produced during procedures need to be stored and archived for quality, follow-up, and legal requirements in a picture archiving and communication system (PACS). Ideally the data should be accessible from a remote site as well.

The EHR should have the following elements: (1) full history and physical exam including vascular exam, noninvasive vascular lab findings, indication for the procedure, pre- and postprocedure medications including antiplatelet drugs, anticoagulants, and statins; (2) procedure notes including site verification, type of anesthesia, vital signs during the procedure, the amount of radiation, and the amount of contrast; (3) equipment used including wires, catheters, balloons, stents, and other devices; (4) technical details of the procedure and medications administered; (5) a report should generate for the referring provider; and (6) documentation of follow-up visits/phone calls to document the outcomes of the procedure.

Biomedical and Electrical

There should be enough plugs and power to supply all electrical equipment in the room. Some devices may need a 220-V connection. There should also be an emergency generator. All equipment should be serviced at recommended intervals and have a sticker to identify the date of the last service. Portable oxygen should be available. A portable suction machine should also be available; wall suction is not required.

Accreditation

There are currently no organizations equipped to specifically accredit office-based endovascular centers. Various labs have received accreditation from different entities like The Joint Commission (JACHO), Accreditation Association for Ambulatory Health Care (AAAHC), and the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF). To ensure safe, effective, consistent, and comparable care at all office-based endovascular centers, an organization needs to be developed to specifically accredit these labs. Some of the principles used by the JACHO and other agencies could also apply in certifying these labs. All the procedures performed are percutaneous and no body cavities are opened. The procedures are very similar in nature and do not require elaborate, complex, or varied monitoring tools. In the accreditation process, none of these organizations look at indications and outcomes, which should be considered to ensure the safety and efficacy indicated by the accreditation. However, excessive regulatory burden will make office-based labs too difficult and expensive to operate, and thus oversight of these centers by a specific organization is essential.

Running a Center

Medical Records

With a good EHR, medical records should be completed in a timely manner. These records include history and physical, preoperative plan and discussion with the patient, informed consent, procedure notes, record of anesthesia, postprocedure recovery records, and follow up. By law, patients must have access to some part of their records via the Internet. Inaccurate medical records can result in poor or dangerous care of the patient and result in legal complications.

Policies and Procedures

The policy and procedures manual is the brain of your practice. It defines your best practices, and describes the conduct of the procedure and standard set by the lab to be followed for optimal outcomes. The policies need to be followed by staff and physicians alike. A clear definition and description of the procedures, equipment needed to carry out the procedure, and conduct of the procedure should be detailed in the manual. If there is a complication, there should be a plan established to manage each complication. This would include emergency protocols and transfer protocols. If there are state or accreditation body requirements, these will be defined in the manual and followed accordingly.

Coding Compliance

Overcoding and undercoding are both illegal under federal law. Every year there are changes in coding for office-based procedures. The lab should have a certified coder who remains updated with the various changes. Periodic audits performed internally or by a third party are highly recommended because the cost of inaccurate coding is significant.

Billing

Billing can be done internally or outsourced depending on the current practice of the office. If the billing is outsourced, it is critical to ensure the billing is done in a timely manner and there is appropriate follow-up with insurance companies and patients in case an insurance company requires more data to be submitted. The charges should be set in a reasonable manner keeping the Medicare allowable charges in mind. A policy should be established for dealing with overdue bills if there is precipitous drop in collection of bills greater than 90 days past due. If

preauthorization from the insurance company is required, it should be obtained before the procedure is performed; otherwise the insurance company will not pay and a potentially very dissatisfied patient will be left with a large bill. Because patients are more frequently required to provide copayments, the lab should take these into account when assessing cash flow.

Data Management

Data within a medical practice exists in many forms, including administrative and clinical records, which consist of both image and text files. A good EHR is crucial in providing quality care. There is need for software that can manage office notes, ultrasound and x-ray images, medications, inventory, billing outcomes, and be able to transmit data to a registry. The data should be contemporaneous, easy to access, and in a format that can be analyzed. Most of the commercially available generic EHRs are not suited to good data management, and thus there is a need for new carefully designed data management software.

Quality Control

To ensure the quality of the practice, data should be analyzed at regular intervals. There should be monthly meetings of physicians and staff to look at all untoward incidents and complications. Root cause analysis should be carried out for major or unexpected complications and appropriate measures should be taken to avoid them in the future.

The data should be compared to national results published in peer-reviewed journals. Indications for the procedure should be clearly delineated and should follow the published guidelines. If the lab is part of a registry,[53] data should be compared to other centers to make sure there are no significant deviations. Some states have regulations that require reporting of serious complications, unplanned transfer to the hospital, transmission of blood-borne pathogens, and any deaths that occur within 30 days of the procedure.

Outcome Measurement

Outcome measurement is important for marketing, quality control, and success of the practice. When establishing your practice, one can quote the results from the literature to patients while getting informed consent. As the practice matures, patients will want to know the results from your specific practice or with a specific physician. With appropriate data collection, the operators in the lab should be able to provide these results. Outcomes can only be measured if the patient has appropriate follow-up after the procedure. The best marketing tool you have is your results. If the lab is a part of a registry, outcomes can be compared internally between practice physicians and externally with other labs. Measurement of outcomes includes success of the procedure, complications, death, and long-term follow up. Different parameters may need to be measured for different procedures. These outcomes are well defined in the literature and should be comparable to the procedures being carried out in the hospital. One goal of the office-based lab should be to surpass the hospital outcomes because there is inherent efficiency in the office and nosocomial infections should not be part of the complications. The Vascular Quality Initiative under the auspices of the Society for Vascular Surgery has become an important tool in measuring outcomes in a hospital setting[53] and is currently being adapted to office-based endovascular labs.

Management of Complications

There are very few reports describing complications observed in the office-based setting. However, complications should be similar to those encountered in the hospital setting (Table 198.6). Due to limited resources, there should be written protocols to manage complications. In the most comprehensive report published,[6] the overall complication rate in 6458 procedures was 0.8%. The specific rates were: venous 2.2%; diagnostic aortogram 1%; arteriogram and intervention 2.7%; fistulogram 0.5%; catheters 0.3%; and venous filter related 2%. Twenty-six patients out of 2822 required hospital transfer and 10 patients needed an operation. As expected, operative site bleeding/hematoma was the most common reason to transfer the patient. There was no 30-day mortality rate related to the procedures. Oskui et al. also published data supporting the safety of these procedures in the office-based setting.[54] A protocol should be established concerning how serious complications will be handled. Specific personnel should be identified as responsible for calling 911 to enable patient transfer to the hospital. Ideally, the patient should be transferred to the hospital where the vascular surgeon has privileges. If a nonvascular surgeon is performing the procedure and the patient needs to be transferred, the interventionist should have an arrangement with the receiving hospital or a vascular surgeon to manage any complications. A written transfer agreement with the hospital is not required.

TABLE 198.6 Types of Complications Observed Following Endovascular Procedures

Access Site Complications	Target Site Complications	Anesthesia Complications	Cardiac Complications	Device Related Complications	Other Complications
Active Bleeding	Rupture	Hypoxia	Myocardial infarction	Retained wire	Syncope
Pseudoaneurysms	Dissection	Need to intubate	Arrhythmia	Broken catheter	Seizure
Hematoma	Occlusion			Catheter embolization	Renal failure
Closure of vessel	Thromboembolism			Stent migration

Marketing

Enjoy what you do and let the world know it is your passion. Marketing is not advertising; advertising is part of marketing. All marketing is local and the key to any marketing program is communication. There are various ways to communicate your message. The easiest and most cost-effective (free) method is to interact with local referring physicians. To market the vascular center, the center needs to know its own outcomes, strengths, and weaknesses. Great outcomes speak for themselves. Let consumers know your strengths and figure out a way to get rid of weaknesses. Data should be collected and shared appropriately with referring physicians and patients. The age-old teaching of availability, affability, and ability has stood the test of time. If a patient's dialysis access is clotted and you can take care of it "now," you will have a strong relationship with the nephrologist and the dialysis center. If you also thank the nephrologist, and the patient is dialyzed without missing a treatment, you have won the physician's confidence and referrals for a long time. With staff and patient turnover, the success of your practice relies on successful marketing. In other words, marketing is an ongoing process.

Marketing starts with you and your staff. If the patient and the referring physician have a good experience with you and your staff, they will become your ambassadors. The physician and the staff should dress professionally, act professionally, provide information in a brochure form and online, and be polite and accessible. The center should be clean and inviting, a place where patients would like to return.

Avenues for Marketing

Personal contacts: It is important to let referring physicians know what you do. You will be surprised how often they send you a patient but do not truly understand the variety of care you can provide. For the success of the center, key specialties to contact besides primary care are nephrologists, cardiologists, gynecologists, interventional radiologists, emergency room physicians, and podiatrists. In many hospitals, cardiologists and interventional radiologists do not perform peripheral arterial interventions, thus your center is the ideal place for these procedures to occur. Personal contact can be made by phone or in person. A brochure sent to the referring physician with information pertaining to the procedures done in the center is an inexpensive way of keeping physicians aware of your center's capabilities. The center could also create a newsletter for physicians, which would serve as a continual reminder of the care you provide. You can also educate physicians and patients, making your center an important part of the endovascular field in your area.

Local meetings: These meetings could be physician meetings, social meetings (i.e., rotary club), or patient-oriented meetings. You should be able to explain what you do. Most people do not know the basic premise of office-based procedures. You could also arrange educational meetings for physicians, other midlevel providers, and patients.

Print media: The local newspaper is always looking for articles about the latest advances in medicine. You could write an article or arrange for an interview regarding a new procedure you are offering. Advertising in print media is declining rapidly as the penetration of this media is on the decline. However, if a newspaper has a strong presence in your community, an advertisement may be worthwhile, although it likely has decreasing returns.

Audio and visual media: Advertising on radio is more cost effective than TV. If you have a venous center, this medium is crucial to its success. There are opportunities in every community where local radio and TV stations have a need for a medical segment. Approach these stations and offer your services to educate the public. If a new technology becomes available, arrange for an interview.

Internet: This medium continues to grow at the fastest pace. A comprehensive website is essential to any modern-day practice. It should include pertinent information about the center and educational material about the procedures you do. The site should be regularly assessed for accuracy and updated as the medical information evolves. There are various social media outlets that can be used for advertising. It is best to work with marketing people who understand this medium.

Research: Not every practice wants to participate in research. If you know your data and you are doing clinical research, you can publish it. The data you publish can be shared with your referral base. This builds trust and confidence in your abilities. Currently there is very little data in the published literature about office-based endovascular procedures, thus the field needs data and is willing to support genuine research efforts.

If you decide to advertise, you need to follow certain guidelines as advocated by the American Medical Association (AMA) code of medical ethics, opinion 5.02. Be careful to abide by federal regulatory standards that apply to commercial advertising, and make only objective and factually supportable claims about experience, competence, and quality. Avoid aggressive high-pressure tactics and refrain from using testimonials that do not reflect typical patient outcomes. Be careful when claiming to have treated a particular ailment successfully in a large number of cases, because this can imply a certainty of results or create unjustified patient expectations. Finally, eschew claims of unique medical skills unless this is true for a particular geographic area.

Radiation

Radiation safety[51,55] is an important part of all the safety measures undertaken in the office-based lab. Appropriate precautions need to be taken to minimize exposure of the patient, operator, and staff in the room. This includes appropriate lead shielding as required for the room and that all personnel need to wear appropriate lead-lined aprons, thyroid shield, head cover, and lead-lined glasses. Everyone should pass a radiation safety test every 2 years and records should be maintained. Radiation badges should be worn and checked at regular intervals. For younger members of the team, the potential cumulative dose over a lifetime should be assessed and managed.

Patient Satisfaction

It is paramount for the success of these centers to have a very high satisfaction rate, because this impacts the patient return rates. In a patient satisfaction survey administered in an office-based laboratory, two questions were asked: (1) were they satisfied and (2) will they return to the office if another procedure is needed; in these surveys the patient satisfaction rate was 98% to 99%.[4,6] There are many reasons patients cited for being highly satisfied. They see the same staff every time, there is no hospital maze to navigate, no hospital registration, no preprocedure workup in most patients, the time spent in the center is significantly less than in the hospital, access is easier for the patient, and the results are comparable to a hospital-based procedure. The main reason patients may not be satisfied is occasional poor pain control in the office-based setting if conscious sedation is not used judiciously. There are currently no standard surveys available that assess patient satisfaction in these centers. An example of a patient satisfaction survey can be found in Box 198.1.

Evaluation of the Center by Physicians

A quarterly evaluation of marketing efforts, screening programs, outcomes, complications, rates of hospital transfer, and financial data should be performed by the physicians in the group. At these meetings, the minutes should be documented and maintained. In case of a sentinel event, an emergency meeting of all parties concerned, including the medical director of the center, should occur. If the center is failing to meet its own goals, root cause analysis should be conducted and any appropriate actions should be taken. A quarterly profit/loss report is crucial for the financial viability of the center. As new devices come to the market, a cost analysis should be completed before procuring the device for the center. Processes should be streamlined to enhance the effectiveness of the center. Various operators should have a consensus about device use to minimize the number of products on the shelf. Finally, the center should not offer inferior care as compared to the community standard based on cost.

BOX 198.1 Sample Patient Satisfaction Survey

Using the number scale described below, please circle the appropriate number to indicate your agreement with each statement:
1. Highly disagree
2. Moderately disagree
3. Agree
4. Moderately agree
5. Highly agree

Were you satisfied with our care?
1 2 3 4 5
If you need another procedure will you come back to our office?
1 2 3 4 5
Have you had a similar procedure in the hospital?
Yes No
If yes, where will you prefer to have your next procedure?
Hospital Office
If not in the hospital, what are the reasons?
Poor pain control
Did not feel safe
Staff was not competent
Other reason:_____

Future

The future of outpatient office-based endovascular labs is bright. As healthcare payers continue to demand efficiency and institute a value-based payment system, office-based care will have an increased demand because it has proven to be safe, cost effective, and patient friendly. In the future, payments to physicians will be made under the Medicare Access and Children's Health Insurance Program (CHIP) Reauthorization Act, Public law No. 114-10 Act (MACRA). Starting in 2019, physician payment will be provided through a new merit-based incentive payment system (MIPS). An increasing number of patients are demanding outpatient services as demonstrated by the success of ASCs providing endoscopy, plastic, and ophthalmology services. However, there is a paucity of data supporting the efficient use of outpatient vascular centers. As more data becomes available, the value of these centers will be recognized by patients and payers alike, making these centers the preferred location for treatment of peripheral vascular disease.

ACKNOWLEDGMENT

The authors thank John Munn MD, Mark Rummel MD, Dan Johnston MD, Syed Alam MD, and staff for all the work they do in the office-based vascular center, Chris Longton RN for providing business management of the center, Laura Bauler PhD for her help with the manuscript, and Jeff Smith Esq. for legal guidance.

INTRODUCTION

Registries contain troves of information, generally collected in the course of routine clinical practice. The usefulness or value of that information depends on many issues but primarily whether it is used for a purpose consistent with the intent of the registry and whether the registry data are regarded as valid. This chapter will summarize the characteristics of registries, and examine how they might—or might not—add value to the practice of vascular surgery. A comprehensive review of medical registries is also available.[1]

WHAT IS THE DEFINITION OF A MEDICAL REGISTRY?

Although most practitioners intuitively understand the concept, it is useful to unambiguously define a medical registry. Some have applied the term to almost any database that collects information about patients or clinical events. However, there are specific characteristics that make a collected data set a true registry. The most useful definition was advanced by Solomon in 1991 and subsequently subscribed by many others:

> *A systematic collection of a clearly defined set of health and demographic data for patients with specific health characteristics, held in a central database for a predefined purpose.*[2,3]

Understanding the predefined purpose of the registry is paramount, as this will govern downstream decisions about which data should be collected.[4] Others have termed this predefined purpose as the *Inclusion Principle*—or the defining feature of the registry and the information it collects. In other words, what characteristic(s) of a patient or medical event qualifies it for registry inclusion?[5]

One way of operationalizing this definition has been termed the **MDR-OK** model:[5]

Mergeable data facilitates aggregation of information submitted from various individual sources that can be combined into a larger, more representative, data set.

Data set standardization means that the same characteristics are collected on every patient or case included in the registry. The predefined purpose of the registry will inform the process

Abstract

Registries can vary widely in scope and content but generally reflect collections of "real-world" clinical data accumulated in the course of routine care. Thus, registry data differ from that collected by randomized controlled trials in important ways. Although possibly less accurate or robust in terms of consistency and accuracy, registry data are arguably generalizable to more patients than conclusions drawn from randomized controlled trials. This chapter reviews the characteristics of registries, highlights advantages vs disadvantages and discusses the role registry data can play in improving the quality of vascular surgical care.

of selecting the characteristics to be collected for later analysis. Adherence to collecting a clearly defined standardized data set should reduce the subsequent problem of missing information during analyses. Completeness of data collection is a key factor in determining the quality or external validity of a registry.

Rules for data collection provide guidelines for translating raw source data into definitions established by the registry. These guidelines are typically contained in a protocol and data dictionary developed during conception of the registry. Observance of these rules will ensure that data in the registry are reproducible and consistent, even if collected by different people at different times in different locations about different patients or events. The degree to which these rules are complied with affects the consistency of a registry which is a measure of internal validity. Examples of this process are mapping blood pressure information into a registry data element such as "Hypertension" or creatinine values into a data element termed "Renal Insufficiency."

The aforementioned characteristics are fundamental to a **M**edical **D**ata **R**egistry. Several additional features may enhance the value of a registry:

Observation over time means that a registry collects longitudinal patient data, which are then linked to the initial patient record.

Knowledge of outcomes may allow a registry to indicate which characteristics collected as part of the initial registry record are more or less likely to lead to a particular clinical outcome. It is important to recognize that the outcome in question must be as carefully defined and standardized as any of the initial data elements. Outcomes assessment may be determined actively (by their specific addition to the registry by its participants) or passively (by linkage to administrative data). An example of the latter is tracking vital status by using a common identifier such as a social security number to link the initial registry record with the Social Security Death Index.

The diversity of medical registries arises from the various reasons or predefined purposes for their existence. Registries have been generally categorized according to their inclusion principle, their intended function, or both.[6] Categories based on the inclusion principle might be disease-based, procedure- or therapy-based, or population-based. A more functional classification would be research, quality measurement, or quality improvement. A single registry might be classified under multiple schemes. For instance, a disease- or population-based registry might primarily exist to facilitate clinical research, while a procedure-based registry might be used to measure and improve quality. Other registries—often operated by regulatory agencies—exist for purposes of public reporting.

WHY DO REGISTRIES EXIST?

Like virtually all physicians, vascular surgeons strive to provide the best outcomes for their patients. To do this, information is needed about which procedures or treatments work best for which patients at which times. It is an axiom of quality improvement that "you can't improve what you don't measure." Registries measure activities that occur during routine clinical care, as opposed to information derived from randomized clinical trials,

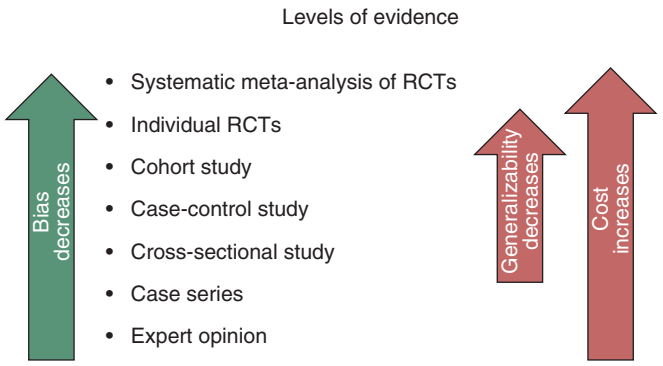

Figure 199.1 Relationship of bias in medical evidence relative to generalizability and cost. *RCT,* Randomized controlled trials.

which are in reality experiments designed to answer specific questions or test explicitly stated hypotheses.

Further, in recent years, many payers have restricted the use of new or evolving technology unless the results of these procedures are followed carefully in registries.[7,8] The FDA is also exploring use of medical registries for purposes of postapproval device surveillance.[9]

There is a well-recognized hierarchy of medical evidence based primarily on whether the conclusion delivered by a particular type of study is felt to be biased (Fig. 199.1).[10,11] Systematic meta-analyses of related randomized controlled trials (RCTs) are regarded as the highest quality evidence followed by individual RCTs themselves. Randomization is the feature that minimizes bias introduced by known and unknown confounders. *Internal validity* refers to the confidence that a study's results are free from bias and therefore more likely to reflect a true difference between the comparison groups.[1] However, randomization also requires that true uncertainty exist in the minds of the investigators and participants as to the superiority of one treatment assignment—a concept known as clinical equipoise. Well-designed and run RCTs also tend to have highly developed protocols that precisely define data elements and study outcomes, as well as a schedule of study visits that optimize data collection and outcome ascertainment. The high regard for results produced by RCTs owes primarily to randomization but also to their highly structured, reliable study protocols.

However, RCTs have numerous drawbacks. Randomization is unethical in situations where clinical equipoise does not exist, no matter how valuable or useful the answer might be. The highly restrictive inclusion/exclusion criteria of RCTs may raise questions about whether the results apply to the broader population of patients seen in routine clinical practice. The degree to which a study's conclusions can be generalized to a broader population is termed *external validity*.[1] Finally, the elaborate structure that makes RCTs valuable also makes them expensive—too expensive to use to answer every clinical question of interest. Because RCTs tend to be mounted to answer a focused question, their infrastructure is typically not preserved or recycled to answer additional or subsequent related questions.

The disadvantages of RCTs create the niche and rationale for medical registries. Randomization is not a prerequisite for

enrollment, so there are rarely ethical objections. Maintaining confidentiality of protected health information (PHI) is usually the major concern with registries. Systematic and broad registration of patients or events according to the predefined inclusion principle should make registry-based results more generalizable to everyday patients and minimize selection bias. The large case volume accumulated by many registries allows detection of relatively low-frequency events that are unlikely to be recognized in an RCT. Broad participation also facilitates benchmarking, which is the comparison of an individual or group's performance to the average performance (or best performance) of another. Benchmarking is a purpose typically not fulfilled by RCTs.

Highly structured protocols and elaborate infrastructure do not have to be features exclusive to RCTs, but they do tend to increase the expense of creating, running, and participating in a registry. On the other hand, registries are typically intended to last for many years, and may serve as platforms for multiple studies, making them more economical in the long term.

WHAT DETERMINES THE VALUE OF A REGISTRY?

The quality of data collected and maintained by a registry is the greatest determinant of that registry's value.[4] Registry data quality has been defined as the "totality of features and characteristics of a data set that bear on its ability to satisfy the needs that result from the intended use of the data." Two major attributes of registry data quality are recognized: **completeness** and **accuracy**.[3]

Completeness is a measure of the extent to which all data eligible for registry entry have actually been included. Since one of the major advantages of registries are their increased representativeness or broad inclusion of relevant cases, any concern that a registry's data is not inclusive or representative will lower its value and raise questions of selection bias. Lack of completeness is a threat to a registry's external validity or generalizability. These issues may be more likely to affect procedure-based as opposed to disease-based registries, as well as those that depend on self-reported data as opposed to data entry by a third party or automatic process.[12] Lack of completeness would severely compromise the value of a registry established for the purpose of public reporting. Another issue that may affect a registry's external validity is cost of participation. If cost becomes a barrier to participation, data that are entered into the registry may be less representative, again raising the possibility of selection bias.[12]

Accuracy refers to the degree to which registered data conform to reality, or a predetermined gold standard.[3] Flaws in data accuracy will primarily affect a registry's internal validity or confidence that conclusions based on registered information are free from bias or error.

A registry can increase its internal and external validity by establishing user-friendly data-handling processes (ease of entry, clear dictionaries and help text, etc.) in the design of the registry, as well as quality control measures that assess data accuracy after the entry (some form of auditing).[3,4,13] An appropriately focused auditing strategy or policy should be a feature of all high-quality registries. The nature and scale of the audit should be consistent with the registry's purpose and will ideally test for both completeness and accuracy.

Concerns about validity pertain to all types of registries, whether they exist primarily for research or other clinical purposes. For instance, a registry's signal about poor clinical outcomes may be dismissed if there is suspicion that the underlying data are suspect.[14]

There is also a tension between registry complexity and both internal and external validity. Typically the more complex registries will collect and contain more clinical information, theoretically increasing their value since they can analyze the relationship of more clinical characteristics with outcomes than registries that contain simpler data sets. A hierarchy of data for arthroplasty registries has been described that can be extrapolated to other clinical, procedure-based registries.[15]

- Level 1—Simple demographics, date of procedure, dx, type of procedure, medical device info, surgeon and hospital identifier
- Level II—Patient clinical characteristics, surgical technique, intraoperative events/processes
- Level III—PROs, clinical or functional outcomes, economic data
- Level IV—Radiographic assessments (possibly by a central imaging core)

Obviously a registry collecting Level III or IV information will have much richer data and be able to address a wider variety of clinical questions than a registry that only contains Level I information. At first glance, it may appear to deliver greater value. However, a complex registry that strives to collect detailed information but sacrifices representativeness or has quality issues because of complicated or confusing data entry processes may ultimately not be as useful as a simpler registry. In general, a registry should be no more complex than necessary to meet its stated purpose.

At inception and throughout its life cycle, a registry must address and balance multiple issues that create tension between its value and validity. Although registries are not typically as costly as RCTs, they are frequently not subsidized or externally funded. Thus even a relatively low-cost registry may be very expensive for some centers or groups.

WHERE DO REGISTRIES FIT AS MEDICAL EVIDENCE?

As mentioned earlier, there is a hierarchy of medical evidence ranging from systematic reviews of randomized controlled trials regarded as the most authoritative to isolated case reports regarded as least authoritative. RCTs are so highly regarded because they are prospectively designed as focused clinical experiments and the randomization allocation minimizes the possibility that the trial outcomes will be affected by confounding influences. However, RCTs cannot address every issue for which we need data to help guide clinical decision-making.

TABLE 199.1 Types of Registry-Based Studies

Study Design	Level of Evidence (for a Registry Study)	Sample Selection	Advantages	Disadvantages
COHORT	High	An "exposure" defines the cohort, which is then followed prospectively for an "outcome" of interest	Temporal relationship between "exposure" and "outcome" established	Bias still possible but largely related to the structure of the registry
CASE-CONTROL	Medium	An "outcome" defines the cohort of cases. Controls are matched to cases based on prespecified matching criteria.	Useful to study possible exposures associated with rare outcomes	No temporal relationship established between exposure and outcome; selection bias possible when selecting matching criteria for controls
CROSS-SECTIONAL	Low	Inclusion of a subject in the sample determined by existence of either the exposure or the outcome	Can establish prevalence of a practice/condition or the mere coexistence of the exposure and outcome	No temporal relationship established

While data from registries do not represent the highest level of evidence, they do provide valuable information that cannot be obtained from any other source. There are essentially three types of studies that leverage registry data (Table 199.1).[15] The highest level registry-based study is the cohort analysis. A cohort study selects its sample prospectively based on an exposure of interest (also known as the independent variable) and then follows that sample over time to detect an outcome of interest (dependent variable). Cohort studies establish a temporal relationship between the exposure and outcome, and results are typically described in terms of a survival analysis, such as a Kaplan-Meier curve.

Case-control studies use registry data to identify patients who have a particular outcome of interest (cases) and then look for characteristics associated with that outcome by assembling a control cohort that resembles the cases based on prespecified matching criteria. Properly done, large case-control studies use already collected registry data to provide important information not available through any other method. The case-control study does not establish a temporal relationship between possible risk factors and the outcome, and the matching process is a possible source of bias.

Registries can also provide prevalence information through cross-sectional studies in which an exposure and outcome are determined simultaneously. An example would be an analysis of the proportion of AAA treated with endovascular repair at any given time.

Differences between registry data and those collected in the course of a randomized controlled trial are important to recognize.[4] First, subject enrollment into a trial is typically strictly controlled occurring only after stringent assessment of carefully defined, prospectively applied inclusion and exclusion criteria. Enrollment criteria for registry entry are usually not so strict (giving registries a "real-world" flavor), but then the possibility that ineligible subjects are included may corrupt the relationship between a particular characteristic and outcome. Also, treatment allocation in a registry is almost never random, so the factors governing the choice of one type of treatment over another are frequently unknown.

Because participants in randomized trials are so valuable, follow-up for adverse events and clinical outcomes is typically active and aggressive. This type of information may only find its way into registries passively and can produce problems with missing data in terms of outcomes of interest. For that matter, outcome ascertainment in a formal trial is frequently blinded to the treatment allocation but not necessarily so in a registry. When an outcome of interest such as mortality is definitive and not open to interpretation, linkage to administrative databases may alleviate this problem. For less definitive outcomes, the possibility of ascertainment bias remains a significant issue in registries.

Because registry data are often affected by various confounders (e.g., selection bias, ascertainment bias, inconsistent treatment protocols and others that may not be recognized), data analysis can be complicated. Numerous statistical methods to account for known confounding have been developed, including adjustment techniques, regression analysis, instrumental variable analysis, and various types of propensity-matching.[15]

For the clinician evaluating a registry-based article, a standardized approach can be useful, as outlined here.[4]

1. Generalizability. Are the enrollment criteria clearly specified? If so, are the registry patients similar to my patients?
2. Relevance. Is the purpose of the registry clearly stated, and are the data pertinent to the question being posed?
3. Quality. Does the registry have procedures in place to assess the accuracy and completeness of its data? This information is typically found in a publication describing the registry and its operation, frequently cited in the Methods section.
4. Meaningful outcomes. How objective are the criteria used to define the outcome of interest? Were outcomes determined systematically? This is especially important if a comparison group is included. There should be an equal opportunity or likelihood to identify the outcome in the comparison group.

5. Follow-up. This property is closely related to the previous question. Poor or inconsistent follow-up will result in many cases of missing data.
6. Characterization of the comparison group. Cohort and case-control registry studies compare outcomes between different groups of subjects. It is important to understand whether these groups are different in ways besides the defined exposure variable. This is typically the area where many of the more sophisticated statistical and analytic techniques are applied, because the subjects were not assigned to the case or control groups randomly.

A *randomized registry trial* is an effort to leverage the existing infrastructure of high-quality registries and still gain the powerful advantages of randomization.[16] A randomized registry trial is a clinical experiment targeting a specific question conducted within the context of a registry, thus avoiding the time-consuming and expensive task of creating the infrastructure necessary to answer the question. During a randomized registry trial, a "randomization module" unique to the question at hand is applied at the time of registry entry. Randomized registry trials still require informed consent and equipoise regarding the risks or benefits to the patient of allocation to one group or the other.

Probably the best example of a randomized registry trial is the TASTE (Thrombus Aspiration in ST Elevation MI) study performed in Scandinavia.[17,18] This study randomized patients experiencing STEMI to a specific attempt at thrombus aspiration during percutaneous coronary intervention (PCI) versus standard PCI alone. Enrollment was relatively straightforward, since STEMI patients in Scandinavia are typically entered into the Swedish Web System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapies (SWEDEHEART), a well-developed registry. Following informed consent, patients were randomly allocated to thrombus aspiration or standard PCI. The outcome was "hard" (mortality at 30 days) and ascertained by querying SWEDEHEART. Most patients agreed to participate, and the incremental cost of enrolling a patient in the TASTE study, as opposed to just the underlying registry, was $50.[18] Thrombus aspiration was found not to provide a survival advantage, compared with standard PCI for STEMI.[17]

Existing Vascular Surgery Registries (Table 199.2)

Vascular Quality Initiative

The Vascular Quality Initiative (VQI) sponsored and administered by the Society for Vascular Surgery (SVS) is the largest vascular-focused registry family in the United States, with more than 370 participating centers, more than 2500 providers from multiple specialties, and nearly 300,000 cases entered in 12 distinct procedure-related registries as of June 2016 (Fig. 199.2). The purpose of the VQI registries is to provide information regarding indications, patient characteristics, procedure performance, and clinical outcomes that will support quality improvement efforts.[19] The participating centers are also organized into 17 regional groups, most of which have in-person semiannual meetings to facilitate more informal sharing of best practices and lessons learned (see Fig. 199.2).[20]

The SVS VQI is organized as a Patient Safety Organization (PSO), which is a legal entity defined by the Patient Safety Act of 2005. As long as it meets certain statutory requirements concerning confidentiality and operates according the rules specified by the Patient Safety Act, institutions participating in the PSO can transmit PHI to the registry without obtaining informed consent. By law, a PSO's primary purpose must be quality improvement, so there are also provisions in the Patient Safety Act that promote transparent reporting of adverse outcomes and prevent use of the data for disciplinary or corrective action. Thus information regarding clinical outcomes and processes of care—also termed Patient Safety Work Product—can only be publicly distributed in de-identified fashion. Public comparison of performances between identified centers or providers is also prohibited.

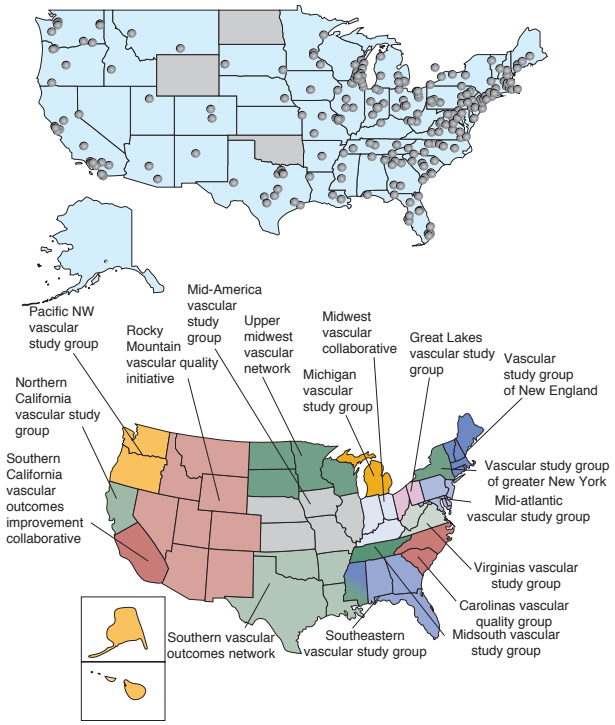
VQI participants enter clinical data into a commercially operated web-based data platform. The method of data collection is not prescribed, allowing flexibility in workflows that can be tailored to each individual center. Thus some centers have providers enter data at the point of care, others rely on employed data coordinators, and some use commercial data abstraction services.

As mentioned earlier, completeness of case capture and accuracy are the key determinants of registry validity. The VQI requires that all cases eligible for registry entry be submitted—a

TABLE 199.2 Vascular Registries

Registry NSQIP	Sponsor	Strengths	Limitations
VQI	Society for Vascular Surgery	100% data collection, extensive procedural detail, 1-year follow-up	Cost, data completeness, complexity
NSQIP	American College of Surgeons	Systematic data collection approach; rigorous auditing	Limited clinical detail, sampling, limited long-term follow-up
Vascunet	European Society for Vascular Surgery	Multitude of countries and regions represented	Heterogeneous data input policies and completeness
National Cardiovascular Data Registry	American College of Cardiology	Extensive detail on peripheral vascular intervention, multidisciplinary	Limited detail on non-PVI procedures

NSQIP, National Surgical Quality Improvement Program.



Total procedures captured (as of 6/1/2016)	298,303
Peripheral vascular intervention	93,996
Carotid endarterectomy	68,466
Infra-inguinal bypass	30,947
Endovascular AAA repair	27,326
Hemodialysis access	25,450
Carotid artery stent	11,183
Supra-inguinal bypass	10,508
Open AAA repair	8,322
Thoracic and complex EVAR	6,426
IVC filter	5,541
Leg amputations	5,399
Varicose vein	4,739

Figure 199.2 Status of the Society for Vascular Surgery Patient Safety Organization as of June 2016. There were 379 participating centers from 46 states and the Canadian province of Ontario organized into 17 regional quality groups. *EVAR,* Endovascular aneurysm repair.

process that is audited by the review of claims records. The lack of a requirement for individual patient-informed consent also facilitates completeness of case capture. The VQI does not systematically audit a random sample of records for accuracy of specific data, but rather uses statistically targeted auditing. According to this policy, centers or specific case records may be audited based on their apparent outlier status, depending on the analysis.

Another important distinctive of the VQI is a requirement for follow-up of outcomes approximately 1 year after the procedure. While this requirement significantly raises the effort necessary to participate in the VQI (increased complexity), the registry can thus provide information about which patients undergoing vascular intervention are most likely to have sustained benefit (as opposed to simply surviving the perioperative period). Since many vascular procedures are performed for preventive (e.g., asymptomatic carotid stenosis or intact AAA) or lifestyle (e.g., claudication) indications, knowing which patients are likely to survive long enough to benefit from the intervention is critical information during preoperative decision-making.

American College of Surgeons National Surgical Quality Improvement Program

The National Surgical Quality Improvement Program (NSQIP) is operated by the American College of Surgeons (ACS) and is patterned after the earlier Veterans Administration Surgical Quality Improvement Program (VASQIP).[21-23] In its current form, it offers several options for participation, depending on the size of the hospital and associated resources for data collection. NSQIP contains a procedure-targeted vascular module.[24] Under this option, a hospital collects 100% of procedures performed defined by a specific subset of vascular CPT codes. Procedure data are abstracted by trained personnel who are periodically audited by NSQIP. A number of procedure-relevant outcomes are captured, but follow-up is limited to 30 days after surgery.

National Veterans Administration Surgical Quality Improvement Program

This registry served as the prototype for the American College of Surgeons National Surgical Quality Improvement Program mentioned previously.[21] The two programs function very similarly, except that this program is restricted to United States Veterans Administration hospitals.

Vascunet

Vascunet is a collection of international registries (or audits) organized by the European Society for Vascular Surgery.[25,26] The participating countries are Australia, Denmark, Finland, Germany, Hungary, Iceland, Italy, New Zealand, Norway, Spain, Sweden, Switzerland, and the United Kingdom. Each country operates its own registry, which can vary in types of procedures and data elements collected, as well as length of follow-up. Case registration is not always mandatory.

For the Scandinavian registries, vital status and relatively long-term follow-up can be obtained through linkage with national administrative databases. Although not comprehensive nor covering all countries participating in Vascunet, formal auditing for data capture and consistency have been performed in Hungary[27] and Sweden[28] with acceptable results.

For some registries reporting is mandatory, and for others it is voluntary. In the United Kingdom, reporting is mandatory and data are collected for the purposes of public reporting of outcomes following AAA, carotid endarterectomy (CEA), and lower extremity procedures. Public reports for both hospitals and individual consultant surgeons are released.[29]

The Vascunet collaboration has published several articles describing variation in indications and outcomes for AAA,[30,31] popliteal aneurysm,[32] infrainguinal bypass surgery,[33] and CEA.[34,35] Other reports have highlighted the challenges of reconciling and harmonizing data from numerous national registries in order to properly leverage the large numbers of cases that can be pooled by such collaborations.[36]

National Cardiovascular Data Registry

The National Cardiovascular Data Registry (NCDR) administered by the American College of Cardiology operates a suite of registries mostly focused on cardiac procedures. In 2014, the NCDR launched its PVI Registry to collect lower extremity arterial catheter-based interventions, carotid stent, and endarterectomy procedures.[37]

ROLE OF MEDICAL REGISTRIES IN QUALITY IMPROVEMENT

Most registries established for QI purposes (VQI, ACS-NSQIP, VASQIP) return information to their participants in the form of benchmarking (crude and risk-adjusted). ACS-NSQIP and VQI also make available de-identified data sets that allow focused QI research into a particular topic. VQI also facilitates customized querying of an individual site's own data through an online analytics engine incorporated into the web-based data entry platform.

Within the context of the SVS VQI, information from the registries serves as the substrate for separate and distinct quality improvement efforts. The VQI is governed by its participants, who commission the Patient Safety Organization (owned and operated by the SVS) to analyze the registry data in order to uncover variations in practice performance and clinical outcomes in order to identify opportunities to improve vascular care. The VQI communicates these findings to its participants in the form of Center Opportunity Profile for Improvement (COPI) reports, along with other report formats informing individual providers of their performance in selected areas, such as smoking cessation counseling or prescription of antiplatelet/statin medication at discharge.

An individual COPI report focuses on a particular clinical issue or outcome such as surgical site infection (SSI) after lower extremity bypass or stroke/death following carotid intervention. A multivariable model predicting the outcome of interest is developed based on nationwide data from the relevant VQI registry. This multivariable model is then used to predict the likelihood of the outcome occurring for a given center, which is then compared with the observed frequency of the outcome at that center, in the form of an observed/expected (O/E) ratio. Individualized feedback to participating centers is then provided, along with information regarding the rates of risk factors or clinical characteristics associated with the outcome of interest. When these risk factors or clinical characteristics are modifiable, the center could potentially improve its performance through attention to these particular factors through a change in process of care. For other risk factors that may not be modifiable (e.g., patient co-morbidities), knowledge of these characteristics could assist in optimizing patient selection for a particular procedure or making the informed consent process more relevant for an individual patient.

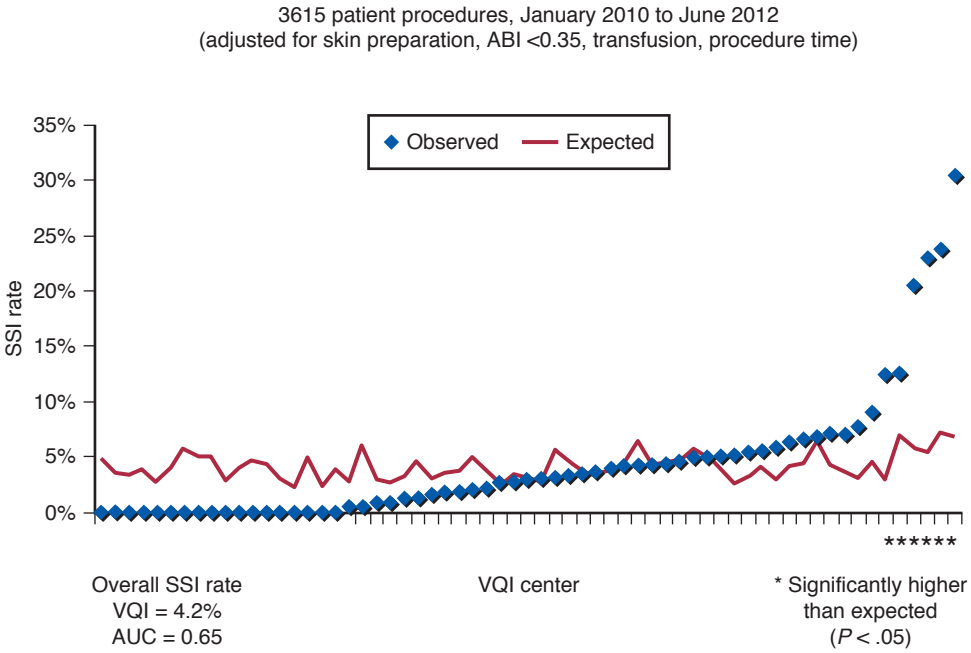
The impact of the VQI COPI report for SSI after lower extremity bypass is presented as an example.[38] SSI is an outcome of interest following lower extremity bypass and is specifically captured by VQI at the time of discharge after the index procedure. Significant variation in the occurrence of SSI was noted, ranging from 0% to 30% (Fig. 199.3). The multivariable model identified low ABI, increased operative time, transfusions, and use of a nonchlorhexidine skin preparation agent as risk factors for SSI; the latter three are potentially modifiable process measures (Fig. 199.4). The COPI report for each center participating in the lower extremity bypass registry reported that center's O/E ratio for SSI and whether the O/E ratio was significantly different. Each center also received information about the prevalence of pertinent risk factors for SSI specific to their patients (see Fig. 199.4).

Following the release of the SSI COPI report, there was a significant increase in use of chlorhexidine for skin preparation, a reduction in transfusions, and reduced operating time. There was a trend toward reduced SSI, which was not statistically significant nationwide. However, there was a statistically significant decline in SSI among centers that had the greatest increase in chlorhexidine usage (Fig. 199.5).

The VQI has released other COPI reports focusing on length of stay (LOS) after elective CEA and endovascular aneurysm repair (EVAR), with corresponding reductions in LOS among participating centers (Fig. 199.6).

The initial experience with VASQIP showed a relatively dramatic improvement in surgical quality (27% and 45% reductions in 30-day mortality and major morbidity, respectively) within the VA system, coinciding with delivery of individualized feedback regarding outcomes.[39] It is very common to see reports of improved quality connected to registry participation.[12] However, these reports typically are not controlled for secular trends in overall improvement in care, and the observed quality improvement may not be a direct result of registry participation.

There is now increasing recognition that simply providing information about a center's performance may not result in consistently improved performance.[14] Two recent reports that did control for an overall secular improvement in care indicated that the rate of improvement in mortality or major morbidity among centers participating in NSQIP did not exceed the observed rate of improvement in the same outcomes among centers that did not participate in NSQIP.[40,41] The current interpretation of these potentially sobering reports is that some form of organized quality improvement process must be implemented in response to the data to truly drive improved performance.[14,42] Such QI processes may take the form of Plan-Do-Study-Act (PDSA)



Variable	*OR*	*95% CI*	*P*
ABI <0.35	1.54	1.03–2.30	<.04
Procedure time >220 minutes	2.11	1.05–4.23	<.04
Transfusion >2 units pRBCs	3.30	2.17–5.02	<.001
Chlorhexidine w / wo alcohol prep	0.53	0.35–0.79	.002

ABI, ankle-brachial index; *CI*, confidence interval; *OR*, odds ratio; *pRBCs*, packed red blood cells; *w/wo*, with or without.

Figure 199.3 Variation in surgical site infection *(SSI)* following lower extremity bypass in individual vascular quality initiative *(VQI)* centers between January 2010 and June 2012. Rates of SSI ranged from 0% to 30%. Six centers were statistical outliers with high O/E ratios *(asterisks)*. cycles, LEAN, or Six Sigma programs operating at the local center level. So while robust reliable data, often collected through a registry, is **necessary** for quality improvement, it may not be **sufficient**.[14]

PUBLIC REPORTING OF REGISTRY DATA

There is a strong presumption that the public has a right to information about surgical quality performance in order to make the most informed choices regarding where to obtain healthcare. To this end, public reporting of surgical outcomes may be desirable. On the other hand, there is concern that public access to quality performance information will reduce the willingness of providers and centers to be forthright when discussing adverse events, thereby compromising quality improvement efforts that are widely believed to be enhanced by assurances of confidentiality.[43]

When evaluating a registry, it is important to know whether the data are used for public reporting, as there may be conditions applied to the collection and reporting of the data that will affect its validity and the overall confidence in the data. Information about how outliers are identified and confirmed should be available to both participants and consumers of the information. At a minimum, reports of mortality and morbidity should be risk-adjusted so that hospitals and providers caring for sicker, more complex patients are not unfairly labeled as subpar because of the expected higher incidence of adverse outcomes occurring in this higher risk population.

Two prominent examples of public reporting of cardiovascular outcomes are the New York State Cardiac Registries[44] and the Vascular Services Quality Improvement Program (VSQIP) in the United Kingdom, covering AAA, CEA, and lower extremity PAD procedures.[45,46] Registration of all eligible patients is mandatory in both programs and both programs report both hospital-specific and surgeon-specific risk-adjusted outcomes.

COPI	VQI wound infection rate			3.6%	SVS PSO
	Center name				
	Your center's number of procedures			21	
	Your center's wound infection rate			28.6%	
	Your center's wound infection expected rate			5.9%	
	Observed rate vs. expected rate			Rates significantly different $P < .01$	
	Predictors of wound infection			**Your center**	
VQI Average	Chlorhexidine skin prep **60%**	Transfusion ≥3 units **5.8%**	Procedure time >220 minutes **50%**	Improvement opportunity	
	Higher is better	**Lower is better**	**Lower is better**		
Your center	57%	33%	71%	Significantly higher infection rate than expected. Switch to chlorhexidine. Reduce number of transfusions.	

Note: This patient safety work product generated within the SVS PSO,LLC, is considered privileged and confidential.

Figure 199.4 Example of Center Opportunity Profile for Improvement *(COPI)* report regarding surgical site infection (SSI) after lower extremity bypass to a fictional vascular quality initiative *(VQI)* center. In this center's case, the observed (28.6%) to expected (5.9%) SSI rate is statistically high ($P < .01$). Increasing chlorhexidine use, reducing transfusions, and shortening procedure times represent opportunities for changes in the process of care that would be predicted to lower future SSI rates. *SVS PSO,* Society for Vascular Surgery Patient Safety Organization. (Courtesy of Society for Vascular Surgery Patient Safety Organization.)

Following the onset of public reporting, risk-adjusted cardiac surgery mortality in New York fell 41%.[44] In an attempt to determine if public reporting in New York was associated with a differential impact on mortality, comparison with other states who did not publicly report outcomes showed that New York's outcomes were significantly better, with a calculated odds ratio for short-term mortality of 0.66.[44] There is some controversy as to whether public reporting has produced risk aversion (thus potentially denying high-risk patients needed care) among New York hospitals and surgeons; data have been published supporting both sides of the issue.[44]

Similar concerns have been raised in the United Kingdom, and Karthikesalingam et al.[46] have advanced strong arguments specifically against surgeon-specific outcomes reporting. Important points include the fact that case numbers for individual surgeons are much lower than hospital-specific numbers, leading to greater statistical uncertainty. Also, they note the possibility of risk aversion and unfair attribution of any particular patient's death to an individual surgeon in an era where team-based care is increasingly emphasized and recognized as correlating with patient outcomes.

Defenders of public reporting recognize that such a practice introduces unwanted incentives to maximize the risk profile or underreport mortality. Rigorous external auditing assessing both completeness and accuracy is necessary to maintain the confidence of both public and the healthcare community in these registries.[44]

Registries such as the SVS VQI are organized under legislation (Patient Safety Act of 2005) that specifically prohibits the public release of hospital- or surgeon-specific outcomes. PSOs are intentionally designed to foster the free exchange of information between hospitals and providers in order to promote the transparency and dissemination of best practices/lessons learned. The primary purpose of the SVS VQI is to improve quality, not to inform the public of the specific performance of individual hospitals or surgeons.

THE FUTURE OF MEDICAL REGISTRIES

In our opinion, medical registries—even more specifically vascular registries—are here to stay. The information they provide is distinctly different from formal RCTs. Their data represent a real-world experience that can be extremely valuable, assuming the data contained in the registry are believable.[6] Many important clinical questions can only be answered by the systematic collection of clinical data obtained during the routine delivery of vascular care—especially information that allows characterization of relatively low-frequency events unlikely to be seen in statistically valid numbers by any single center or practitioner.[12]

Cost is the primary challenge facing clinical registries. The more complex registries collect and analyze information at a granular level that can support detailed and valuable analyses. But the more complex registries are more expensive in terms of infrastructure, as well as the time and effort required by sites to enter the data. As the value of registries is increasingly recognized by regulatory agencies and industry and third-party payers, it is likely that the cost of participation will be

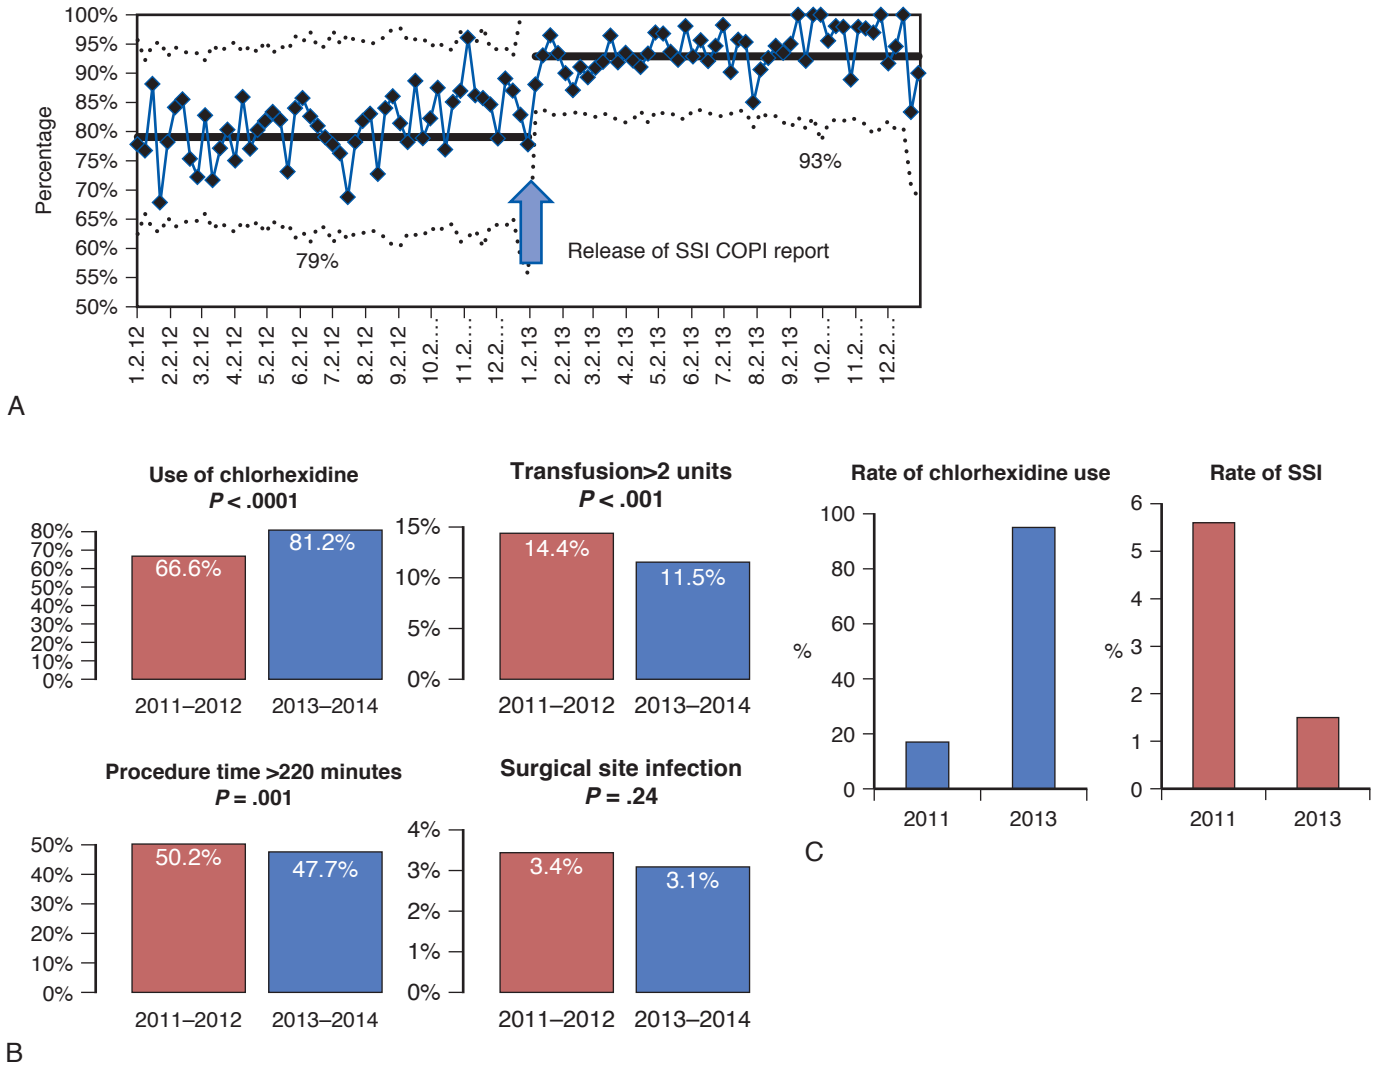

Figure 199.5 **Impact of Surgical Site Infection Center Opportunity Profile for Improvement *(SSI COPI)* Report in the Vascular Quality Initiative (VQI).** (A) Statistical process control chart showing the rate of chlorhexidine use across the VQI before and after the release of the SSI COPI report *(blue arrow)*. (B) There were significant beneficial changes in chlorhexidine use, transfusion practice, and procedure time following release of the SSI COPI report. Coincidentally, SSI rates across the VQI decreased, but not to a statistically significant degree. (C) Among select VQI centers who had the greatest increase in chlorhexidine use (low to high utilizers), a statistically significant decrease in SSI rate was observed. subsidized.[12] Alternatively, participation may be motivated by policies of payers or regulatory agencies that will give preferred status to registry participants.

INTERNAL MARKETING 2575
EXTERNAL MARKETING 2575
IMPLEMENTATION 2576
REVIEW 2576
SUMMARY 2577

With the changing nature of healthcare, the competition for patients by hospital systems, private practices, and other entities is intensifying. Now most vascular surgeons are competing for patients not only with other vascular surgeons but also with physicians in other specialties. To some degree, then, marketing has become an imperative for vascular practices to survive. However, many medical professionals may be uncomfortable with marketing, comparing such activities to those of used car salespersons. However, if other physicians are unaware of the vascular surgeon's prowess and expertise, then they will be unlikely to refer their patients to that surgeon. Furthermore, if patients are unaware of the surgeon's experience or reputation, they will be less likely to consult with that doctor. Nor will they be as trusting of the surgeon's opinions and advice. This applies even to surgeons who get their referrals through the reputation of the university or hospital in which they work.

Accordingly, it behooves all vascular surgeons to consider marketing of some form. This does not necessarily imply high expense or sometimes distasteful television advertisements. Rather, marketing can be done in ways that, in and of itself, result in improved patient care and outcomes.

This chapter outlines the five principles of marketing to both patients and referring physicians: **Discovery, Strategy, Solutions, Implementation, and Review**. The vascular surgeon needs to understand what constitutes a marketing plan and how to evaluate its effectiveness. Not all marketing can achieve positive results, and poorly planned strategies can be costly and inefficient and even have a contrary result.

DISCOVERY

An essential aspect of marketing is self-discovery. There are two fundamental questions to ask oneself. First the vascular surgeon has to know what is the goal of a marketing campaign. Is the goal to simply increase new patients or is the goal to increase a specific type of new patient? For example, is it patients with a specific type of insurance, such as Medicare, or rather cash pay cosmetic clients? Is it patients with a specific vascular condition, such as patients with venous disease or perhaps abdominal aortic aneurysms? In general, targeted marketing will be more efficient and more likely to succeed. For some practices the object may be to maintain the current volume of established patients. Second, one has to look inward to identify what makes the individual surgeon or practice unique or marketable. Usually this will be because the surgeon has specific experience in certain procedures. However, it may be his or her reputation in the community as a caring physician. It could be contributions to local community charities or other nonmedical activities. It may be worthwhile to provide current patients with a brief questionnaire to identify why they first came to see the surgeon and why they are continuing as a patient. The office staff will also be able to provide this information because they are usually well aware of patients' regard for their doctor. This knowledge becomes even more important when marketing a multiperson practice where some individuals will not be as marketable as others. If this is the case the program may decide to highlight the practice reputation rather than one of its high-profile individuals.

Discovery also involves assessing potential market competitors. This will include not only other specialists who treat vascular conditions, such as cardiologists and interventional radiologists, but also dermatologists, podiatrists, and many general practitioners. Although not directly competitive, health insurers, hospitals, and multispecialty groups and accountable care organizations will also impact the vascular surgeon's ability to recruit patients. For example, a hospital with its own vascular surgeons may contract with a local business to provide all health services for that company's employees, thus excluding those

Abstract

Marketing is key to a successful practice. This chapter describes the general concepts necessary to establish a marketing campaign.

implementation

employees from the available pool of potential patients. Similarly, the demographics of a community also need to be taken into account when assessing the market potential. Certainly, a more aged community would be more likely to provide the patient population most suited to a vascular surgeon. As a corollary, a young population may be more appropriate for a practice trying to increase market share of patients with spider veins. Information about the market potential can be obtained from the local chamber of commerce.

Once the "competition" has been identified, it is also important to attempt to discern why they are successful. What attributes do they have that the practice does not possess? Similarly, what does the practice offer that they do not? Analyze also all aspects of their marketing. It may not be profitable, for example, to compete with television advertisements if their budget for such marketing far exceeds the vascular surgeons' own available funds.

STRATEGY AND SOLUTIONS

The strategy for marketing can be divided into internal marketing efforts and an external marketing campaign. However, the vascular surgeon must first assess the budget that he or she would be willing to spend. Television and newspaper advertisements can be very expensive. Furthermore, although large groups may be able to afford a marketing consultant, most individual or small practices will need to rely on partnering with other like-minded physicians, organizations, or institutions. Some insurance companies will advertise their medical panel in direct mailing as well as newspaper advertisements. A local hospital may be willing to advertise a unique aspect of the surgeon's practice. The local medical society may be willing to co-host a lecture series promoting that activity. The Society for Vascular Surgery has also prepared multiple documents on how to market a vascular practice. The society also has produced patient information brochures that are extremely useful for marketing purposes.

Most vascular surgeons who are already in practice will realize that the majority of patients come to them by direct referral from other physicians. Accordingly, it is imperative that, at a minimum, the surgeon must make networking with local referring physicians a priority. Therefore giving lectures at hospital grand rounds, socializing in the doctor's lounge, and becoming active on hospital or medical society committees are all important ways to improve patient referrals. Educational dinner meetings for referring doctors are an excellent method of demonstrating special techniques or therapies that the surgeon offers. The Society for Vascular Surgery has provided templates for how to run such a meeting, including how to analyze the effectiveness of the evening.

INTERNAL MARKETING

Other than referrals from other physicians, patient word of mouth comments are the most beneficial. Internal marketing to established patients enhances the potential for these patients to encourage new patients to come to the practice. Furthermore, it maintains loyalty to the practice and ensures that patients will return for regular follow-ups. A list of methods to provide internal marketing is included in Box 200.1.

However, it is usually beneficial for the practice to first develop a branding identity. This may include a logo or a catch phrase. Even an individual surgeon may benefit from a logo design. After this has been created, it should be used on all publications, stationery, clinical reports, brochures, and so on. Examples of internal marketing include patient education brochures; letters or electronic communication such as emails or text messages (provided that they are Health Insurance Portability and Accountability Act [HIPAA] compliant) informing patients of needed return visits or tests; and communications about upcoming lectures or new advances in vascular therapy that may benefit the patient. Telephone on-hold audio information about a new procedure or therapy can be more useful than music. Often overlooked, but extremely important, is ensuring that the office staff is polite, friendly, professional, and fully supportive of the practice identity. A rude front desk person can make all marketing meaningless! Similarly, an unkempt or untidy office or a habit of untimely patient appointments will be equally detrimental.

In this new electronic age, a website is almost essential. Many patients will turn to the web for information about the practice, including the physician's credentials, as well as general information such as the practice address and phone number. The website will also provide an opportunity to provide valuable information about the various conditions that patients will be inquiring about. Accordingly, a well-constructed professional website may enhance the practice reputation, as well as providing an important opportunity to market the practice. It will be extremely beneficial if the site is optimized by the major search engines to appear prominently on their web searches.

EXTERNAL MARKETING

Opportunities for external marketing abound. Many of these are listed in Box 200.2. However, some of these can be extremely expensive, such as television advertisements and billboards. Furthermore, television and radio, as well as newspaper advertisements, need to be repetitive and run over a prolonged period before they will have any effect. In general, practices advertising arterial therapies will probably not benefit from many of these. On the other hand, practices advertising cosmetic services for

BOX 200.1 Internal Marketing Opportunities

- Practice brochure CV of each physician and his/her special expertise
- Medical information brochures (e.g., AAA, varicose veins, carotid endarterectomy)
- Stationery with practice logo and catch phrase
- On-hold audio information
- Patient recall letters
- Product packaging (e.g., stockings) with logo
- Website
- Email newsletters
- Training the staff to best represent the practice
- Staff uniforms with practice logo

BOX 200.2 External Marketing

- Website
- Newspaper and magazine ads
- Free standing inserts for magazines and newspapers
- Radio and television commercials
- Billboards
- Promotions
- YouTube videos
- Direct mail postcards
- Yellow Page ads
- Val-Pak coupons
- External signage
- Facebook
- Twitter
- Blogs
- Dinner and hospital lectures

varicose veins may be obliged to use these methods because competitors may be using these approaches. It is important for practices to realize that external marketing to patients will also be seen by referring physicians. This can work to the practice's advantage if the marketing is performed in a tasteful and professional manner. Referring physicians may not have realized that the practice offered the services that are being advertised.

One form of advertising on television that is extremely effective and free, is to be interviewed as a local expert. Local channels frequently look toward local doctors to add commentary about a medical news item. Accordingly, making oneself available to the local channels can be very helpful.

Vascular screenings at health fairs are another method of advertising that can be effective and helpful for patients, if advertised and performed in a professional manner. Screening advertisements should not imply that patients are at risk if they do not attend. Nor should the benefits be exaggerated.

Social media such as Facebook and Twitter are increasingly being used to market medical practices. For these to be effective, they need to be updated frequently with compelling information. This can be time consuming for the practice, and therefore the assistance of a professional agency may be beneficial. Vascular surgeons also need to pay attention to the multitude of physician-rating agencies and websites where patients rate their doctors. A few malicious patient reviews can be very damaging to the surgeon's reputation. On the other hand, mention by one of the more widely known companies such as Castle Connolly can be helpful.

Finally, as managed care organizations increasingly control where patients receive their treatment, vascular surgeons need to make sure that they are included in these organizations' roster of specialists. In most cases it will be beneficial to prove that the practice not only delivers quality care but that it is cost-efficient. Therefore the practice must be knowledgeable about data such as hospital length of stay, cost of services, return to surgery, and hospital readmissions.

IMPLEMENTATION

Most internal marketing can easily be achieved without any professional assistance other than perhaps the development of a catch phrase or branding logo. As already described, the Society for Vascular Surgery provides information on how to market, as well as patient education and physician education brochures, as a valuable service to members. However, for internal marketing to be effective, someone in the practice has to spend the time to make sure that it is effective.

On the other hand, it is probably advisable that practices embarking on external marketing hire an advertising agency to assist in developing a marketing campaign. For example, although the practice can quite easily create a YouTube video, an unprofessional video may be counterproductive. Furthermore, creating media for newspaper advertisements, and especially television, will usually require significant expertise and expense. Although using an advertising agency is costly, a well-constructed marketing plan that is appropriately budgeted and executed should provide the desired results in a cost-effective manner. Practices must understand that even though they have hired an outside agency a hands-off approach, leaving everything up to that agency, will not work. The practice will have to invest time educating the agency about the practice, its goals, and the medical information the practice wishes to convey in its advertising. Failure to oversee the agency's work may result in embarrassing and counterproductive media content.

Identifying an advertising agency that is best suited to the practice can be difficult. However, it is generally advisable to use a local company because that agency will be more likely to know the intricacies of the local market. On the other hand, there are now multiple companies advertising their services on the web. However, these usually offer generic advice and content that may not work in the practice's community.

REVIEW

Perhaps reviewing the advertising is as important as discovery. It is critical to know whether the advertising is working or not and whether the practice is getting its "bang for the buck." This is especially so if a large amount of capital outlay was required. There are many metrics that can be analyzed to evaluate the benefit of advertising. The billing office can provide information on the numbers of new patients according to age, gender, disease process, insurance carrier, and other demographics such as patients' zip code. Similarly, the income derived from these new patients is also critical information. It is clearly not cost-efficient to spend $10,000 on an advertisement that generates only $2000 in revenue.

Other methods should also be used to determine what aspects of the advertising are most or least effective. For example, if a newspaper advertisement is placed for a cosmetic vein therapy, the ad could offer a discount if the patient brings in the advertisement. These inducements may not be practical for other forms of advertising. Accordingly, the most effective method is to request new patients complete a brief questionnaire about why the patient chose the practice or physician. Because patients will often have a primary and secondary reason or sometimes even a third reason for coming to the practice, these questions have to be very carefully developed. For

example, a patient may be referred to the practice by the primary physician but made the appointment only after they saw an advertisement in the newspaper or were encouraged by a friend or relative. In addition, if the practice is advertising in multiple print media it does not help to simply ask whether they saw a practice advertisement. Rather, there needs to be a checkbox for each magazine or newspaper in which that advertisement appears. An analysis of patients' experience in the office after their appointment is also very helpful in assessing internal marketing. For example, questions about the cleanliness of the office, waiting times, or their overall experience with the physician may unmask areas for potential improvement. Because some patients may be unwilling to complete these questionnaires, it may be helpful to offer the opportunity for them to win a small monthly prize for those completing these forms.

It is advisable that the practice performs the review process on a regular basis. This will allow manipulation of the various marketing materials to better conform to changing conditions. However, the benefits of a marketing campaign may take some time to manifest.

SUMMARY

Although some vascular surgeons consider marketing distasteful, almost all are marketing their practices in one way or another. Furthermore, vascular surgery has become a highly competitive field as nonsurgeons increasingly become involved in treating vascular conditions. To some degree, then, marketing has become an imperative for vascular surgeons' practices to survive. This chapter provides an overview of what is necessary for a marketing effort. How a vascular surgeon goes about marketing will be dependent on local factors, as well as their own priorities, abilities, and finances.
